Table 2 Consolidated statements of earnings (J&J)

	For the year 2011 (in millions)
Sales to customers	\$ 61,587
Cost of products sold	18,792
Gross profit	42,795
Selling, marketing and administrative expenses	19,424
Research and development expense	6,844
Purchased in-process research and development (Note 20)	
Interest income	−107
Interest expense, net of portion capitalized (Note 4)	455
Other (income) expense, net	−768
Restructuring (Note 22)	
Earnings before provision for taxes on income	16,947
Provision for taxes on income (Note 8)	3,613
Net earnings	\$ 13,334

A correct procedure to arrive at the amount of net cash flow from operations is to measure change in each operating account on balance sheet to determine whether any changes in balance sheet accounts caused an increase or decrease in cash. A few important points should be noted here:

1. Changes in operating accounts shown on J&J's SCF do not equal the balance sheet changes. For example, the SCF shows that accounts receivables increased by \$207,000. However, the balance sheet reports an increase of only \$135,000. Similarly, accounts payable increase by \$20,000 as per the SCF but the balance sheet shows an increase of \$82,000 in accounts payable. It is not clear what accounts for these and other discrepancies in operating assets and liabilities. Perhaps the company has made some adjustments and aggregations, but they are not explained.
2. The SCF shows an increase of deferred taxes of \$356,000. A careful look at the balance sheet reveals that deferred taxes are reported thrice: In current assets, in long-term assets and also in long-term liabilities. Moreover, the total of the three is not equal to the amount reported in the SCF.
3. J&J reports an increase in almost all of its long-term assets in the balance sheet, (Land, building, machinery and equipment, construction and goodwill all went up significantly) but the SCF provides only a single number of additions to property, plant and equipment of \$2,384,000, which does not add up to all the increases in asset. Moreover, the SCF reports proceeds from sale of assets in the investing section, but which assets were sold and whether they were sold at a gain or a loss is not revealed. The company also reports significant transactions in investments and in short term debt instruments in the SCF but balance sheet does not even have a category named investments in its asset section. Moreover, the short-term debt does not match the short-term loans payable in the balance sheet. Why is this

Table 3 Indirect method Johnson & Johnson (J&J) company

Statement of cash flow for the year ended December 31, 2011	
Net income/starting line	13,334,000.00
Depreciation	2,939,000.00

Cash from financing activities	-4,980,000.00
Foreign exchange effects	-6,000.00
Net change in cash	3,545,000.00
Net cash – beginning balance	15,810,000.00
Net cash – ending balance	19,355,000.00
Cash interest paid	491,000.00
Cash taxes paid	2,442,000.00

information not deemed important and why the cash paid for operating assets is not shown in the operating section are major concerns that FASB should address.

72.3.1.2 Cash Flow from Investing Activities

Capital expenditures for long-term assets such as plant, property and equipment, land and Buildings are the primary component of investing cash flow. Capital expenditures may be reported net or gross of proceeds from the sale of these assets. However, trends in gross capital expenditures contain useful insight into management plans. The J&J cash flow statement reports only a net figure for all plant property and equipment, without providing details about changes in their composition.

Other components of cash flow from investing activities include consequences of acquisitions, investments in affiliates and joint ventures. However, segregating operating assets and liabilities acquired in acquisitions may provide useful information about payments made in cash. The J&J cash flow statement reports a capital expenditure of \$2,384,000 for purchase of various fixed assets. Moreover, they report a cash outflow of \$1,269,000 for acquisition of business and another cash outflow of \$5,470,000 as “Other cash outflow.” It is clear that the company engaged in significant acquisition activity during the year. Since most of the company’s long term assets went up during the year, it is impossible to figure out how much of the increase in assets is due to purchase of new assets and how much is due to acquisition of another business and its assets and liabilities. This is probably the reason why the changes in balance sheet accounts do not correspond to changes in the cash flow statement.

72.3.1.3 Cash Flow from Financing Activities

Cash inflows from financing activities include additional borrowing and equity financing and cash outflows include repayment of debt, dividend payments and equity repurchase or retirement. The calculation of equity financing cash flows requires separation of net income, dividend declared and changes in valuation accounts included in equity. The J&J cash flow statement reports a significant cash payment for dividends and repurchase of its common stock. The debt undertaken also increased in both short term and long term categories.

Once the cash flow from operating, investing and financing operations is calculated, the last step is to summarize the net cash flow, which, by definition, must be equal to the change in cash. As indicated at the bottom of the SCF, net increase in cash of \$3,545,000 is the same as shown in the balance sheet.

Academics and experts in finance argue that Cash flow statements prepared using the indirect method suffer from a serious drawback: Since this method reports only the net cash flow from operations, it does not allow a comparison and analysis of operating cash inflows and outflows by function with the revenues and expense activities that generated them. Hence it provides little new information about the specific components of a firm’s cash generating ability.

As a majority of firms provide only the indirect method statement, it is often necessary to convert an indirect one into a direct one. The main advantage of **the direct method** is that it shows operating cash collections and payments and is therefore more consistent with the basic purpose of the statement – to provide information about company's cash receipts and payments. Advocates of the direct method argue that information about the specific sources of operating cash receipts and the purposes for which operating cash payments were made is more useful to users than the net cash flow from operating activities.

Under the direct method, net cash from operations is computed by adjusting each item in the income statement from the accrual basis to the cash basis. An efficient way to apply the direct method is to adjust each revenue and expense reported in the income statement in the order in which it is listed. Table 4 shows a direct method statement of cash flows for J&J Company. We use the data from Table 1 (Comparative Balance Sheets) and Table 2 (Income statement) to calculate the following:

Cash Collections: The income statement reported revenues from customers of \$61,587,000. But in order to determine how much of it was collected in cash, we have to look at the change in accounts receivable during the year. Since it increased by \$207,000, this much revenue did not translate into cash. Thus, it will be deducted from sales revenue to arrive at the amount of cash collected from customers. Net income also reports interest collection of \$107,000. Finally there is “Other net income” of \$768,000, which could be gain from sale or purchase of business or other assets.

Cash payments: J&J income statement reported cost of goods sold of \$18,792,000. To determine cash payments to suppliers, we deduct increase in accounts payable of \$20,000, since the company paid less cash than the expenses incurred. Similarly we deduct a portion of the total depreciation expense from cash payment to suppliers, since it is a non-cash charge. Since the indirect method cash flow statement reported a total depreciation and amortization expense of \$2,939,000, it has to be added back to the expenses to arrive at the total cash payments made during the period. We prorated the depreciation amount between suppliers and employees, in the absence of any further information. However, it does not influence the net cash provided by operations. Finally, an increase in inventories of \$196,000 implied that purchases exceeded cost of goods sold. As a result, it will be added to cost of goods sold to arrive at cash purchases.

The company reported operating expenses of \$19,424,000 in the income statement. To determine the cash paid for operating expenses, we must adjust this amount for any changes in prepaid expenses and accrued expenses payable. A decrease in prepaid expenses of \$224,000 implies that cash paid for operating expenses was lower than operating expenses reported in income statement. Hence, it should be deducted from operating expenses. However, the indirect method statement combines this adjustment with a pool of others and reports an increase in “Other non cash items” of \$626,000. It is virtually impossible to determine what is hiding inside that number.

Table 4 Direct method: (J&J)

Item	Income statement	Adjustment	Cash
Cash collected from customers			
Net sales	61,587.0		
Increase in accounts receivables		−207.0	61,380.0
Cash received from other sources	768.0		768.0
Cash collected from interest	107.0		107.0
Total cash collected	62,462.0		62,255.0
Cash payments			
To suppliers			
COGS	18,792.0		
Increase in inventory		196.0	
Increase in accounts payable		−20.0	
Depreciation		−1,445.2	
Total payments to suppliers			−17,522.80
To employees			
Selling and administrative expenses	19,424.0		
Litigation gain		−50.0	
Non cash items		−626.0	
Depreciation		−1,493.8	
Total payments to employees			−17,254.2
For R&D	6,844.0		
Net cash paid for “other assets”		501.0	
Total cash payments for R&D			−7,345.0
For interest	528.0		
Interest payable		−37.0	
Total cash payments for interest			−491.0
For income taxes	3,613.0		
Deferred taxes		−356.0	
Total cash payments for taxes			−3,257.0
Total cash payments	49,201.0		−45,870.0
Net cash provided by operating activities	13,261.0		16,385.0

The R&D expense of \$6,844,000 is adjusted for \$501,000 to reflect a net increase in assets that were paid in cash but were not expensed. The SCF prepared by the indirect method shows an increase in “Other Assets” of \$574,000. The company’s footnote to income statement shows an interest capitalized of \$73,000. Since capitalized interest is a source of cash, we subtracted this amount before taking the net amount ($\$574,000 - \$73,000 = \$501,000$) as an increase in cash outlay on some long-term assets.

The income statement reported an interest expense of \$528,000, but the cash expense on interest was only \$491,000, as reported at the bottom of the indirect method statement. Hence, the difference must be an increase in accrued interest payable of \$37,000, which will be deducted from operating interest expense to arrive at the cash payments for interest.

Finally, the income-tax expense of \$3,613,0,000 needs adjustment to arrive at the amount of cash taxes paid. The indirect method statement reports that the deferred taxes increase by 356,000, meaning that the company did not pay this amount in cash. If we subtract this from income tax expense, we arrive at \$3,257,000 as cash payment for taxes. However, at the bottom of the indirect method statement provided by the company, we are told that the company paid only \$2,442,000 for taxes, implying that an additional \$815,000 has been added to cash by non-payment of some taxes. It is hard to deduce the company's intention behind this massive aggregation. Sometimes, a careful reading of footnote data may reveal additional information on aggregated accounts.

It should be noted that the net cash of 16,385,000 provided by operating activities under the direct method is the same as the number in the indirect method statement.

72.4 Problems with Cash Flow Statements

An operating cash flow Statement has long been considered a reliable barometer of a firm's financial health and less susceptible to creative accounting than its cousins the income statement and the balance sheet. However, recent corporate scandals as well as some research suggest that cash flow statements may also be susceptible to manipulation by corporate managers.¹⁰

The events surrounding the accounting debacles of Adelphia,¹¹ Dynegy, Qwest, Tyco,¹² WorldCom, and others demand a new look at this key financial statement, particularly because these cases reflect problems in reporting of cash flows by these corporations. Certain accounting shenanigans have been used to artificially boost reported cash flow or mask declines in operating cash flow.¹³

As further evidence of potential manipulation, the Securities and Exchange Commission recently forced seven well-known companies to amend their financial statements. Harley-Davidson, Caterpillar, and General Motors were among the companies affected by the ruling. Their 2002 and 2003 financial statements classified money owed to them by dealerships as an outstanding investment, meaning that the operating cash flows they reported were artificially high. Harley's 2003 cash flow was 29% lower after the restating; Caterpillar's tumbled by a staggering 372%. At GM, these reclassifications reduced its operating cash flow from \$7.6 billion to \$3 billion.¹⁴

¹⁰See for example, Sender (2002).

¹¹See Solomon, Deborah (2002).

¹²See Maremont (2002).

¹³"For example, after WorldCom's reverse-engineering subterfuge, many have learned to look for excessive capitalization of cash expenditures. Others now scrutinize the cash flow statements for non-recurring sources of cash, such as receipt of an income tax refund and securitization of payables." Mark A. Siegel, "Accounting shenanigans on the cash flow statement" March 2006.

¹⁴Judith Burns, "SEC tells Automakers to re-tool cash flow accounting", Wall street Journal Online (February 28, 2005).

Research out of Georgia Tech's business school has also found that a number of prominent companies routinely "miscategorize money due from vendors, such as members of their distribution network. Typically, firms record the IOUs as part of their cash flow from investments rather than as reductions to their operating cash flow."¹⁵ Other practitioners and researchers have also pointed out to the existing flaws in rules regarding cash flow statements.¹⁶

The accounting problems brought to light raise important questions about current accounting standards for the statement of cash flows and how they are being applied: Is the statement as useful to investors and creditors as it should be?¹⁷ Can it and should it be improved? Would improvements in the statement increase investors' and creditors' confidence in financial accounting and reporting? We will classify our criticism of existing rules under three categories: Problems due to the arbitrariness of classifications of cash flows of different types, problems due to the method chosen for the preparation of the SCF and problems due to a possible manipulation of several items reported in the SCF.

72.4.1 Arbitrariness of Classifications

Most classification systems are somewhat arbitrary. Classification involves weighing the relative significance of similarities and differences. Under SFAS-95, the unavoidable arbitrariness of the three-way classification sometimes results in classifying similar cash flows differently and different cash flows similarly. Additionally, although the three-way classification of cash flows under SFAS-95 links certain related cash flows, it does not link other cash flows that are either functionally or legally related.

72.4.1.1 Operating Versus Investing Activities

Under the current rules, FASB classifies the purchases of inventory as operating activities and purchases of plant assets as investing activities largely because "payments to suppliers for inventories are regarded normally as part of operating activities and payments for property, plant, and equipment as part of investing activities."

¹⁵"SEC acts to curb cash flow shenanigans" by Darren Dahl, Inc.com, June9, 2005.

¹⁶See for example, Cash flow myths. By: Rosen, Al, Canadian Business, 00083100, 3/12/2007, Vol. 80, Issue 6, "We tell our institutional money-managing clients that all cash flow mistakes result from the arbitrary timing or classification of management actions or inactions. The cash flow statement represents cash amounts. But, they are unevenly categorized, and worst of all, smoothed and shifted from period to period. . . . Investors tend to forget that accounting cash flows are not "real." Actual cash flows into a company are first recorded using an accrual (non-cash) income basis, and then translated back into a quasi-cash basis on the cash flow statement. This back-and-forth dance creates what I like to call leakage. Leakage can be caused by pension plans, income taxes, stock options, corporate acquisitions, minority interests, asset securitizations and a host of other factors."

¹⁷See for example, Livnat and Zarowin (1990).

During the past 20 years, many researchers have argued that the purchase and sale of inventories is fundamentally the same as the purchase and sale of plant assets; both are usually considered part of a firm's normal operating activities. The case for treating the purchase and sale of plant assets differently from the purchase and sale of inventories must be based on the grounds that they are of different significance to those interested in the cash inflows and cash outflows of a business enterprise. Although the purchase and sale of plant assets are of special significance because they are of relatively infrequent occurrence, because they are often relatively large in amount, and because management is likely to have more control over their timing than it does over the purchase and sale of inventories, Nonetheless, distinguishing between operating and investing activities is likely to be troublesome.

Thus, to the extent that payments for inventories and plant assets are fundamentally alike, the distinction between operating and investing activities is flawed or unnecessary. This notwithstanding, a consensus has developed that payments for inventories should be classified as operating outflows whereas payments for plant assets should be classified as investing outflows, consistent with the finance literature.

72.4.1.2 Operating Versus Financing Activities

Although the accounting profession talks about the importance of comparability of financial information, the fact that interest paid is treated as an operating activity while dividends paid is treated as a financing activity makes it difficult, if not impossible, to compare the performance of companies that make different financing choices.

Clearly, interest and dividend collections result from making loans or investments in debt and equity securities and, therefore, relate to investment activities. Similarly, interest payments result from incurring debt and, therefore, relate to financing activities. Indeed, the finance literature emphasizes the similarity of interest and dividend payments – interest is paid for the use of debt capital, whereas dividends are paid for the use of equity capital. It follows, therefore, that interest and dividend receipts are not operating inflows and interest payments are not operating outflows, notwithstanding SFAS-95.

The FASB acknowledges that a reasonable case could be made for classifying interest payments as financing outflows and interest and dividend collections as investing inflows. But the FASB notes that traditionally, interest collections and interest payments have been classified as operating flows. Additionally, it perceives widespread support for what might be referred to as the inclusion concept, whereby "... operating cash flow should, insofar as possible, include items whose effects are included in determining net income to facilitate an understanding of the reasons for the differences between net income and net cash flow from operating activities." Because of this inclusion concept, the FASB concludes that it "... was not convinced that changing the prevalent [prior] practice ... would necessarily result in a more meaningful presentation of cash flows."

It is inconsistent, however, for the FASB to cite the inclusion concept and prior practice to decide that cash flow from operating activities should include interest payments and interest and dividend collections but exclude cash flows relating to

gains and losses from plant asset disposals. Like interest payments and interest and dividend collections, gains and losses on plant asset disposals are traditionally included in net income, and the cash flows relating to these gains and losses have been included in operating funds flow under prior practice.

By classifying interest and dividend collections and interest payments as operating cash flows, the FASB has foregone the opportunity to more substantially improve the quality of financial reporting by sharpening the distinction among operating, investing, and financing cash flows. It should reconsider the issue.

A similar ambiguity arises in classifying payments of amounts borrowed. Cash outflows to suppliers and lenders are fundamentally alike, yet the former are classified as operating whereas the latter are classified as financing under SFAS-95. It is generally argued that some activities with a financing dimension, such as inventory purchases on account, should be excluded from financing activities because their spontaneous financing components are incidental to an enterprise's operations and do not affect its capital structure. In its 1980 Discussion Memorandum, the FASB also notes this ambiguity in the three-way classification. Nevertheless, FASB still favors classifying cash outflows to suppliers as operating and cash outflows to lenders as financing.

There are at least two inconsistencies in the reasoning underlying this classification. First, it assumes that inventory purchases on account always involve current liabilities. Second, it assumes that report users are interested principally in the capital structure, which excludes current liabilities. What about those admittedly less common situations where inventory purchases on account involve long-term liabilities? What about those report users interested in the financial structure, which includes all liabilities, not just long-term liabilities?

Because cash outflows to suppliers and lenders are fundamentally alike, the distinction between operating and financing activities based on payee is ambiguous. This ambiguity has been resolved by classifying outflows to suppliers as operating and outflows to lenders as financing, consistent with the finance literature.

Another ambiguity in classification involves "**capital leases**." It is true that, on day one, a lease is a noncash transaction. However, the payment for the lease principal and interest in later days is undoubtedly a cash flow event in a single transaction. And yet, the payment for the principal is treated as a financing activity, while the payment for the interest is shown as an operating activity. One transaction is broken into two parts; it has lost its wholeness. It would be more informative if both were brought together as one transaction under financing activities.

72.4.1.3 Investing Versus Financing Activities

SFAS-95 classifies cash flows according to the transactions that cause them. Cash inflows are not classified according to uses and, similarly, cash outflows are not classified according to sources. For example, cash receipts from the sale of plant assets are investing inflows even when the proceeds are used to retire debt, and cash receipts from issuing debt are financing inflows even when the proceeds are used to purchase plant assets. Such cash inflows and outflows might be viewed as functionally related, but are not necessarily "linked" and are not reported in the same section of the cash flow statement under SFAS-95.

72.4.2 Direct Versus Indirect Method Controversy

As mentioned before, companies favor the indirect method of preparing SCF, even though FASB recommends use of the direct method. The main advantage of the direct method is that it shows operating cash collections and payments and is therefore more consistent with the basic purpose of the statement – to provide information about company's cash receipts and payments.¹⁸ Indirect method does not report operating cash receipts and payments. Advocates of the direct method argue that information about the specific sources of operating cash receipts and the purposes for which operating cash payments were made is more useful in determining a company's future ability to generate cash flows to meet its obligations, to reinvest in its operations and to pay dividends to its owners.

Most companies argue that their accounting systems do not collect information in a manner that allows them to determine amounts such as cash received from customers or cash paid to suppliers. They prefer to use the indirect method since it is less costly to adjust net income to net cash flow than it is to report operating cash receipts and payments. Companies have lobbied against the direct method, urging FASB to adopt the indirect method.¹⁹

It is ironical that the statement of cash flows under either method does not meet the needs of the finance community, which is often interested in knowing how much cash was taken out of the business in a given year.²⁰

Finance textbooks and academicians argue that a cash flow statement should be able to summarize the cash activities of a firm much the same way as income statement summarizes the accrual activities of a firm.

Since the balance sheet identity tells us that the value of a firm's assets is equal to the value of its liabilities plus the value of its equity, the cash flow from a firm's assets must be equal to the cash flow to suppliers of capital to the firm. Thus the basic cash flow identity is:

$$\text{Cash flow (CF) from assets} = (\text{CF) to creditors} + (\text{CF) to stockholders}.$$

This identity reflects the fact that a firm generates cash through various activities and that cash is either used to pay creditors or paid out to the owners of the firm.

Cash flow from assets involves three components: operating cash flow, capital spending and change in working capital. Operating cash flow is defined in a slightly

¹⁸Orpurt and Zang (2009) show that direct method leads to a better forecast of future operating performance and cash flows.

¹⁹Accounting Trends and Techniques published by the American Institute of Certified Public Accountants (AICPA2005) reports that of 600 U.S. public firms surveyed over 2001–2004, only seven or eight firms disclosed DM statements of cash flows each year. Because few firms were expected to use the DM, FASB requires DM disclosing firms to also provide an IM schedule for comparability (SFAS No. 95, paras. 29–30). However, no separate DM schedule is required with IM statements. Miller and Bahnson (2002) argue that dual reporting required with DM disclosure may cause managers to prefer the IM.

²⁰See Ross et al. (2010).

different way under finance literature: Expenses associated with firm's financing of its assets, such as interest, are deducted because they are not operating expenses. Depreciation, being a non-cash expense, is added back to earnings.

Capital spending refers to the net spending on fixed assets (purchase of fixed assets minus sale of fixed assets).

Lastly, change in working capital is measured as the net change in current assets relative to current liabilities and represents the amount spent on working capital.

In order to calculate sources and uses of cash in a business, we need to trace the changes in firm's balance sheet to see how the firm obtained and spent its cash during same period. For example in the balance sheet for J&J, net fixed assets increased by 7,766 and its inventory, for all the three categories together, increased by \$198. (All figures are in millions.) Where did the cash come to pay for these purchases? To answer this and related questions, we need to identify those changes that brought in cash (sources) and those that used up cash. Logically, if an asset (liability) account increases (decreases) over the period, the firm must have used cash. Similarly, if an asset (liability) account went down (up) over the period, then the firm must have sold some assets (undertaken new liability) – a source of cash. Table 1, column 3, shows the change in each item on the balance sheet and the direction of the change. An increase in asset, for example, inventory, is a net use of cash because the firm paid to get additional inventory. An increase in Accounts receivable of \$135 is also a use of cash because the company has effectively given a loan receivable by the end of the year. By the same logic, increase in accounts payable of \$82 is a source of cash because the company borrowed this amount from its suppliers for a short term. Accrued liabilities, on the other hand, went down by \$525, so J&J must have paid off \$525 worth of short-term debts- A use of cash. Base on this discussion we can summarize the sources and uses of cash from the balance sheet as follows (Table 5):

Notice that the net addition to cash is same as the \$3,545 change on the balance sheet. This statement, although simple, tells us what happened during the year. The company increased its total liabilities by a lot but also acquired a lot of assets. However, it still does not tell the whole story. For example, it does not explain why the increase in accounts payable figure in the balance sheet does not match with the number reported in the indirect method (Many other numbers like increase in inventory, accounts receivable, deferred taxes and depreciation are also different in the two statements). Second, it would be more enlightening to have more details reported. For example, the increase in retained earnings is net income (a source of funds) less dividend (a use of funds) but we don't see the breakdown. Finally, we see only an increase in net fixed assets. Total or gross spending would be more interesting to know.

72.4.3 Manipulation and Distortion of Cash Flow Statements

Recent focus on SCF has revealed that Companies can either artificially boost reported cash flows or present unsustainable cash flows or mask declines in operating cash flows by using many of the loopholes in the existing rules.

Table 5 Changes in Cash Flow (J&J)

	2011	2010	Change
Sources of cash			
<i>Increase in liabilities</i>			
Loans and notes payable	7,617,000.00	6,318,000.00	1,299,000.00
Accounts payable	5,623,000.00	5,541,000.00	82,000.00
Accrued rebates	2,512,000.00	2,028,000.00	484,000.00
Income taxes	578,000.00	442,000.00	136,000.00
Deferred taxes	1,447,000.00	1,424,000.00	23,000.00
Long-term debt (Note 7)	9,156,000.00	8,223,000.00	933,000.00
Other liabilities	6,567,000.00	5,947,000.00	620,000.00
Retained earnings	77,773,000.00	70,306,000.00	7,467,000.00
<i>Decrease in assets</i>			
Raw materials	1,073,000.00	1,144,000.00	-71,000.00
Deferred taxes	2,224,000.00	2,793,000.00	-569,000.00
Deferred taxes	5,096,000.00	5,507,000.00	-411,000.00
Prepaid and others	2,273,000.00	2,497,000.00	-224,000.00
Doubtful account	-340,000.00	-333,000.00	-7,000.00
Depreciation	-15,873,000.00	-14,492,000.00	-1,381,000.00
Amortization of intangible	-5,509,000.00	-4,857,000.00	-652,000.00
Total sources			14,359,000
Uses of cash			
<i>Increase in assets</i>			
Marketable securities	8,303,000.00	3,615,000.00	4,688,000.00
Accounts receivables – gross	10,114,000.00	9,979,000.00	135,000.00
Goods in process	1,460,000.00	1,395,000.00	65,000.00
Finished goods	2,845,000.00	2,641,000.00	204,000.00
Land improvement	738,000.00	714,000.00	24,000.00
Buildings	9,079,000.00	8,863,000.00	216,000.00
Machinery and equipment	18,032,000.00	17,153,000.00	879,000.00
Construction	2,577,000.00	2,521,000.00	56,000.00
Goodwill	15,294,000.00	14,862,000.00	432,000.00
Intangible – gross	22,225,000.00	21,180,000.00	1,045,000.00
Other assets	3,942,000.00	3,690,000.00	252,000.00
<i>Decrease in liabilities</i>			
Accrued liabilities	4,100,000.00	4,625,000.00	-525,000.00
Accrued compensation and employee relate	2,642,000.00	2,777,000.00	-135,000.00
Employee Obligations	6,087,000.00	6,769,000.00	-682,000.00
Comprehensive Income	-3,531,000.00	-3,058,000.00	-473,000.00
Treasury stock	-20,783,000.00	-19,780,000.00	-1,003,000.00
Total uses			10,814,000
Net addition to cash			3,545,000.00

The following examples show how companies can employ certain techniques (many of which are within GAAP) to show improved reported cash flows.

72.4.3.1 Manipulation of Payables

The easiest thing that companies can do to improve reported operating cash flow is to slow down the rate of payments to their vendors. A direct consequence of this policy is to boost the reported growth in cash flows from operations. If analysts or investors expect the current period improvement to continue, they may be mistaken; vendors will eventually put increasing pressure on the company to pay more timely. Therefore, any benefit may be unsustainable or, at minimum, any year-over-year improvement in operating cash flow may be unsustainable.

The extension of payables can be identified by monitoring number of days' sales in payables (DSP).²¹ This metric is calculated as the end-of-period accounts-payable balance divided by the cost of goods sold and multiplied by the number of days in the period. As DSP grow, operating cash flows are boosted.

A look at J&J accounts payables reveals that the company has been experiencing huge fluctuations in this figure over the years: Its accounts payable increase by a modest \$20,000 in the current year, although it went down by \$507,000 and \$272,000 in the previous 2 years. The figures show that while the company received a significant benefit to cash flows from operations in 2009 and 2010, that benefit began to slow in subsequent periods, indicating that J&J will probably be unable to continue to fuel growth in operating cash flow using this method.

Another important point to note is that the firm shows an increase of \$20,000 in accounts payables in the SCF, the balance sheet shows an increase of \$82,000. It is surprising that one of the most popular adjustments to accrued expenses is not shown clearly and accurately.

72.4.3.2 Financing and Securitization of Payables

A more complicated version of stretching out payables is the financing or securitization of payables. This occurs when a company uses a third-party financial institution to pay the vendor in the current period, with the company then paying back the bank in a subsequent period. In recent years, increasing concern on keeping debt off the balance sheet has led companies to sales of receivables, with and without recourse. Economically, these activities still represent a form of financing. The accounting rules, however, allow these transactions to be treated as operating activities instead of financing activities. This makes these transactions doubly attractive to companies: They keep the borrowing off the balance sheet and inflate cash provided by operations. Theoretically, the pledge of accounts receivable is the same as the sale of accounts receivable, but they are treated differently in the cash flow statement. This treatment is inconsistent.

An interesting corollary to the impact on operating cash flow from securitizations is the impact on earnings. Specifically, in many cases companies can report gains

²¹ For a detailed analysis of problems with payables, see Nurnberg (2006).

when long-term accounts receivable are securitized. This occurs because the book value of the receivables at the time they are securitized does not include all the future interest income that is to be earned. Yet the entity purchasing the receivables will have to pay for that interest. As a result, because the amount received for the receivables is greater than the book value, a gain is generated. The amount of the gain can be affected as well by a variety of management assumptions, such as the expected default rate of the receivables securitized, the expected prepayment rate, and the discount rate used.

GAAP does not prescribe where on the income statement this gain is to be recorded. While one company may report the gain on sale of the receivables within revenues (the most aggressive approach), another might record it as an offset to selling, general, or administrative expenses. Another company might report the gain “below the line” in other non-operating income.

72.4.3.3 Deferred Employee Compensation

Another serious distortion involves deferred employee compensation. Many companies pay deferred compensation in the form of stock options that are off the balance sheet when issued. When the company later redeems the options by paying cash, the move is treated as a financing activity – as though it were a capital allocation, when in reality this payment is not any different from wages. As such, it should be treated as an operating activity.

72.4.4 Stock Buybacks

A second issue related to stock options that affects reported cash flows is the buyback of company stock. A large number of companies have, in recent periods, been buying back their own stock on the open market. In a majority of cases, this activity is due to stock-option activity. Specifically, when the price of a company’s stock rises, many of those who hold stock options exercise those relatively cheap options. If companies do nothing to offset the larger number of outstanding shares that exist as a result of the growing number of in-the-money options, earnings per share can be negatively affected. Management of such companies, therefore, face a choice: They can allow earnings per share to be diluted by the growing share count or they can buy back company stock to offset that dilution.

From an accounting standpoint, the impact of options on the income statement is usually minimal, as discussed above. On the cash flow statement, the tax benefit of option exercises is a source of operating cash flow, benefiting those companies whose option exercises grow. Cash expended by a company for the buyback of corporate stock, however, is considered a financing activity on the cash flow statement. Consequently, as option exercises grow, so does the boost to operating cash flows for the tax benefit, but the outflows for stock buybacks to offset dilution of earnings are recorded in the financing section of the cash flow statement.

Interestingly, as a company’s stock price rises, more options are generally exercised and the company must buy back more stock at the ever-higher market

prices. In some cases, the entire amount of cash flow generated by operations in recent periods could be expended to buy back company stock to offset the dilution from in-the-money options. (J&J used \$27,970,000 to buy back its own shares. This amount is reported as a financing outflow.) Therefore, when analyzing the true earnings power of a company as measured by cash flows, it is important to consider the cash expended to buy back stock to offset dilution. This cash outflow should be subtracted from the operating cash flow in order to calculate the true free cash flow the company generated in the period in question.

72.4.4.1 Marketable Securities

For many years, the distinction between cash equivalents (investments having no principal risk) and other marketable securities has caused serious confusion for the untrained reader of financial statements. Cash equivalents are treated as part of cash, while marketable securities are shown as investing activities. Where a company's portfolio manager does a lot of trading and switching between these two types of securities, very large numbers will appear in the investing activities section as "purchases of marketable securities" and "sales of marketable securities." It is not uncommon to see financial statements in which these numbers represent the largest cash flows. In J&J's balance sheet, marketable securities represent the largest cash outflow: an increase of \$4,688,000. Similarly, the SCF reports "Sale of investments" at \$11,101,000, which is classified as cash inflow under investing activity. If an untrained reader is asked what the most significant events for the company were during the year, the answer might be the purchasing and selling of marketable securities. Yet these numbers are irrelevant for understanding the company's performance. They merely clutter up the statement and cause confusion. Because SFAS 102 requires the buying and selling of securities to be treated as operating activities, the situation will be even worse.

72.4.4.2 Dividend from Affiliated Companies

Another problem that causes distortions in operating cash flows stems from the treatment of dividends received as an operating activity rather than as an investing activity. When a company has significant investments in affiliated companies, it has the ability to manipulate its own "cash provided by operations" by increasing the dividends it receives from such companies. Furthermore, dividend income comes from investments. If the former is shown in the section of operating activities, and the latter placed in investing activities, the reader of financial statement will not be able to visualize the whole picture of investment strategy.

72.4.4.3 Income Taxes

Another potentially serious distortion to operating cash flows comes from the rule that requires taxes to be treated as an operating activity, even when the gain being taxed is included in investing activities. For example, consider a company that has low operating profit but has a large gain from the sale of investments. The bulk of the pretax income is from this gain, and therefore the bulk of the income tax expense is related to this gain. On the statement of cash flows, however, the gain is removed

from operating activities and included under investing activities instead, as part of the proceeds from the sale of the investments. But the income tax expense on that gain remains in the operating activities sections, generating substantial negative cash from operations. This clearly is misleading, and violates the matching rules required on the income statement.

Because income tax payments and refunds are operating cash flows under SFAS-95, cash flow from operating activities includes the income tax effects of gains and losses relating to investing or financing activities, such as gains and losses on plant asset disposals and similar items.

Income taxes should be allocated in the cash flow statement in order to more accurately distinguish among cash flows from operating, investing, and financing activities.

Under the current rules of SFAS-95, when the amounts are material, it is recommended that firms disclose the income tax effects of gains and losses relating to investing and financing activities, to alert report users that the reported cash flow from operating activities is contaminated by the tax effects of these gains and losses. The J&J cash flow statement reports income taxes under current assets, current liabilities as well as in long-term assets. Although no detail is provided, it is possible that the figures pertain to income tax effects of gains and losses in purchase of businesses or sale of assets.

72.4.4.4 Sale and Purchase of Assets

A major problem with the investing activities section is that it is based on the rule that only cash amounts may be shown in investing and financing activities. Thus, for example, if one company acquired another at a cost of \$10 billion, but only \$1 billion of it was in cash, with the rest paid in the form of debt and equity instruments, the cash flow statement would show only the \$1 billion cash amount paid as the **cost of the acquisition**. The other \$9 billion would be relegated to a footnote. The untrained reader would get a false picture of the true cost of the acquisition. This is another example showing the deficiency of the current rules in preparing the cash flow statement. The rules ignore the vision of a complete transaction.

Moreover, there are certain inconsistencies in reporting installment purchases and sales of plant assets under SFAS-95. For installment purchases of plant assets, only early payments of principal, such as advance payments and down payments, are investing cash outflows; subsequent installment payments of principal are financing outflows. For installment sales of plant assets, however, all installment receipts of principal are investing inflows – not just the early receipts of principal.

The inconsistency results from classifying all installment receipts of principal on sales of plant assets as investing inflows but only some installment payments of principal on purchases of plant assets as investing outflows. Moreover, because most installment payments of principal on purchases of plant assets are classified as financing outflows, a comparative cash flow statement for a series of years does not report all the investing and financing activities of a firm.

72.4.4.5 Non-cash Transactions

In the Exposure Draft to SFAS-95, the FASB proposed that the primary purpose of the cash flow statement is to provide information about the cash receipts and cash payments of a firm during a period, and that a secondary purpose is to provide information about the investing and financing activities of the firm during the period. Consistent with these two purposes, the Exposure Draft required disclosure of noncash investing and financing transactions either in the cash flow statement or in a separate schedule. Examples of noncash investing and financing transactions include: converting debt to equity, acquiring assets by assuming directly related liabilities, such as purchasing a building by incurring a mortgage to the seller, obtaining an asset by entering into a capital lease, and exchanging noncash assets or liabilities for other noncash assets or liabilities.

Unlike the Exposure Draft, however, SFAS-95 retains the primary purpose but deletes the secondary purpose of the cash flow statement. The FASB concluded that the effectiveness of the cash flow statement would be enhanced if its purpose was restricted to reporting only cash flows, and therefore prohibits reporting noncash transactions in the cash flow statement. Nevertheless, SFAS-95 requires disclosure of all noncash investing and financing transactions that affect recognized assets or liabilities but that do not result in cash inflows or outflows. The FASB reasons (that although these noncash transactions result in no cash inflows or outflows in the periods in which they occur, they generally have a significant effect on cash flows in subsequent periods. SFAS-95 makes more uniform the reporting of noncash investing and financing transactions by prescribing supplemental disclosure outside the cash flow statement and prohibiting their disclosure in the cash flow statement. Unfortunately, the result of this narrower focus is that a comparative cash flow statement, unlike a comparative statement of changes in financial position, does not report all of a firm's investing and financing transactions.

For example, if a firm acquires equipment under capitalized leases, the inception of the lease is a noncash investing and financing transaction to be disclosed outside the cash flow statement, whereas the subsequent lease payments are allocated between interest and principal and reported in the cash flow statement as operating and financing outflows, respectively. Accordingly, a comparative cash flow statement for a series of years does not report all investing and financing transactions relating to this lease. Neither the original investment outflow nor the original borrowing inflow is reported in the cash flow statement, but the repayment is reported later as a financing outflow. From a cash flow statement perspective, the firm appears to be paying off a phantom loan, although the loan itself is reported in the balance sheet.

A similar result occurs when a firm acquires real estate by assuming an existing mortgage or by giving a mortgage or installment note to the seller. Only the down payment is reported as an investing outflow; all subsequent principal payments are reported as financing outflows.

Still another example of the incomplete reporting of financing activities in the cash flow statement under SFAS-95 is the conversion or exchange of debt for equity. A comparative cash flow statement reports the original borrowing as a financing inflow, but settlement of the debt by conversion or exchange is not reported as a financing outflow because it does not involve cash.

72.4.4.6 Free Cash Flows

Another important deficiency in the current cash flow statement is the absence of the concept of “free cash flow.”

Free cash flow is defined as cash without any restrictions on its use. It is available for any purpose at any time. It is similar to the concept of un-appropriated retained earnings. Since earnings are usually appropriated for dividend payout, plant expansion, contingencies, and other needs, cash available after these appropriations would be more useful for management planning.

Free cash flow has become increasingly important in financial statement analysis, yet the accounting profession has ignored it. The authors suggest that the profession take a serious look at free cash flow, with a view to narrowing and standardizing the conceptual definitions. If the traditional cash flow statement can be extended to include a consistent concept of free cash flow, it would become far more informative and useful.

72.5 Conclusion

This chapter compares the distinctions in SFAS-95 among operating, investing, and financing activities with similar distinctions in the finance literature. It identifies several inconsistencies and ambiguities in the three-way classification of cash flows under SFAS95, and demonstrates how the effectiveness of the cash flow statement to distinguish among operating, financing, and investing activities is impaired.

More specifically, this chapter demonstrates that the three-way classification result in reporting similar cash flows differently and different cash flows similarly, just the opposite of the desired characteristic of financial reporting to report similar things similarly and different things differently. The paper pinpoints that the classification of interest, income taxes, and dividend collections as operating cash flows results in contaminating cash flow from operating activities with the interest and dividend effects of investing and financing activities as well as with the tax effects of gains and losses relating to investing and financing activities. Finally, this chapter highlights that the requirements to report third-party financing transactions and disclose noncash investing and financing transactions are ambiguous.

By highlighting these inconsistencies and ambiguities, it is hoped that readers will be more aware of certain limitations of cash flow statements prepared under SFAS-95. More specifically, it is hoped that readers have been made aware that the amount reported as cash flow from operating activities does not reflect all of the cash flow consequences of operating activities and, similarly, that the amounts reported as cash flow from investing and financing activities do not reflect all of the cash flow consequences of investing and financing activities, respectively. Accordingly, these amounts should not be incorporated into operating, investing and financing decision models without adjustment. We hope that FASB will soon recommend some important changes to make cash flow statements more transparent and useful to the investing community.

Do CEO Gender and Marital Status Affect Firm's R&D and Value? An Empirical Analysis Using Nonlinear Models

73

Keshab Shrestha, Cheng-Few Lee, and Abdul Ghafoor

Abstract

This chapter reviews some nonlinear models used in corporate finance research. We also propose and empirically test some hypotheses regarding the effects of CEO gender and marital status on firm's R&D investment and firm values. We find that there is no association between the R&D investment and CEO gender. Similarly, there is not an association between the R&D investment and CEO marital status. However, using the usual Tobin's Q to represent the firm value, we find that both single CEO and male CEO enhance the firm value. We also find a nonlinear relationship between firm value and each of the two variables like firm size and institutional ownership. Finally, we find a significant positive association between the free cash flows and firm value but a significantly negative association between the firm value and leverage.

73.1 Introduction

In many corporate finance research, linear relationships are used to express association among different variables of interest. Furthermore, linear relationships are also used to estimate and test various theories in empirical studies. However, the relationships among variables are the outcome of optimization process and equilibrium conditions, which could in general lead to nonlinear relationships instead of linear relationships. Sometimes, a linear relationship is assumed or estimated to simplify the relationship. On the estimation side, such simplification has been done to save costs due to high computational costs in the past. Due to low computational costs as well as the development of symbolic computation, analyzing nonlinear models is more feasible now. Furthermore, linear relationships are special cases of nonlinear relationships, therefore, there is no cost to analyzing a possible nonlinear relationship.

Since Zerambka (1968), the function form papers in economics and finance research have started paying more attention to nonlinear models. For example, Lee (1976) has applied the functional form methodology to dividend policy to test for linear, log-linear, and nonlinear relationships. There are many other studies that use nonlinear models in corporate finance, and these studies are briefly discussed in the literature review section of this chapter.

In this chapter, we present four hypotheses regarding the effects of CEO's gender and marital status on a firm's R&D investment and firm values. We test these hypotheses using nonlinear models using the US data for 2008. Our empirical analysis indicates that there is no association between the R&D investment and CEO gender. Similarly, there is no association between the R&D investment and CEO marital status. However, there is significant association between the R&D investment and variables like firm value, free cash flows, and firm leverage. As to the hypothesis regarding firm value and CEO gender and marital status, we find some interesting results. Using the usual Tobin's Q to represent the firm value, we find that both single CEO and male CEO enhance the firm value. There are nonlinear relationships between firm value and each of the two control variables, firm size and institutional ownership. Finally, we find a significant positive association between the free cash flows and firm value, but a significantly negative association between the firm value and leverage.

73.2 Literature Review

This section presents a brief literature review on nonlinear models in corporate finance. Detailed information on some of the studies presented here can be found in Chen et al. (2004). Many studies use nonlinear models to examine the relationship between firm value (or firm performance) and ownership structure. Some examples of these studies include Jensen and Meckling (1976), Leland and Pyle (1977), Demsetz (1983), Fama and Jensen (1983), Stulz (1988), Morck et al. (1988), McConnell and Servaes (1990), Bagnani et al. (1994), Cho (1998), Holderness et al. (1999), Short and Keasey (1999), Himmelberg et al. (1999), Anderson and

Reeb (2003), Joh (2003), Florackis et al. (2009), Yu et al. (2012), and Hamadi and Heinen (2015).

Other studies analyze the nonlinear dependence of the effects of equity issuance on ownership structure (e.g., Wruck (1989), Hertz and Smith (1993), Fields and Mais (1994), Brous and Kini (1994), Mikkelsen et al. (1997), Slovin et al. (2000), and Aggarwal et al. (2002)). Cook et al. (2006) show that the greater the promotion efforts by investment bankers, prior to IPOs, the larger the underpricing of the issue. Similarly, Kim et al. (2010) examine whether the relationship between issue size and underwriting spreads is nonlinear and U-shaped.

Some studies use nonlinear models to analyze the corporate payout policy. These studies include Schooley and Barney (1994), Cook and Easterwood (1994), Alangar et al. (1999), Lie (2000), Setia-Atmaja et al. (2009). Lee et al. (2011) present a theoretical model that shows a nonlinear payout policy dependent on growth rate. Ham et al. (2020) analyze the information content of dividends regarding future earnings. They find a nonlinear effect of a dividend increase and decrease, whereby dividend increases have a more persistent effect on earnings compared to dividend decreases.

Nonlinear relations are also common in corporate capital structure research (e.g., Diamond (1991), Bagnani et al. (1994), Bae et al. (1994), Barclay and Smith Jr. (1995), Stohs and Mauer (1996), Roth and McDonald (1999), and Anderson et al. (2003)). Recently, Chen et al. (2021) used the interaction effect with a recession dummy variable and found that (i) debt maturity is pro-cyclical, (ii) higher-beta firms tend to have a longer maturity, and (iii) shorter maturity amplifies the sensitivity of credit spreads to aggregate shocks. Nonlinear models are also used in analyzing cash holdings (Opler et al. 1999) and corporate investment decisions (Allen and Cebenyoyan 1991; Thomas 1995; Martin 1996; Subrahmanyam et al. 1997; Denis et al. 1977a; Cho 1998; Ghosh and Ruland 1998). Recently, Bustamante (2016) has used the quadratic equation model to analyze corporate investments. Some studies use nonlinear models in antitakeover provisions research (e.g., McWilliams (1990) and Boyle, Carter and Stover (1998)).

Nonlinear models are also used to analyze the impact of board structure (Byrd and Hickman 1992; Denis et al. 1977b; Rosenstein and Wyatt 1997; Yermack 1996; Andres and Vallelado 2008; Coles et al. 2008). For example, Byrd and Hickman (1992) find a nonlinear relationship between bidding firms' abnormal returns and the proportion of independent outside directors on the board. Similarly, Denis et al. (1977b) found the probability of top executive turnover is significantly less sensitive to performance when officers and directors own between 5% and 25% of the firm's shares than when they own less than 5%.

Some studies use nonlinear models to analyze the relationship among price per share, dividend per share, and retained earnings per share for US industrial firms. Lee (1976) and Gilmore and Lee (1986) developed a generalized functional form (GFF) to analyze the relationship among the stock price, dividends, and retained earnings. They find that the linear form (sometimes even the log-linear form) is not a correct functional form for investigating the dividend effect of the electric utility industry. Moreover, the dividend effect is not significantly different from the retained earning

effect for 60% of the cross-section results after the true functional relationship has been determined. The GFF explicitly takes the interrelation between dividends and retained earnings into account; the functional form parameter also reflects the different relationships among the stock price, dividends, and retained earnings under various economic conditions. In sum, it has been established that the previous studies of determining the dividend effect of the electric utility industry may have pre-judged an important issue – the correct functional form. While linear and logarithmic forms are easy to handle, this consideration alone is not enough to justify the employment of either of these forms. In fact, it has been shown that there exists a generalized functional form, which allows a compact analysis of the effects of choice of functional form on determining the dividend effect of the electric utility industry.

Chang and Lee (1977) used two alternative techniques to analyze pooled time-series and cross-section data to test the importance of the firm effect and time effect in the financial analysis. Their techniques are also integrated with the functional form parameter estimation method to show the importance of appropriate functional form in handling a pooled time-series and cross-section type econometric model. The data on the electric industry show that both the time effect and cross-section effect are important in explaining stock price variation. It is also found that linear form (and/or) log-linear form is not always appropriate in testing the importance of both the time and firm effects in financial analyses.

The remaining part of this section is devoted to a discussion of the model specifications. Since there are numerous models, we will only discuss the model specifications not covered in Chen et al. (2004). When trying to understand whether a relationship among variables is linear or nonlinear, it would be helpful to use a specification where a possible linear relationship is a particular case of a nonlinear model. One of the ways to achieve this is to use the functional form as suggested by Zarembka (1968) and Lee (1976) using Box and Cox (1964) transformation $X^{(\lambda)}$ of variable X as defined below:

$$X^{(\lambda)} = \frac{X^\lambda - 1}{\lambda} \quad (1)$$

This transformation has the following property:

$$\lim_{\lambda \rightarrow 0} \frac{X^\lambda - 1}{\lambda} = \ln(X) \quad (2)$$

For example, Lee (1976) considers the following possible nonlinear model, depending on the value of the parameter λ ,

$$P_{it}^{(\lambda)} = \alpha_0 + \alpha_1 D_{it}^{(\lambda)} + \alpha_2 R_{it}^{(\lambda)} + \varepsilon_{it} \quad \varepsilon_{it} \sim N(0, \sigma^2) \quad (3)$$

where P_{it} , D_{it} , and R_{it} are the price, dividends, and retained earnings per share for the firm i and period t , respectively. The parameters α_0 , α_1 , α_2 , σ , and λ can be estimated

using the maximum likelihood estimator. It is important to note that the Eq. (3) becomes linear if λ equals 1 and log-linear if λ equals 0.

Alternately, one can use logistic transformation instead of Box and Cox (1964) transformation, where the logistic transformation of X is given by

$$\ln\left(\frac{X}{1-X}\right) \quad (4)$$

Lee et al. (2011) consider the following nonlinear model

$$\ln\left(\frac{X_{it}}{1-X_{it}}\right) = \alpha + \beta_1 Risk_{it} + \beta_2 D_{it}(g_{it} < cROA_{it})Risk_{it} + \beta_3 Growth_{it} + \beta_4 Risk_{it} \times Growth_{it} + \beta_5 \ln(Size)_{it} + \beta_6 ROA_{it} + e_{it} \quad (5)$$

Another specification is to use the smooth transition function instead of a piecewise regression. Christopoulos and Leon-Ledesma (2007) suggest using either the logistic smooth transition (LSTR) or exponential smooth transition model (ESTR). An example is given below for two independent variables (X and Z) case:

$$Y_t = \alpha + \beta_1 X + \beta_2 Z_t + \beta_3 F(Z_t : \gamma, c) + e_t \quad (6)$$

where for LSTR, the transition function $F(Z_t : \gamma, c)$ is given by

$$F(Z_t : \gamma, c) = \frac{1}{1 + e^{-\gamma(Z_t - c)}} \quad (7)$$

And, for ESTR, the transition function $F(Z_t : \gamma, c)$ is given by

$$F(Z_t : \gamma, c) = 1 - e^{-\gamma(Z_t - c)^2} \quad (8)$$

where c gives the location parameter and γ is the speed parameter.

73.3 Hypotheses

The main objectives of this chapter are to analyze the impact of characteristics like (i) CEO gender and (ii) CEO marital status on a firm's R&D investment and firm value measured by Tobin's Q. It is well recognized that managers are not a homogeneous group of individuals. According to the Upper Echelons Theory (Hambrick and Manson 1984; Hambrick 2007), managers are heterogeneous, and that firm-related decisions are affected by managers' experiences, values, and personalities.

There exists a body of research examining whether corporate outcomes can be influenced by more women on boards (e.g., Adams and Ferreira (2009), Ahern and Dittmar (2012), and Matsa and Miller (2013)). Some researchers argue that women tend to have a higher expectation of their responsibilities and that women have to demonstrate extra competence to reach executive positions (Fondas and Sassolos

2000; Eagly and Carli 2003; Dunn 2010). Researchers in Psychology have found evidence that indicates that women have better communication skills, and women tend to perform better in group problem-solving and decision-making tasks (Dallas 2002; Fondas 1997; Maznevski 1994; Robinson and Dechant 1997; Wood et al. 1985). We refer to this hypothesis that female CEOs are more responsible, more competent, better problem solvers, and better decision makers than male CEOs as the *competency hypothesis*. Furthermore, there exists literature on gender differences that suggest women are more conservative and risk-averse than men (see, e.g., Byrnes et al. (1999), Jianakoplos and Bernasek (1998), Johnson and Powell (1994), Levin et al. (1988), and Sunden and Surette (1998)). We refer to this argument as the *risk-aversion hypothesis*.

As to the marital status of the CEO, there is some interesting evidence. For example, Roussanov and Savor (2014) found that firms run by single CEOs exhibit higher stock return variance, use more aggressive investment policies, and do not respond to changes in idiosyncratic risk. Their findings hold when they use variation in divorce laws across states as an instrument for the CEO's marital status. This evidence indicates that the marital status itself drives choices rather than just reflecting innate heterogeneity in preference.

Now, we come to the hypothesis regarding R&D investment. Managers may prefer a quiet life (Hart 1983; Bertrand and Mullainathan 2003; Holmstrom 1979) and dislike the costly efforts associated with innovation projects like R&Ds (Chen et al. 2018). These arguments imply low investments in R&D, in general. However, when we compare a female CEO to a male CEO, the *competency hypothesis* implies that female CEO would invest more in R&D because they feel more responsible and are competent. However, the *risk aversion hypothesis* suggests that a female CEO would invest less in R&D, because R&D activities involve higher risk. Therefore, whether a female CEO would invest more or less in R&D compared to a male CEO is an empirical question. Therefore, we state our first hypothesis regarding CEO gender and R&D investment in the null form as follows:

Hypothesis 1: *There is no association between the CEO gender and R&D investment.*

As to the marital status of the CEO, Roussanov and Savor (2014) found that a single CEO invests more in R&D plus advertising compared to a married CEO. However, in the presence of CEO gender, we do not know the outcome. Therefore, we present the following hypothesis in the null form:

Hypothesis 2: *There is no association between the CEO gender and R&D investment.*

Regarding the firm value, the *competency hypothesis* implies that the firm value with a female CEO will be higher than the firm with a male CEO. On the contrary, the *risk-aversion hypothesis* implies that the female CEO may not take enough risk. Therefore, it will lead to a lower firm value. Therefore, the nature of the association

between the CEO gender and the firm value is an empirical question. We present the hypothesis regarding the CEO gender and firm value in the null form:

Hypothesis 3: *There is no association between the CEO gender and firm value.*

As to the CEO's marital status and firm value, one can argue that a single CEO will be able to take more risks because he or she does not have any family responsibilities. However, there is still the question that the risk a single CEO takes may be higher than the optimal level of risk for the firm. Therefore, we do not have a predetermined nature of relationship between the marital status of the CEO and firm value. Therefore, we present the last hypothesis in the null form.

Hypothesis 4: *There is no association between the firm value and the marital status of the CEO.*

In this chapter, we will test all four hypotheses using nonlinear models that will be presented in the next section.

73.4 Empirical Analysis

In this section, we estimate two nonlinear relationships between dependent variables and independent variables of interest. The first dependent variable is the R&D investment and the second dependent variable is the firm value. Recently, corporate finance researchers are interested in the impact of CEO characteristics like gender (Bugeja et al. 2012) and marital status (Roussanov and Savor 2014). Therefore, we will also empirically test the impact of CEO gender and marital status on the R&D investment and firm value. We specifically test the four hypotheses presented earlier.

In the cross-sectional analysis, we used the data for the fiscal year 2008 obtained from Roussanov and Savor (2014). The dataset consists of 908 firms. There are 213 firms with single CEOs, and the remaining 695 firms have married CEOs. Furthermore, there are 28 female CEOs and 880 male CEOs in our sample. All the continuous variables are winsorized at the top and bottom 1% level.

73.4.1 R&D Investments

In this section, we estimate the nonlinear dependence of R&D investment on the firm size. We will estimate three versions of the R&D investment function: (i) with no switching point, (ii) with one switching point, and (iii) with two switching points. In Eq. (9), only the linear effect of firm size is included. In Eq. (10), a piecewise linear function with one switching point (S_1) is used to express the nonlinear effect of firm size. Equation (11) shows a piecewise linear function with two possible switching points (S_1 and S_2).

With no switching points:

$$RDS = \beta_0 + \beta_1 EVS + \beta_2 Single + \beta_3 Male + \beta_4 INST + \beta_5 CFS + \beta_6 LTD + \beta_7 ADVS + \sum_{j=1}^{44} \beta_{7+j} IND_j + \theta SIZE + Error \quad (9)$$

With one switching point:

$$RDS = \beta_0 + \beta_1 EVS + \beta_2 Single + \beta_3 Male + \beta_4 INST + \beta_5 CFS + \beta_6 LTD + \beta_7 ADVS + \sum_{j=1}^{44} \beta_{7+j} IND_j + \theta_1 SIZE_1 + \theta_2 SIZE_2 + Error$$

$$RDS = \beta_0 + \beta_1 EVS + \beta_2 Single + \beta_3 Male + \beta_4 INST + \beta_5 CFS + \beta_6 LTD + \beta_7 ADVS + \sum_{j=1}^{44} \beta_{7+j} IND_j + \theta_1 SIZE_1 + \theta_2 SIZE_2 + Error \quad (10)$$

where

$$SIZE_1 = \begin{cases} SIZE, & \text{if } SIZE < S_1 \\ S_1, & \text{if } SIZE \geq S_1 \end{cases},$$

and

$$SIZE_2 = \begin{cases} 0, & \text{if } SIZE < S_1 \\ SIZE - S_1, & \text{if } SIZE \geq S_1 \end{cases}.$$

With two switching points:

$$RDS = \beta_0 + \beta_1 EVS + \beta_2 Single + \beta_3 Male + \beta_4 INST + \beta_5 CFS + \beta_6 LTD + \beta_7 ADVS + \sum_{j=1}^{44} \beta_{7+j} IND_j + \theta_1 SIZE_1 + \theta_2 SIZE_2 + \theta_3 SIZE_3 + Error \quad (11)$$

where

$$SIZE_1 = \begin{cases} SIZE, & \text{if } SIZE < S_1 \\ S_1, & \text{if } SIZE \geq S_1 \end{cases}$$

$$SIZE_2 = \begin{cases} 0, & \text{if } SIZE < S_1 \\ INSD - S_1, & \text{if } S_1 \leq SIZE < S_2 \\ S_2 - S_1, & \text{if } SIZE \geq S_2 \end{cases}$$

$$SIZE_3 = \begin{cases} 0, & \text{if } SIZE < s \\ SIZE - s, & \text{if } SIZE \geq s \end{cases}$$

The variable definitions are as follows:

<i>RDS</i>	=	R&D expenditures divided by sales
<i>EVS</i>	=	(market value of equity + book value of long-term debt – book value of total assets)/sales
<i>CFS</i>	=	Free cash flow divided by sales, where free cash flow equals operating income before depreciation – Interest expense – Taxes – Dividends
<i>LTD</i>	=	Long-term debt/(long-term debt + market value of equity)
<i>SIZE</i>	=	Log(market value of equity)
<i>ADVS</i>	=	Advertising expenses divided by sales
<i>INST</i>	=	Institutional holdings
<i>Male</i>	=	Male dummy = 1 if CEO is male
<i>IND_{1 to}</i>	=	Industry dummies
<i>IND₄₄</i>	=	
<i>Single</i>	=	Single dummy = 1 if CEO is single

The switching points are not assumed to be known in advance. They are rather empirically estimated. The locations of switching points are estimated using a grid search technique. The number and locations of switching points are chosen based on the log-likelihood test.

The summary statistics are presented in Table 1. The sample mean of EVS is positive with a negative median. This indicates that the distribution is far away from being symmetric. The mean for the variable Single is 0.235 as there are 213 firms with single CEOs out of 908 firms. Similarly, the mean for variable Male is 0.969 with 28 out of 908 firms having female CEOs. The average for RDS, CFS, LTD, ADVS, SIZE and INST are 0.034, 0.083, 0.269, 0.010, 7.233, and 0.787, respectively.

The correlation coefficients are presented in Table 2. The minimum correlation is –0.45 or negative 45%, which is between EVS and LTD. The maximum correlation is 38 percent which is between CFS and Size. The correlation between EVS and RDS is 25 percent. The correlation between RDS, one of the two dependent variables, and Single is 6%, and the correlation between RDS and Male is 1%. Similarly, the correlation between EVS and Single is 6%, and the correlation between EVS and

Table 1 Summary statistics: This table presents the mean, median, standard deviation, and the number of observations for each of the variables used in the chapter

	N	Mean	Median	Standard Deviation
EVS	908	0.083	−0.124	0.936
Single	908	0.235	0.000	0.424
Male	908	0.969	1.000	0.173
RDS	908	0.034	0.000	0.072
CFS	908	0.083	0.091	0.199
LTD	908	0.269	0.229	0.243
ADVS	908	0.010	0.000	0.023
SIZE	908	7.233	7.212	1.666
INST	908	0.787	0.828	0.172

Table 2 Correlation coefficient: This table presents correlation coefficients for the variables used in the study

	EVS	Single	Male	RDS	CFS	LTD	ADVS	SIZE
EVS	1.00							
Single	0.06	1.00						
Male	0.05	0.04	1.00					
RDS	0.25	0.06	−0.01	1.00				
CFS	0.24	−0.01	0.06	−0.15	1.00			
LTD	−0.45	−0.04	0.02	−0.26	−0.21	1.00		
ADVS	0.11	0.01	−0.05	0.01	−0.05	−0.03	1.00	
SIZE	0.24	−0.21	0.02	−0.03	0.38	−0.18	0.01	1.00
INST	0.19	0.08	0.01	−0.00	0.15	−0.12	−0.01	0.12

Male is 5%. Based on the two variables analysis, the CEO’s gender and marital status seem to affect the R&D and firm value. However, we will test the significance of these effects in the multivariate analysis to be presented later.

The results of the piecewise regression represented by three models (Eqs. 9, 10, and 11 are presented in Table 3. The log-likelihood test statistics are presented in Table 4. If we use the standard 5% level, then we conclude that there is one switching point for SIZE at 6.056. Therefore, rest of the conclusion is based on the model reported in Table 3 and Eq. (10), that is, the third column. The results indicate that there is no association between the R&D investment and the CEO’s gender. Similarly, there appears to be no association between the R&D investment and the marital status of the CEO. The coefficient of EVS is highly significant even at the 1% level. This is consistent with the high correlation between EVS and RDS. Since the coefficient of CFS is negative and significant at the 1% level, free cash flow seems to have negative association with RDS. Similarly, the coefficient of LTD is negative and significant at the 1% level implying that high levered firms spend less on R&D.

Table 3 Piecewise regression results: This table presents the result of the nonlinear piecewise regression represented by Eqs. (9), (10), and (11)

	No switching Eq. (9)	Single switching, Eq. (10)	Two switching, Eq. (11)

* $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table 4 Log-likelihood ratio statistics: This table presents the log-likelihood value and log likelihood ratio test statistics used in determining the number of switching points

	Log-likelihood function	Likelihood ratio statistics
No switching point	1427.711	
Single switching point at 6.058 (SIZE)	1431.319	7.216***
Two switching points at 3.336 and 7.561 SIZE	1433.011	3.383*

* $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. The log-likelihood ratio test statistic is given by $2[\ln(L_{i+1}) - \ln(L_i)]$ where $\ln(L_i)$ is the value of the log-likelihood function with number of switching points. The log-likelihood statistics have chi-squared distribution with degrees of freedom equal to 1

73.4.2 Firm Value

In order to test our third and fourth hypotheses, we estimate the nonlinear relationship between firm value (EVS) with two independent variables, SIZE and INST in the presence of other variables. Specifically, the following equation is estimated:

$$EVS = (\text{control variables}) + \beta_1 \text{Male} + \beta_2 \text{Single} + \theta_1 z_1 + \theta_2 z_1^2 + \theta_3 z_1^3 + \gamma_1 z_1 z_2 + \gamma_2 z_1 z_2^2 + \varphi_1 z_2 + \varphi_2 z_2^2 + \varphi_3 z_2^3 + e \quad (12)$$

where $Z_1 = \text{SIZE}$ and $Z_2 = \text{INST}$. The control variables used are *RDS*, *CFS*, *LTD*, *ADVS*, and the 44 industry dummies. We also analyze the impact of CEO gender and marital status. The results are presented in Table 5.

The results presented in Table 5 indicate that the coefficient of Single is positive and significant at the 10% level. Actually, the p-value is 0.052, which is almost significant at the 5% level. This implies that a single CEO has a positive impact on firm value. Similarly, the coefficient of Male is positive and significant at the 1% level. This implies a strong contribution of Male to the value of the firm. The nonlinear relationship between EVS and SIZE is only through the interaction effect with INST. But, INST clearly has a nonlinear relationship with EVS both through main effect and interaction effect.

In Table 5, we used EVS, which is firm value scaled by sales, as the dependent variable. However, the firm value is normally scaled by total assets and this definition is known as Tobin's Q, which is defined below:

Table 5 Nonlinear regression results with EVS: This table presents results of the estimation of Eq. (12) with EVS as the dependent variable. SIZE2 and SIZE3 represent SIZE raised to power 2 and 3, respectively. Similarly, INST2 and INST3 represent INST raised to power 2 and 3, respectively

$Q = (\text{Total assets} - \text{book value of equity} + \text{market value of equity}) / \text{Total assets}$

The estimation of Eq. (12) with Tobin's Q as the dependent variable is presented in Table 6. The coefficients of Single are significantly positive, even at the 1% level. Similarly, the coefficient of Male is positive and significant at the 5% level. This indicates that both a Single CEO and Male CEO enhance the value of the firm. The result regarding Male CEO seems to indicate that the *risk-aversion* effect seems to dominate the *competency* effect in the sense that the female CEO seems to take less risk than the optimum risk level for the firm, and, therefore, a lower firm value. Also, with Tobin's Q, both the SIZE and INST seem to have nonlinear effect. This result is quite different from the one obtained with EVS as the dependent variable. The coefficient of CFS is significantly positive, even at the 1% level. This implies free cash flows have a positive impact on the firm value. Similarly, the coefficient of LTD is significantly negative at the 1% level, indicating a negative impact of leverage on firm value.

73.5 Conclusion

In this chapter, we present a brief review of nonlinear models used in the corporate finance research. We also briefly present nonlinear specification used in the empirical studies. We also present four hypotheses regarding the effects of CEO gender and marital status on a firm's R&D investment and firm values.

We also perform an empirical analysis using the US data for 2008 to test these hypotheses. Our empirical analysis indicates that there is no association between the

R&D investment and CEO gender. Similarly, there is no association between the R&D investment and CEO marital status. However, there is significant association between the R&D investment and variables like firm value, free cash flows, and firm leverage.

As to the hypothesis regarding firm value and CEO gender and marital status, we find some interesting results. Using the usual Tobin's Q to represent the firm value, we find that both single CEO and male CEO enhance the firm value. There are nonlinear relationships between firm value and each of the two control variables, firm size and institutional ownership. Finally, we find a significant positive association between the free cash flows and firm value but a significantly negative association between the firm value and leverage.

Three Alternative Methods for Estimating Hedge Ratios

74

Sheng-Syan Chen, Cheng-Few Lee, Fu-Lai Lin, and Keshab Shrestha

Abstract

This chapter first discusses four different theoretical models, which include minimum variance, mean-variance, expected utility, and value-at-risk method. Then we use S&P 500 data to show how three alternative estimation methods can be used to estimate hedge ratio. These three methods include OLS method, GARCH method, and cointegration and error correction method. We found that OLS method is not sufficient for estimating hedge ratio.

Keywords

Hedge ratio · Cointegration · Minimum variance · Mean-variance hedge ratio · ARCH GARCH model

74.1 Introduction

A **future contract** is a standardized legal agreement between a buyer and a seller, who promise now to exchange a specified amount of money for goods or services at a future time. Of course, there is nothing really unusual about a contract made in advance of delivery. For instance, whenever something is ordered rather than purchased on the spot, a futures (or forward) contract is involved. Although the price is determined at the time of the order, the actual exchange of cash for the merchandise takes place later. For some items, the lag is a few days, while for others (such as a car) it may be months. Moreover, a futures contract imparts a legal obligation to both parties of the contract to fulfill the specifications. To guarantee fulfillment of this obligation, a “good-faith” deposit, also called **margin**, may be required from the buyer (and the seller, if he or she does not already own the product).

Future contracts are frequently used to hedge spot contracts to review the risk. Therefore, hedge ratio estimation is important for risk management. One of the best uses of derivative securities such as futures contracts is used to hedge the risk. For the last half century, both academicians and practitioners have shown great interest in the issue of hedging with futures, therefore theoretical analysis and empirical investigation for future hedge ratio are important for both academicians and practitioners. This is quite evident from the large number of articles written in this area.

The main theoretical issue in hedging involves the determination of the optimal hedge ratio. However, the optimal hedge ratio depends on the particular objective function to be optimized. In this chapter, we will carefully discuss different objective functions used to derive optimal hedge ratio. For example, one of the most widely-used hedging strategies is based on the minimization of the variance of the hedged portfolio (e.g., see Johnson 1960; Ederington 1979; and Myers and Thompson 1989). This so-called minimum-variance (MV) hedge ratio is simple to understand and estimate. However, the MV hedge ratio completely ignores the expected return of the hedged portfolio. Therefore, this strategy is inconsistent with the mean-variance tradeoff framework unless the individuals are infinitely risk-averse or the futures price follows a pure martingale process (i.e., expected futures price change is zero).

Some more realistic strategies that incorporate both the expected return and risk (variance) of the hedged portfolio have been developed (e.g., see Howard and D’Antonio 1984; Cecchetti et al. 1988; and Hsin et al. 1994). These strategies are consistent with the mean-variance framework. In fact, it can be shown that if the future price follows a pure martingale process, then the optimal mean-variance hedge ratio will be reduced to the MV hedge ratio.

Another aspect of the mean-variance-based strategies is that even though they are an improvement over the MV strategy, for them to be consistent with the expected utility maximization principle, either the utility function needs to be quadratic or the returns should be jointly normal. Unless these assumptions are valid, then the hedge ratio may not be optimal with respect to the expected utility maximization principle. Some research has solved this problem by deriving the optimal hedge ratio based on

the maximization of the expected utility (e.g., see Cecchetti et al. 1988; and Lence 1995, 1996). It should be noted that this approach requires the use of specific utility function and specific return distribution.

Attempts have been made to eliminate these specific assumptions regarding the utility function and return distributions. Some of them involve the minimization of the mean extended-Gini (MEG) coefficient, which is consistent with the concept of stochastic dominance (e.g., see Cheung et al. 1990; Kolb and Okunev 1992, 1993; Lien and Luo 1993a; Shalit 1995; and Lien and Shaffer 1999). Shalit (1995) shows that if the prices are normally distributed, then the MEG-based hedge ratio will be the same as the MV hedge ratio.

Recently, hedge ratios based on the generalized semivariance (GSV) or lower partial moments have been proposed (e.g., see De Jong et al. 1997; Lien and Tse 1998, 2000; and Chen et al. 2001). These hedge ratios are also consistent with the concept of stochastic dominance. Furthermore, these GSV-based hedge ratios have another attractive feature, whereby they measure portfolio risk by the GSV, which is consistent with the risk perceived by managers, because of its emphasis on the returns below the target return (see Crum et al. 1981; and Lien and Tse 2000). Lien and Tse (1998) show that if the futures and spot returns are jointly normally distributed, and if the futures price follows a pure martingale process, then the minimum-GSV hedge ratio will be equal to the MV hedge ratio. Finally, Hung et al. (2006) have proposed a related hedge ratio that minimizes the value-at-risk associated with the hedged portfolio when choosing hedge ratio. This hedge ratio will also be equal to MV hedge ratio if the futures price follows a pure martingale process. However, the future price in general does not follow the pure martingale process; therefore, generalized hedge ratio should be considered to improve the effectiveness of hedging decision.

It should be noted that most of the studies mentioned above (except Lence (1995, 1996)) ignore transaction costs as well as investments in other securities. Lence (1995, 1996) derives the optimal hedge ratio where transaction costs and investments in other securities are incorporated into the model. Using a CARA utility function, Lence finds that under certain circumstances, the optimal hedge ratio is zero; that is, the optimal hedging strategy is not to hedge at all.

In addition to the use of different objective functions in the derivation of the optimal hedge ratio, previous studies also differ in terms of the dynamic nature of the hedge ratio. For example, some studies assume that the hedge ratio is constant over time. Consequently, these static hedge ratios are estimated using unconditional probability distributions (e.g., see Ederington 1979; Howard and D'Antonio 1984; Benet 1992; Kolb and Okunev 1992, 1993; and Ghosh 1993). On the other hand, several studies allow the hedge ratio to change over time. In some cases, these dynamic hedge ratios are estimated using conditional distributions associated with models such as ARCH and GARCH (e.g., see Cecchetti et al. 1988; Baillie and Myers 1991; Kroner and Sultan 1993; and Sephton 1993). The GARCH based method has recently been extended by Lee and Yoder (2007) where regime-switching model is used. Alternatively, the hedge ratios can be made dynamic by considering a multi-period model where the hedge ratios are allowed to vary for different periods. This is the method used by Lien and Luo (1993b).

When it comes to estimating the hedge ratios, many different techniques are currently being employed, ranging from simple to complex ones. For example, some of them use such a simple method as the ordinary least squares (OLS) technique (e.g., see Ederington 1979; Malliaris and Urrutia 1991; and Benet 1992). However, others use more complex methods, such as the conditional heteroscedastic (ARCH or GARCH) method (e.g., see Cecchetti et al. 1988; Baillie and Myers 1991; and Sephton 1993), the random coefficient method (e.g., see Grammatikos and Saunders 1983), the cointegration method (e.g., see Ghosh 1993; Lien and Luo 1993b; and Chou et al. 1996), or the cointegration-heteroscedastic method (e.g., see Kroner and Sultan 1993). Recently, Lien and Shrestha (2007), Maghyereh et al. (2019), and Sultan et al. (2019) have suggested the use of wavelet analysis to match the data frequency with the hedging horizon. Finally, Lien and Shrestha (2010) also suggest the use of multivariate skew-normal distribution in estimating the minimum variance hedge ratio.

By now it is clear that there are several different ways of deriving and estimating hedge ratios. In this chapter, we will review these different techniques and approaches, and examine their relations. In addition, we also use S&P 500 index future data to show how three different econometrics methods can be used to estimate hedge ratios.

There are four sections in this chapter. In section 74.2, four alternative theories for deriving the static optimal hedge ratios are carefully reviewed. Section 74.3 will use three alternative estimation methods to perform an empirical study to estimate minimal hedge ratio. Finally, in Sect. 74.4 we provide a summary. Appendix A presents the monthly data of S&P 500 index and its future from January 2005 to August 2020, and Appendix B explains the applications of R language in estimating three optimal hedge ratios.

74.2 Alternative Theories Used for Deriving the Static Optimal Hedge Ratios

By combining investments in the spot market and futures market to form a portfolio, we can eliminate (or reduce) fluctuations in its value by hedging. Consider a portfolio consisting of C_s units of a long spot position and C_f units of a short futures position.¹ Following Lee et al. (2013) and Chen et al. (2003), let S_t and F_t denote the spot and futures prices at time t , respectively. Since the futures contracts are used to reduce the fluctuations in spot positions, the resulting portfolio is known as the hedged portfolio. If the hedge ratio is discussed in terms of price changes (profits), then the profit on the hedged portfolio, ΔV_H , and the hedge ratio, H , are, respectively, given by:

¹ Without loss of generality, we assume that the size of the future contract is 1.

$$\Delta V_H = C_s \Delta S_t - H C_f \Delta F_t \text{ and } H = \frac{C_f}{C_s}, \quad (1)$$

where $\Delta S_t = S_{t+1} - S_t$ and $\Delta F_t = F_{t+1} - F_t$.

The main objective of hedging is to determine and estimate the optimal hedge ratio (either h or H). It should be noted that optimal hedge ratio will depend on a particular objective function to be used. Hedge ratio can be classified into either static hedge ratio or dynamic hedge ratio.

It is important to note that in the above setup, the cash position is assumed to be fixed, and we only look for the optimum futures position. Most of the hedging literature assumes that the cash position is fixed, a setup that is suitable for financial futures. However, when we are dealing with commodity futures, the initial cash position becomes an important decision variable that is tied to the production decision, which has been discussed by Lence (1995, 1996).

Static hedge ratio means the hedge ratio remains constant over time. In general, there are nine static hedge ratios as follows: (a) Minimum-Variance Hedge Ratio, (b) Optimum Mean-Variance Hedge Ratio, (c) Sharpe Hedge Ratio, (d) Maximum Expected Utility Hedge Ratio, (e) Minimum Mean Extended-Gini Coefficient Hedge Ratio, (f) Optimum Mean-MEG Hedge Ratio, (g) Minimum Generalized Semivariance Hedge Ratio, (h) Optimum Mean-Generalized Semivariance Hedge Ratio, and (i) Minimum Value-at-Risk Hedge Ratio. In this section, we will discuss static hedge ratios (a), (b), (c), and (i) in detail. The information for the other five static hedge ratios can be found in Chen et al. (2003).

74.2.1 Minimum-Variance Hedge Ratio

The most widely used static hedge ratio is the minimum-variance (MV) hedge ratio. Johnson (1960) derives this hedge ratio by minimizing the portfolio risk, where the risk is given by the variance of changes in the value of the hedged portfolio as follows:

$$Var(\Delta V_H) = C_s^2 Var(\Delta S) + C_f^2 Var(\Delta F) - 2C_s C_f HCov(\Delta S, \Delta F).$$

The MV hedge ratio, in this case, is given by:

$$H_J^* = \frac{C_f}{C_s} = \frac{Cov(\Delta S, \Delta F)}{Var(\Delta F)}. \quad (2a)$$

Alternatively, if we use $Var(R_h)$ to represent the risk of hedged portfolio return (R_h), then the MV hedge ratio is obtained by minimizing $Var(R_h)$ which is given by:

$$Var(R_h) = Var(R_s) + h^2 Var(R_f) - 2hCov(R_s, R_f).$$

where h is the so-called hedge ratio, R_s and R_f are the so-called one-period returns on the spot and futures positions, respectively. In this case, the MV hedge ratio is given by:

$$h_f^* = \frac{Cov(R_s, R_f)}{Var(R_f)} = \rho \frac{\sigma_s}{\sigma_f}, \quad (2b)$$

where ρ is the correlation coefficient between R_s and R_f , and σ_s and σ_f are standard deviations of R_s and R_f , respectively.

The attractive features of the MV hedge ratio are that it is easy to understand and simple to compute. However, in general, the MV hedge ratio is not consistent with the mean-variance framework since it ignores the expected return on the hedged portfolio. For the MV hedge ratio to be consistent with the mean-variance framework, either the investors need to be infinitely risk-averse or the expected return on the futures contract needs to be zero.

74.2.2 Optimum Mean-Variance Hedge Ratio

Various studies have incorporated both risk and return in the derivation of the hedge ratio. For example, Hsin et al. (1994) derive the optimal hedge ratio that maximizes the following utility function:

$$\underset{C_f}{Max} \quad V(E(R_h), \sigma; A) = E(R_h) - 0.5A\sigma_h^2, \quad (3)$$

where A represents the risk aversion parameter. It is clear that this utility function incorporates both risk and return. Therefore, the hedge ratio based on this utility function would be consistent with the mean-variance framework. The optimal number of futures contract and the optimal hedge ratio are, respectively, given by:

$$h_2 = -\frac{C_f^* F}{C_s S} = -\left[\frac{E(R_f)}{A\sigma_f^2} - \rho \frac{\sigma_s}{\sigma_f} \right]. \quad (4)$$

One problem associated with this type of hedge ratio is that in order to derive the optimum hedge ratio, we need to know the individual's risk aversion parameter. Furthermore, different individuals will choose different optimal hedge ratios, depending on the values of their risk aversion parameter.

Since the MV hedge ratio is easy to understand and simple to compute, it will be interesting and useful to know under what condition the above hedge ratio would be the same as the MV hedge ratio. It can be seen from Eqs. (2b) and (4) that if $A \rightarrow \infty$ or $E(R_f) = 0$, then h_2 would be equal to the MV hedge ratio h_f^* . The first condition is simply a restatement of the infinitely risk-averse individuals. However, the second condition does not impose any condition on the risk-averseness, and this is important. It implies that even if the individuals are not infinitely risk averse, then the MV hedge ratio would be the same as the optimal mean-variance hedge ratio if the expected return on the futures contract is zero (i.e., futures prices follow a simple martingale process). Therefore, if futures prices follow a simple martingale process,

then we do not need to know the risk aversion parameter of the investor to find the optimal hedge ratio.

74.2.3 Sharpe Hedge Ratio

Another way of incorporating the portfolio return into the hedging strategy is to use the risk-return tradeoff (Sharpe measure) criteria. Howard and D'Antonio (1984) consider the optimal level of futures contracts by maximizing the ratio of the portfolio's excess return to its volatility:

$$\underset{C_f}{Max} \theta = \frac{E(R_h) - R_F}{\sigma_h}, \quad (5)$$

where C_f is the level of futures contracts. $\sigma_h^2 = Var(R_h)$ and R_F represents the risk-free interest rate.

The classic one-to-one hedge is a naïve strategy based upon a broadly defined objective of risk minimization. The strategy is naïve in the sense that a hedging coefficient of one is used regardless of past or expected correlations of spot- and futures-price changes. Working's (1953) strategy brings out the speculative aspects of hedging by analyzing changes in the basis and, accordingly, exercising discrete judgment about when to hedge and when not to hedge. The underlying objective of Working's (1953) decision rule for hedgers is one of profit maximization. Finally, Johnson (1960), in applying the mean-variance criteria of modern portfolio theory, emphasizes the risk-minimization objective but defines risk in terms of the variance of the hedged position. Although Johnson's method improves on the naïve strategy of a one-to-one hedge, however, it essentially disregards the return component associated with a particular level of risk. Rutledge (1972) uses both mean and variance information to derive hedge ratio.

Howard and D'Antonio (1984) use an objective function defined in Eq. 5 to derive the hedge ratio as defined in Eq. 6.

In deriving this hedge ratio, they use a mean-variance framework, and their strategy begins by assuming that the "agent" is out to maximize the expected return for a given level of portfolio risk. With a choice of putting money into three assets – a spot position, a futures contract, and a risk-free asset – the agent's optimal portfolio will depend on the relative risk-return characteristics of each asset. For a hedger, the optimal portfolio may contain a short futures position, a long futures position, or no futures position at all. In general, the precise futures position to be entered into will be determined by (1) the risk-free rate, (2) the expected returns and the standard deviations for the spot and futures positions, and (3) the correlation between the return on the spot position and the return on the futures.

$$\text{Hedge ratio } H = \frac{(\lambda - \rho)}{\gamma\pi(1 - \lambda\rho)} \quad (6)$$

where:

$\pi = \sigma_f / \sigma_s$ = relative variability of futures and spot returns;

$\alpha = \bar{r}_f / (\bar{r}_s - i)$ = relative excess return on futures to that of spot;

$\gamma = P_f / P_s$ = current price ratio of futures to spot;

$\lambda = \alpha / \pi = (\bar{r}_f / \sigma_f) / [(\bar{r}_s - i) / \sigma_s]$ = risk-to-excess-return relative of futures versus the spot position;

P_s, P_f = the current price per unit for the spot and futures, respectively;

ρ = simple correlation coefficient between the spot and futures returns;

σ_s = standard deviation of spot returns;

σ_f = standard deviation of futures returns;

$\bar{r}_s$ = mean return on the spot over some recent past interval;

$\bar{r}_f$ = mean return on the futures over some recent past interval; and

i = risk-free rate.

Based upon Eqs. 6 and 1, the optimal number of futures positions, C_f^* , is given by:

$$C_f^* = -C_s \frac{\left(\frac{S}{F}\right) \left(\frac{\sigma_s}{\sigma_f}\right) \left[\frac{\sigma_s}{\sigma_f} \left(\frac{E(R_f)}{E(R_s) - R_F} \right) - \rho \right]}{\left[1 - \frac{\sigma_s}{\sigma_f} \left(\frac{E(R_f)\rho}{E(R_s) - R_F} \right) \right]}. \quad (7)$$

From the optimal futures position, we can obtain the following optimal hedge ratio:

$$h_3 = - \frac{\left(\frac{\sigma_s}{\sigma_f}\right) \left[\frac{\sigma_s}{\sigma_f} \left(\frac{E(R_f)}{E(R_s) - R_F} \right) - \rho \right]}{\left[1 - \frac{\sigma_s}{\sigma_f} \left(\frac{E(R_f)\rho}{E(R_s) - R_F} \right) \right]}. \quad (8)$$

Again, if $E(R_f) = 0$, then h_3 reduces to:

$$h_3 = \left(\frac{\sigma_s}{\sigma_f} \right) \rho, \quad (9)$$

which is the same as the MV hedge ratio h_f^* .

By analyzing the properties of λ Howard and D'Antonio (1984) discern some important insights for the coordinated use of futures in a hedge portfolio. Numerically, λ expresses the relative attractiveness of investing in futures versus the spot position. When $\lambda < 1$, $\lambda = 1$, and $\lambda > 1$, the futures contract offers less, the same, and more excess return per unit of risk than the spot position, respectively. Since this analysis is being undertaken from a hedger's point of view, it is assumed $\lambda < 1$. An assumption that $\lambda > 1$ would inappropriately imply that theoretically it is possible to hedge the futures position with the spot asset. In addition, they also consider the effect of the relationship of λ to ρ on the optimal hedge ratio, H . Other detailed analysis can be found in Table 4 of Howard and D'Antonio's (1984) paper.

74.2.4 Minimum Value-at-Risk Hedge Ratio

Hung et al. (2006) suggest a new hedge ratio that minimizes the Value-at-Risk of the hedged portfolio. Specifically, the hedge ratio h is derived by minimizing the following Value-at-Risk of the hedged portfolio over a given time period τ :

$$VaR(R_h) = Z_\alpha \sigma_h \sqrt{\tau} - E[R_h] \tau \quad (10)$$

The resulting optimal hedge ratio, which Hung et al. (2006) refer to as zero-VaR hedge ratio, is given by

$$h^{VaR} = \rho \frac{\sigma_s}{\sigma_f} - E[R_f] \frac{\sigma_s}{\sigma_f} \sqrt{\frac{1 - \rho^2}{Z_\alpha^2 \sigma_f^2 - E[R_f]^2}} \quad (11)$$

It is clear that, if the futures price follows martingale process, the zero-VaR hedge ratio would be the same as the MV hedge ratio.

74.3 Applications of OLS, GARCH, and CECM Models to Estimate Optimal Hedge Ratio

In this section, we will discuss different approaches to estimating the optimum hedge ratios and apply these methods in practice to estimate the optimal stock index futures hedge ratio for S&P 500 index. We first introduce how to apply the ordinary least square (OLS) technique to estimating the optimum hedge ratios and discuss its restrictions. Secondly, considering the heteroscedastic nature of the error term, generalized autoregressive conditional heteroskedasticity (GARCH) technique is introduced to estimating the hedge ratio. In addition, we describe cointegration and error correction method to take into account the possibility of long-run equilibrium between spot and futures prices. Finally, we provide an empirical study using OLS, GARCH, and CECM models to estimate the optimal stock index futures hedge ratio for S&P 500 index through R language.

74.3.1 OLS Method

The conventional approach to estimating the MV hedge ratio involves the regression of the changes in spot prices on the changes in futures price using the OLS technique (e.g., see Junkus and Lee 1985). Specifically, the regression equation can be written as:

$$\Delta S_t = a_0 + a_1 \Delta F_t + e_t, \quad (12)$$

where the estimate of the MV hedge ratio, H_j , is given by a_1 . The OLS technique is quite robust and simple to use. However, for the OLS technique to be valid and

efficient, assumptions associated with the OLS regression must be satisfied. One case where the assumptions are not completely satisfied is that the error term in the regression is heteroscedastic. This situation will be discussed later.

Another problem with the OLS method, as pointed out by Myers and Thompson (1989), is the fact that it uses unconditional sample moments instead of conditional sample moments, which use currently available information. They suggest the use of the conditional covariance and conditional variance in Eq. (2a). In this case, the conditional version of the optimal hedge ratio (Eq. (2a)) will take the following form:

$$H_J^* = \frac{C_f}{C_s} = \frac{\text{Cov}(\Delta S, \Delta F) \mid \Omega_{t-1}}{\text{Var}(\Delta F) \mid \Omega_{t-1}}. \quad (13)$$

Suppose that the current information (Ω_{t-1}) includes a vector of variables (X_{t-1}) and the spot and futures price changes are generated by the following equilibrium model:

$$\Delta S_t = X_{t-1}\alpha + u_t,$$

$$\Delta F_t = X_{t-1}\beta + v_t.$$

In this case, the maximum likelihood estimator of the MV hedge ratio is given by (see Myers and Thompson (1989)):

$$\hat{h} \mid X_{t-1} = \frac{\hat{\sigma}_{uv}}{\hat{\sigma}_v^2}, \quad (14)$$

where $\hat{\sigma}_{uv}$ is the sample covariance between the residuals u_t and v_t , and $\hat{\sigma}_v^2$ is the sample variance of the residual v_t . In general, the OLS estimator obtained from Eq. (12) would be different from the one given by Eq. (14). For the two estimators to be the same, the spot and futures prices must be generated by the following model:

$$\Delta S_t = \alpha_0 + u_t, \quad \Delta F_t = \beta_0 + v_t.$$

In other words, if the spot and futures prices follow a random walk, then with or without drift, the two estimators will be the same. Otherwise, the hedge ratio estimated from the OLS regression (12) will not be optimal.

74.3.2 GARCH Method

Ever since the development of GARCH models, the OLS method of estimating the hedge ratio has been generalized to consider the heteroscedastic nature of the error term in Eq. (12). In this case, rather than using the unconditional sample variance and covariance, the conditional variance and covariance from the GARCH model are

used in the estimation of the hedge ratio. As mentioned above, such a technique allows an update of the hedge ratio over the hedging period.

Consider the following bivariate GARCH model (see Cecchetti et al. 1988; and Baillie and Myers 1991):

$$\begin{bmatrix} \Delta S_t \\ \Delta F_t \end{bmatrix} = \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix} + \begin{bmatrix} e_{1t} \\ e_{2t} \end{bmatrix} \text{ and } e_t \mid \Omega_{t-1} \sim N(0, H_t)$$

where Ω_{t-1} is all the available information up to time $t-1$. N denotes a bivariate normal distribution, and H_t is a time-varying 2×2 positive-definite conditional variance-covariance matrix as follows.

$$H_t = \begin{bmatrix} H_{11,t} & H_{12,t} \\ H_{12,t} & H_{22,t} \end{bmatrix}$$

The conditional MV hedge ratio at time t is given by $h_{t-1} = H_{12,t}/H_{22,t}$. This model allows the hedge ratio to change over time, resulting in a series of hedge ratios instead of a single hedge ratio for the entire hedging horizon.

In practice, it is necessary to model the conditional variance-covariance matrix and ensure the positive definiteness of H_t . Different models for H_t have been proposed in the literature, for example, Bollerslev (1988), Bollerslev et al. (1988) and Engle and Kroner (1995). Bollerslev (1988) built up a VECH-GARCH (1,1) model assuming that H_t is a linear combination of its own squared residual e'_{t-1} and past conditional variance-covariance variance H_{t-1} as follows.

$$\text{vec}(H_t) = C + A \text{vec}(e_{t-1}e'_{t-1}) + B \text{vec}(H_{t-1}).$$

where vec is the operator that stacks a matrix as a column vector. A and B are both a 3×3 parameter matrices.

$$\begin{aligned} \text{vec}(H_t) &= \begin{bmatrix} H_{11,t} \\ H_{12,t} \\ H_{22,t} \end{bmatrix} \\ &= \begin{bmatrix} c_{01,t} \\ c_{02,t} \\ c_{03,t} \end{bmatrix} + \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix} \begin{bmatrix} \varepsilon_{1,t-1}^2 \\ \varepsilon_{1,t-1}\varepsilon_{2,t-1} \\ \varepsilon_{3,t-1}^2 \end{bmatrix} + \begin{bmatrix} g_{11} & g_{12} & g_{13} \\ g_{21} & g_{22} & g_{23} \\ g_{31} & g_{32} & g_{33} \end{bmatrix} \\ &\quad \times \begin{bmatrix} H_{11,t-1} \\ H_{12,t-1} \\ H_{13,t-1} \end{bmatrix} \end{aligned}$$

To simplify calculation, Bollerslev et al. (1988) suggest a diagonal VECH-GARCH (1,1) model that parameter matrices A and B are restricted to be diagonal.

$$\begin{aligned}
\text{vec}(H_t) &= \begin{bmatrix} H_{11,t} \\ H_{12,t} \\ H_{22,t} \end{bmatrix} \\
&= \begin{bmatrix} c_{11}^* \\ c_{12}^* \\ c_{22}^* \end{bmatrix} + \begin{bmatrix} a_{11}^* & 0 & 0 \\ 0 & a_{12}^* & 0 \\ 0 & 0 & a_{22}^* \end{bmatrix} \begin{bmatrix} \varepsilon_{1,t-1}^2 \\ \varepsilon_{1,t-1}\varepsilon_{2,t-1} \\ \varepsilon_{2,t-1}^2 \end{bmatrix} + \begin{bmatrix} g_{11}^* & 0 & 0 \\ 0 & g_{12}^* & 0 \\ 0 & 0 & g_{22}^* \end{bmatrix} \\
&\quad \times \begin{bmatrix} H_{11,t-1} \\ H_{12,t-1} \\ H_{22,t-1} \end{bmatrix}
\end{aligned}$$

74.3.3 Cointegration and Error Correction Method (CECM)

The techniques described so far do not take into consideration the possibility that spot price and futures price series could be non-stationary. If these series have unit roots, then this will raise a different issue. If the two series are cointegrated as defined by Engle and Granger (1987), then the regression Eq. (12) will be mis-specified and an error-correction term must be included in the equation. Since the arbitrage condition ties the spot and futures prices, they cannot drift far apart in the long run. Therefore, if both series follow a random walk, then we expect the two series to be cointegrated in which case we need to estimate the error correction model. This calls for the use of the cointegration analysis. Therefore, the cointegration and error correction method should be used to estimate the hedge ratio.

The cointegration analysis involves two steps. First, each series must be tested for a unit root (e.g., see Dickey and Fuller 1981; and Phillips and Perron 1988). Second, if both series are found to have a single unit root, then the cointegration test must be performed (e.g., see Engle and Granger 1987; Johansen and Juselius 1990; and Osterwald-Lenum 1992).

If the spot price and futures price series are found to be cointegrated, then the hedge ratio can be estimated in two steps (see Ghosh 1993; and Chou et al. 1996). The first step involves the estimation of the following cointegrating regression:

$$S_t = a + bF_t + u_t. \quad (15)$$

The second step involves the estimation of the following error correction model:

$$\Delta S_t = \rho u_{t-1} + \beta \Delta F_t + \sum_{i=1}^m \delta_i \Delta F_{t-i} + \sum_{j=1}^n \theta_j \Delta S_{t-j} + e_j, \quad (16)$$

where u_t is the residual series from the cointegrating regression. The estimate of the hedge ratio is given by the estimate of β . Some researchers (e.g., see Lien and Luo

1993b) assume that the long-run cointegrating relationship is $(S_t - F_t)$, and estimate the following error correction model:

$$\Delta S_t = \rho(S_{t-1} - F_{t-1}) + \beta \Delta F_t + \sum_{i=1}^m \delta_i \Delta F_{t-i} + \sum_{j=1}^n \theta_j \Delta S_{t-j} + e_j. \quad (17)$$

Alternatively, Chou et al. (1996) suggest the estimation of the error correction model as follows:

$$\Delta S_t = \alpha \hat{u}_{t-1} + \beta \Delta F_t + \sum_{i=1}^m \delta_i \Delta F_{t-i} + \sum_{j=1}^n \theta_j \Delta S_{t-j} + e_j, \quad (18)$$

where $\hat{u}_{t-1} = S_{t-1} - (a + bF_{t-1})$; that is, the series $\hat{u}_t$ is the estimated residual series from Eq. (15). The hedge ratio is given by β in Eq. (17).

Kroner and Sultan (1993) combine the error-correction model with the GARCH model considered by Cecchetti et al. (1988) and Baillie and Myers (1991) in order to estimate the optimum hedge ratio. Specifically, they use the following model:

$$\begin{bmatrix} \Delta \log_e(S_t) \\ \Delta \log_e(F_t) \end{bmatrix} = \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix} + \begin{bmatrix} \alpha_s(\log_e(S_{t-1}) - \log_e(F_{t-1})) \\ \alpha_f(\log_e(S_{t-1}) - \log_e(F_{t-1})) \end{bmatrix} + \begin{bmatrix} e_{1t} \\ e_{2t} \end{bmatrix}, \quad (19)$$

where the error processes follow a GARCH process. As before, the hedge ratio at time $(t - 1)$ is given by $h_{t-1} = H_{12,t}/H_{22,t}$.

74.3.4 Empirical Studies

Here, we apply OLS, GARCH, and CECM models in practice to estimate optimal hedge ratios through R language. Monthly data for S&P 500 index and its futures were collected from Datastream database, the sample consisted of 188 observations from January 31, 2005, to August 31, 2020. Summary statistics of this data are presented in Table 1.

First, in Eq. (12), we use the OLS method by regressing the changes in spot prices on the changes in futures prices to estimate the optimal hedge ratio. The estimate of

hedge ratio obtained from the OLS technique are reported in Table 2. As shown in Table 2, we can see that the hedge ratio of S&P 500 index is significantly different from zero, at a 1% significance level. Moreover, the estimated hedge ratio, denoted by the coefficient of ΔF_t , is generally less than unity.

Secondly, we apply a conventional regression model with heteroscedastic error terms to estimate the hedge ratio. Here, an AR(2)-GARCH(1,1) model for the changes in spot prices regressed on the changes in futures prices is specified as follow,

$$\Delta S_t = a_0 + a_1 \Delta F_t + e_t, e_t = \epsilon_t - \varphi_1 e_{t-1} - \varphi_2 e_{t-2}$$

$$\epsilon_t = \sqrt{h_t} \epsilon_t, h_t = \omega + \alpha_1 \epsilon_{t-1}^2 + \beta_1 h_{t-1}$$

where $\epsilon_t \sim N(0, 1)$. The estimated result of AR(2)-GARCH(1,1) model is shown in Table 3. The coefficient estimates of AR(2)-GARCH(1,1) model, as shown in Table 3, are all significantly different from zero, at a 1% significance level. This finding suggests that the importance of capturing the heteroscedastic error structures in conventional regression model. In addition, the hedge ratio of conventional regression with AR(2)-GARCH(1,1) model is higher than the OLS hedge ratio for S&P 500 futures contract.

Next, we will apply the CECM model to estimate optimal hedge ratio. Here, standard-augmented Dickey-Fuller (ADF) unit roots and Phillips and Ouliaris (1990) residual cointegration tests are performed, and the optimal hedge ratios estimated by error correction model (ECM) will be presented. Here, we apply the augmented Dickey-Fuller (ADF) regression to test for the presence of unit roots. The ADF test statistics, as shown in Panel A of Table 4, indicates that the null hypothesis of a unit root cannot be rejected for the levels of the variables. Using differenced data, the computed ADF test statistics shown in Panel B of Table 4 suggested that the null hypothesis is rejected, at the 1% significance level. As differencing one

Table 5 Error correction estimates of hedge ratio coefficient

Variable	Estimate	Std. Error	t-ratio	p-value
ΔF_t	0.9892	0.0031	316.60	<0.001
$\hat{u}_{t-1}$	−0.3423	0.0571	−5.99	<0.001

produces stationarity, we may conclude that each series is integrated of order one, $I(1)$, process which is necessary for testing the existence of cointegration. We then apply Phillips and Ouliaris (1990) residual cointegration test to examine the presence of cointegration. The result of Phillips-Ouliaris cointegration test shown is reported in Panel C of Table 4. The null hypothesis of the Phillips-Ouliaris cointegration test is that there is no cointegration present. The result of Phillips-Ouliaris cointegration test indicates the null hypothesis of no cointegration is rejected, at the 1% significance level. This suggests that the spot S&P 500 index is cointegrated with the S&P 500 index futures.

Finally, we apply the ECM model in term of Eq. (16) to estimate optimal hedge ratio. Table 5 shows that the coefficient on the error-correction term, $\hat{u}_{t-1}$, is significantly different from zero, at a 1% significance level. This suggests that the importance of estimating error correction model, and in particular the long-run equilibrium error term cannot be ignored in conventional regression model. In addition, the ECM hedge ratio is higher than the conventional OLS hedge ratio for S&P 500 futures contract. This finding is consistent with the results in Lien (1996, 2004) who argued that the MV hedge ratio will be smaller if the cointegration relationship is not considered.

74.4 Conclusion

In this chapter, we have reviewed four approaches for deriving the optimal hedge ratio. These approaches can be divided into the minimum-variance approach, the mean-variance based approach, and the expected utility maximizing approach. All these approaches will lead to the same hedge ratio as the conventional minimum-variance (MV) hedge ratio, if the futures price follows a pure martingale process and if the futures and spot prices are jointly normal. However, if these conditions do not

hold, then the hedge ratios based on the various approaches will be different, therefore the user should carefully examine what kind of assumption they will use.

Since the statistical properties of the MV hedge ratio are well known, it is easy to estimate and perform the statistical hypothesis test. For example, we can test whether the optimal MV hedge ratio is the same as the naïve hedge ratio. Since the MV hedge ratio ignores the expected return, it will not be consistent with the mean-variance analysis unless the futures price follows a pure martingale process. In general, if the martingale and normality conditions do not hold, then the MV hedge ratio will not be consistent with the expected utility maximization principle in terms of mean and variance.

In order to make the hedge ratio consistent with the expected utility maximization principle, we can derive the optimal hedge ratio by maximizing the expected utility in terms of mean and variance. However, to implement such an approach, we need to assume a specific utility function such as quadratic utility function, and we need to make an assumption regarding the return distribution. Therefore, different utility functions will lead to different optimal hedge ratios.

It should be noted that the derivation of the optimal hedge ratio discussed in this chapter does not incorporate transaction costs. Furthermore, these derivations do not allow investments in securities other than the spot and corresponding futures contracts. As shown by Lence (1995), once we relax these conventional assumptions, the resulting optimal hedge ratio can be quite different from the ones obtained under the conventional assumptions. Lence's (1995) results are based on a specific utility function and some other assumption regarding the return distributions.

In this chapter, we have also reviewed various ways of estimating the optimum hedge ratio. As far as the estimation of the conventional MV hedge ratio is concerned, there are a large number of methods that have been proposed in the literature. These methods range from a simple regression method to complex cointegrated heteroscedastic methods with regime-switching, and some of the estimation methods include a kernel density function method as well as an empirical distribution method.

In this chapter, we have also discussed about the relationship between the optimal MV hedge ratio and the hedging horizon. We feel that this relationship has not been fully explored and can be further developed in the future. For example, we would like to know if the optimal hedge ratio approaches the naïve hedge ratio when the hedging horizon becomes longer.

In this chapter, we used S&P 500 index futures from January 2005 to August 2020 in terms of three estimation methods to estimate hedge ratio. These three methods are OLS regression method, GARCH method, and CECM method. We also compared hedge ratio estimates from these three methods in some detail. The R programs used to estimate this empirical result can be found in Appendix B.

For those who are interested in research in this area, we would like to finally point out that one requires a good understanding of financial economic theories and econometric methodologies. In addition, a good background in data analysis and computer programming would also be helpful.

Appendix A. Monthly Data of S&P500 Index and Its Futures (January 2005 – August 2020)

Appendix B. Applications of R Language in Estimating Three Different Optimal Hedge Ratios

In this appendix, we show the estimation procedure on how to apply OLS, GARCH, and CECM models to estimate optimal hedge ratios through R language. R language is a high-level computer language that is designed for statistics and graphics. Compared to alternatives, SAS, Matlab or Stata, R is completely free. Another benefit is that it is open source. Users could head to <http://cran.r-project.org/> to download and install R language. Based upon monthly S&P 500 index and its futures as presented in Appendix A, the estimation procedures of applying R language to estimate hedge ratio are provided as follows.

First, we use OLS method in term of Eq. (12) to estimate minimum variance hedge ratio. By using linear model (lm) function in R language, we obtain the following program code.

```
SP500= read.csv(file="SP500.csv")
OLS.fit <- lm(C_spot~C_futures, data=SP500)
summary(OLS.fit)
```

Next, we apply a conventional regression model with an AR(2)-GARCH(1,1) error terms to estimate minimum variance hedge ratio. By using rugarch package in R language, we obtain the following program.

```
library(rugarch)
fit.spec <- ugarchspec(
  variance.model = list(model = "sGARCH",
    garchOrder = c(1, 1)),
  mean.model = list(armaOrder = c(2, 0), include.mean = TRUE,
    external.regressors= cbind(SP500$C_futures)),
  distribution.model = "norm")
```

```
GARCH.fit <- ugarchfit(data = cbind(SP500$C_spot),
  spec = fit.spec)
GARCH.fit
```

Third, we apply the ECM model to estimate minimum variance hedge ratio. We begin by applying an augmented Dickey-Fuller (ADF) test for the presence of unit roots. The Phillips and Ouliaris (1990) residual cointegration test is applied to examine the presence of cointegration. Finally, the minimum variance hedge ratio is estimated by the error correction model. By using *tseries* package in R language, we obtain the following program.

```
library(tseries)

# Augmented Dickey-Fuller Test
# Level data

adf.test(SP500$SPOT, k = 1)
adf.test(SP500$FUTURES, k = 1)

# First-order differenced data

adf.test(diff(SP500$SPOT), k = 1)
adf.test(diff(SP500$FUTURES), k = 1)

# Phillips and Ouliaris (1990) residual cointegration test

po.test(cbind(SP500$FUTURES, SP500$SPOT))

# Engle-Granger two-step procedure
## 1.Estimate cointegrating relationship

reg <- lm(SPOT~FUTURES, data=SP500)

## 2. Compute error term

Resid <- reg$resid

# Estimate optimal hedge ratio using the error correction model

n=length(resid)
ECM.fit <-lm(diff(SPOT) ~ -1 + diff(FUTURES) + Resid[1:n-1],
data=SP500)
summary(ECM.fit)
```

Finally, we apply a multivariate GARCH(1,1)-BEKK model to estimate dynamic minimum variance hedge ratio.

```
library(mgarchBEKK)
estimated=BEKK(as.matrix(cbind(SP500$C_futures,SP500$C_spot)),
  order = c(1, 1))
estimated$est.params
estimated$asy.se.coef
```

Credit Risk Modeling: A General Framework **75**

Ren-Raw Chen

Abstract

The two well-known approaches for credit risk modeling, structural and reduced form approaches, have their advantages and disadvantages. Due to the fundamentally different assumptions of the two approaches, the structural models are used for default prediction that focuses on equity prices and reduced form models are used for credit derivatives pricing that focuses on debt values. In this chapter, via a simple discrete binomial structure, we provide a unified view of the two approaches. In particular, in our formulation, the pricing formulas for risky debts are identical under the two approaches. The two approaches differ in only the recovery assumption. This result makes comparison of various models empirically possible. We demonstrate, in a credit derivative example that is sensitive to the recovery assumption, how different recovery assumptions impact its prices.

75.1 Introduction

There have been two well-known approaches, structural and reduced form, for credit risk modeling. Reduced form models, represented by Jarrow and Turnbull (1995) and Duffie and Singleton (1997, 1999) assume defaults (or credit events) occur

I would like to thank Jay Huang and Sanlin Chung for their helpful comments

e-mail: rchen@fordham.edu

exogenously (usually by a Poisson process) and a separately specified recovery is paid upon default.¹ Structural models, on the other hand, assume defaults occur when the value of the firm falls below a certain default point and a certain recovery is paid. The “true structural” model of Geske (1977) and Geske and Johnson (1984) assumes the default point to be the market value of debt that is endogenously computed and the firm value is the recovery. This formulation leads to multi-variate probability functions. The “barrier structural” models, pioneered by Black and Cox (1976), obtain uni-variate valuation formulas by assuming an exogenous default point and an exogenous recovery amount.²

Structural models for credit risk modeling have been mainly used for default prediction³ or capital structure analysis while reduced form models are mainly used by investment banks to price credit derivatives.⁴ This is because structural models rely on the information from equity prices while reduced form models from debt prices. Furthermore, reduced form models are more computationally efficient due to their exogenous default and recovery assumptions, which are important for pricing credit derivatives. Another reason for the reduced form models to be chosen by investment banks is its relative ease to incorporate the term structure of the default free interest rates.⁵

In this chapter, we clarify the difference between the “true structural” model of Geske (1977) and Geske and Johnson (1984) in which defaults occur when the (market) value of the firm falls below the (market) value of debt and the “barrier structural model” in which defaults occur when the value of the firm crosses an exogenously pre-defined barrier. The former valuation leads to multi-variate distributions while the latter is a univariate valuation.⁶ We then show that reduced-form and structural models can be made consistent under a simple discrete binomial formulation. Under this binomial formulation, the two sets of models have identical pricing formulas for risky debts. The only difference is different recovery assumptions. This result makes it possible to compare various models. In an application, we use credit default swaps to examine the impact of different recovery assumptions.

It is generally understood that structural models are difficult to calibrate. For example, for an n -period bond, we need n -dimensional probability functions, which

¹Other reduced form models include, among others, Duffie and Lando (1997), Jarrow et al. (1997), Jarrow and Yu (2001), Lando (1998), Madan and Unal (2000), and Schönbucher (1998).

²Other structural models include, for example, Anderson and Sundaresan (1996), Leland and Toft (1996), Longstaff and Schwartz (1995), Zhou (2001), and Bélanger et al. (2002). Readers can also find a more thorough survey by Uhrig-Homburg (2002).

³For example, see KMV's EDF and Moody's RiskCalc.

⁴It should be noted that structural models are also proposed for pricing risky bonds. However, they have never gained support from the industry due to the difficulty in calibration.

⁵The two most known reduced form models by Jarrow and Turnbull (1995) and Duffie and Singleton (1999) can both be easily incorporated into existing term structure models.

⁶Bélanger et al. (2002) provide a unified model that nests all barrier structural models. This chapter can be viewed as an extension of their work.

are computationally expensive. However, in this chapter, we employ the standard one-dimensional equity binomial model, which can be accurate to the second decimal place in 50 steps.

The remaining of the paper is organized as follows. Section 75.2 lays out the basic valuation equations. In particular, we specify the forward measure technique to incorporate stochastic interest rates. Section 75.3 presents the binomial framework under which all models share the same valuation formula. In Sect. 75.4, we discuss calibration issues of various models and perform model comparison. Section 75.5 concludes.

75.2 Basic Setup

Define a T -maturity default-free pure discount bond price at current time t , denoted $P(t, T)$ with $P(T, T) = 1$ for all T . Also define a set of dates: $0 = T_0 < T_1 < \dots < T_{N-1} < T_N$. For simplicity and without loss of generality, we also assume $h = T_i - T_{i-1}$ for all $i = 1, \dots, N$. Let $\ell(T_i, T_j)$, $0 \leq i < j \leq N$, represent the default free “term” interest rate (annualized) over $[T_i, T_j]$. Hence, by definition:

$$\ell(T_i, T_j) = \frac{1}{T_j - T_i} \left(\frac{1}{P(T_i, T_j)} - 1 \right) \quad (1)$$

Denote by Q the risk neutral measure under which defined the instantaneous short rate r . Then we have:

$$P(t, T) = E_t^Q[\Lambda(t, T)] \quad (2)$$

where

$$\Lambda(t, s) = \exp \left(- \int_t^s r(u) du \right), 0 \leq t < s \leq T \text{ and}$$

$E_t^Q[\cdot]$ represents the expectation conditional on the information set at time t under the risk neutral measure Q .

For the sake of convenience, we further define T_n -forward measure, denoted by F_n , to be equivalent to the measure Q and the corresponding Radon-Nikodym derivative is given by⁷:

$$\frac{dF_n}{dQ} = \frac{\Lambda(t, T_n)}{P(t, T_n)} \quad (3)$$

⁷For the forward measure, see, for example, Jamshidian (1987) and Hull (2000).

Under (3) the forward price is merely the forward expectation of the bond price:

$$F(0, t, s) = E_0^{F_t}[P(t, s)] = \frac{P(0, s)}{P(0, t)} \quad (4)$$

and so is the discrete forward rate:

$$E_0^{F_t}[l(u, t)h] = \frac{1}{F(0, u, t)} - 1 \quad (5)$$

Finally, we reiterate the separation of expectation using the forward measure:

$$\begin{aligned} E_0^Q[\Lambda(0, t)I_{\{t < \tau\}}] &= E_0^Q[\Lambda(0, t)]E_0^{F_t}[I_{\{t < \tau\}}] \\ &= P(0, t)Q(0, t) \end{aligned} \quad (6)$$

where τ is the default time and:

$$Q(0, t) = E_0^{F_t}[I_{\{t < \tau\}}] \quad (7)$$

as the survival probability under the forward measure where $I_{\{\cdot\}}$ is an indicator function and τ is the default time. Equation 6 represents the present of \$1 paid if there is no default and 0 otherwise. Hence, it is also known as the risky discount factor.

75.3 The Unified Model

The unified model is a simple binomial model that defines default and no default states at every period. This model is general to accommodate any form of recovery upon default and any form of cash flows under no default.

Hence, their solution to the risky fixed rate coupon bond can be written as:

$$\begin{aligned} V(0, T_n) &= E_0^Q \left[\sum_{i=1}^n \Lambda(0, T_i) c_n h I_{\{\tau > T_i\}} + \Lambda(0, T_n) I_{\{\tau > T_n\}} \right] \\ &\quad + \Lambda(0, \tau) w_n(A(\tau), r(\tau)) I_{\{\tau < T_n\}} \\ &= \sum_{i=1}^n P(0, T_i) Q(0, T_i) c_n h + P(0, T_n) Q(0, T_n) + R_n(0) \end{aligned} \quad (8)$$

where c_n is the fixed coupon, $w_n(\cdot, \cdot)$, which is a function of some state variable A and interest rate r , represents the recovery amount upon default, and $R_n(0)$ is the current value of expected recovery. Note that the first two terms of the second line follows directly from (6) and (7). They represent the value of coupons and face value. The last term represents the current recover value, which is an expected present value of the recovery amount upon default, a function of some state variable(s), A and the risk free interest rate, r .

The solution to the risky floating rate bond is:

$$\begin{aligned}
 V^*(0, T_n) &= E_0^Q \left[\sum_{i=1}^n \Lambda(0, T_i) \ell(T_{i-1}, T_i) h I_{\{\tau > T_i\}} + \Lambda(0, T_n) I_{\{\tau > T_n\}} \right. \\
 &\quad \left. + \Lambda(0, \tau) w_n(A(\tau), r(\tau)) I_{\{\tau < T_n\}} \right] \\
 &= \sum_{i=1}^n P(0, T_i) Q(0, T_i) \left[F(0, T_{i-1}, T_i)^{-1} - 1 \right] h \gamma_{i-1, i} \\
 &\quad + P(0, T_n) Q(0, T_n) + R_n(0)
 \end{aligned} \tag{9}$$

where

$$\gamma_{i-1, i} = \text{cov}[\ell(T_{i-1}, T_i), I_{\{\tau > T_i\}}]$$

is the covariance under the forward measure between the random interest rate and the default event, which is usually assumed 0. It is generally accepted that default probability is positively correlated with interest rates; but default events (or equivalently, default time) are independent of interest rates. The second line of (9) comes directly from (5). As we can see, the difference between a floater and a fixed rate bond is the coupon payment series, where the former is taken from the forward curve and the latter is a fixed constant. Hence, for the rest of the paper, we simply concentrate on fixed rate bond.

It is not unreasonable to assume that defaults can occur only at discrete points (i.e. coupon payment times). Usually the company does not have to declare default if there is no cash pressure. This assumption validates the use of the Geske-Johnson structural model. So far, we have not used any model specification. The remainder of this section, presents $V(0, T_n)$ in various model specifications.

75.3.1 The Jarrow-Turnbull Model

The Jarrow-Turnbull model assumes that a fixed recovery is paid at maturity regardless of the time of default. Hence, the closed form solution exists for the coupon bond as follows:

$$V_{JT}(0, T_n) = \sum_{i=1}^n P(0, T_i) Q(0, T_i) c_n h + P(0, T_n) Q(0, T_n) + w_n P(0, T_n) \times [1 - Q(0, T_n)] \quad (10)$$

In such a case, $R_n(0) = w_n P(0, T_n) [1 - Q(0, T_n)]$. This model is also recognized as “recovery of proportional to par.” An extended Jarrow-Turnbull model of the following is usually used in the industry in which defaults are allowed only at coupon times and a fixed recovery is paid upon default.

$$\Phi_{JT}(0, T_n) = \sum_{i=1}^n P(0, T_i) Q(0, T_i) c_n h + P(0, T_n) Q(0, T_n) + w_n(T_i) P(0, T_i) [Q(0, T_{i-1}) - Q(0, T_i)] \quad (11)$$

In such a case, $R_n(0) = \sum_{i=1}^n w_n(T_i) P(0, T_i) [Q(0, T_{i-1}) - Q(0, T_i)]$. In many cases, continuous default is necessary, hence a continuous version of recovery is also commonly used: $R_n(0) = \int_0^{T_n} w_n(t) P(0, t) [-dQ(0, t)]$.

75.3.2 The Duffie-Singleton Model

The Duffie-Singleton model assumes recovery is paid immediately upon default and equals a fraction of what the bond is worth immediately prior to default. In our formulation, it means:

$$w_n(t) = \delta V(t, T_n) \quad (12)$$

where δ is the constant recovery ratio on the value of the bond prior to default. Substituting this result back to (8), we get:

$$V_{DS}(0, T_n) = \sum_{i=1}^n P(0, T_i) Q^*(0, T_i) c_n h + P(0, T_n) Q^*(0, T_n) \quad (13)$$

where c_n is the fixed coupon and

$$Q^*(0, T_i) = E_0^{F_i} \left[e^{-(1-\delta) \int_0^{T_i} \lambda(t) dt} \right] = \begin{cases} Q(0, T_i) e^{\delta \int_0^{T_i} \lambda(t) dt} \\ Q(0, T_i)^{1-\delta} \end{cases} \quad (14)$$

where $\lambda(t)$ is the Poisson intensity parameter.⁸ Default occurs when there is a jump with a probability $\lambda(t)dt$ over the period dt . It can be seen that the Duffie-Singleton model cannot differentiate the survival probability from the recovery, a drawback of the model. However, the solution represented by (13) and (14) is a closed form solution of the affine style, more easily to derive closed form solutions when the recovery ratio and the intensity parameter are random.

⁸If the intensity parameter and/or the recovery rate are random, then (14) becomes:

It is clear that in the Duffie-Singleton model, recovery is blended into survival probabilities. In other words, recovery in the Duffie-Singleton model contains survival probabilities. Formally, we can write recovery as:

$$R_n(0) = \sum_{i=1}^n P(0, T_i) Q(0, T_i) [M(0, T_i) - 1] c_n h + P(0, T_n) Q^*(0, T_n) \quad (15)$$

where⁹

$$M(0, t) = e^{\delta \int_0^t \lambda(u) du}$$

75.3.3 The Extended Merton Model

The structural models can be traced back to Black and Scholes (1973) and Merton (1974) who observe that the company's equity is a European call option and hence the single-maturity-date debt contains default risk identical to a covered call. The recovery in the Black-Scholes-Merton model is therefore the firm value if default occurs at maturity. To extend the single period model of Black-Scholes and Merton, as mentioned earlier, there are two approaches. The “barrier structural” models assume an exogenous default barrier. Default is defined as the asset value crossing such a barrier.¹⁰ The extension along this is pioneered by Black and Cox (1976), followed by Leland and Toft (1996) and Longstaff and Schwartz (1995), and recently extended by Bélanger et al. (2002). Another is a “pure structural” model by Geske (1977) and Geske and Johnson (1984) who adopt the compound option approach and treat default as the inability of the company to fulfill its debt obligations (i.e. negative equity value).

In this sub-section, we include multi-period debt structure in the Merton model. We assume defaults occur if the firm fails to meet its coupon obligations at any give time. Since the coupon obligations are exogenously given, the “barrier structural” models can be viewed as the continuous time limit of what is described here.

Consistent with our discrete setup, let $X_1, \dots, X_n$ be the series of external barriers, crossing which by the firm value represents default. These discrete time barriers can be interpreted as cash obligations at each time and failure to make the obligation results in default of the firm. These cash obligations can be regarded as a series of zero coupon bonds issued by the firm. The values of assets and debts (zero coupon) are labeled as $A(t)$, and $D(t, T_n)$ respectively for an arbitrary t . Default is defined as

⁹If the intensity parameter and/or the recovery rate are random, then we have:
where

¹⁰The barrier-based structural models are particularly popular in industry. See, for example, KMV (recently acquired by Moody's) and CreditGrades.

$A(T_i) < X_i$ at time T_i . To obtain closed form solutions, we assume the continuity of $A(t)$, as by Geske (1977) and Geske and Johnson (1984). To arrive at closed form results, we need to assume a log normal process for the firm's asset value and a normal process for the instantaneous short rate:

$$\begin{aligned} \begin{bmatrix} \frac{dA(t)}{A(t)} \\ dr(t) \end{bmatrix} &= \begin{bmatrix} r(t) \\ \mu(r, t) \end{bmatrix} dt + \begin{bmatrix} \sigma_A & 0 \\ 0 & \sigma_r \end{bmatrix} \\ &\quad \times \begin{bmatrix} \sqrt{1 - \rho_{Ar}^2} & \rho_{Ar} \\ 0 & 1 \end{bmatrix} \times \begin{bmatrix} dW_A^Q(t) \\ dW_r^Q(t) \end{bmatrix} \end{aligned} \quad (16)$$

where σ_A , σ_r , and ρ_{Ar} are constants, and $dW_A^Q dW_r^Q = 0$. From (16), we know that the correlation between the (log) asset value and the interest rate is ρ_{Ar} . Also note that both $W_A^Q(t)$ and $W_r^Q(t)$ are Wiener processes under the Q measure. Applying Ito's lemma to (2) in Sect. 75.2, we obtain that:

$$\begin{aligned} \frac{dP(t, T)}{P(t, T)} &= \frac{1}{P(t, T)} \left[\frac{\partial P(t, T)}{\partial r} \mu(r, t) + \frac{1}{2} \frac{\partial^2 P(t, T)}{\partial r^2} \sigma_r^2 + \frac{\partial P(t, T)}{\partial t} \right] dt \\ &\quad + \frac{1}{P(t, T)} \frac{\partial P(t, T)}{\partial r} \sigma_r dW_r^Q(t) \\ &\equiv r(t)dt + \sigma_P(r, t, T) dW_r^Q(t) \end{aligned} \quad (17)$$

The Gaussian models that satisfy (17) are Vasicek (1977), Ho and Lee (1986), and Hull and White (1990), in all of which the diffusion term, $\sigma_P(r, t, T)$, is independent of the interest rate and can be written as $\sigma_P(t, T)$.

Then, we can derive the value of T_n -maturity debt is:

$$\begin{aligned} D(0, T_n) &= E_0^Q[\Lambda(0, T_n) \min \{X_n, A(T_n)\}] \\ &= P(0, T_n) E_0^{F_n}[\min \{X_n, A(T_n)\}] n > 1 \\ &= P(0, T_n) X_n N_n^- + A(0) (N_{n-1}^+ - N_n^+) \end{aligned} \quad (18)$$

where

$$\begin{aligned} N_j^\pm &= N_j \left(h_1^\pm(X_1), \dots, h_j^\pm(X_j); \rho_{ij} \right) \\ \rho_{ij} &= \sqrt{T_i/T_j}, i < j \\ h_i^\pm(X_i) &= \frac{\ln \frac{A(0)}{P(0, T_i) X_i} \pm \frac{1}{2} v^2(0, T_i)}{v(0, T_i)} \\ v^2(0, T_i) &= \int_0^{T_i} \sigma_A^2 + \sigma_P^2(u, T_i) - 2\rho_{Ar} \sigma_A \sigma_P(u, T_i) du \end{aligned}$$

where ρ_{ij} represents the auto-correlation between $\ln A(T_i)$ and $\ln A(T_j)$ which is $\sqrt{T_i/T_j}$ for $T_i < T_j$. The derivation of (18) is given in an appendix. In (18), $N_j(\cdot \cdot)$ is a j -dimensional cumulative normal probability.¹¹ The derivation of (18) is given in an appendix that both N_n^+ and N_n^- are probabilities being in the money, only defined in different probability measures.

Equation 18 has an interesting interpretation. Note that N_n^- is the survival probability from now till T_n and $N_{n-1}^- - N_n^-$ (or $N_{n-1}^+ - N_n^+$ under a different measure) is the *unconditional* default probability between T_{n-1} and T_n . In other words, (18) implies that if default does not happen (with probability N_n^-), the bond receives X_n . If default does happen, it receives $A(T_n)$. Note that any prior default (default before T_{n-1}) should pay no recovery for such a bond since it is the most junior bond and the last to receive recovery. And this recovery is multiplied by the default probability and discounted to be $A(0)(N_{n-1}^+ - N_n^+)$ today.

It should be noted that (18) is not a closed form result unless $v(0, T_i)$ has a closed form expression. Rabinovitch (1989) shows that a closed form expression for $v(0, T_i)$ exists if the term structure model follows Vasicek (1977) and does not exist if it follows Cox-Ingersoll-Ross (1985). We restate the closed form result of Rabinovitch in an appendix.

The T_n -maturity coupon bond that pays hc_n as coupons can be regarded as the total debt of the firm if $X_i = hc_n$ for $i = 1, \dots, n-1$ and $X_n = 1 + hc_n$ where h is defined in (18), as the time period length:

$$\begin{aligned} V_{EM}(0, T_n) &= \sum_{i=1}^n D(0, T_i) \\ &= A(0)[1 - N_n^+] + \sum_{i=1}^n P(0, T_i)X_iN_i^- \\ &= R_n(0) + \sum_{i=1}^n P(0, T_i)Q(0, T_i)hc_n \end{aligned} \quad (19)$$

where the forward survival probability notation $Q(t, T_i)$ replaces multi-variate normal probabilities N_i^- . Eq. 19 resembles (8) remarkably. The only difference is the recovery assumption. Note that the first term $1 - N_n^+$ represents the total unconditional default probability (under a different measure). While (19) is much simpler than (8), it requires the knowledge the underlying asset. But this problem can be easily resolved by a recursive equation:

$$\begin{aligned} &\frac{V_{EM}(0, T_n) - \sum_{i=1}^n P(0, T_i)Q(0, T_i)c_n - P(0, T_n)Q(0, T_n)}{1 - N_n^+} \\ &= \frac{V_{EM}(0, T_{n-1}) - \sum_{i=1}^{n-1} P(0, T_i)Q(0, T_i)c_{n-1} - P(0, T_{n-1})Q(0, T_{n-1})}{1 - N_{n-1}^+} \end{aligned} \quad (20)$$

¹¹ Equations 17 and 18 are consistent with Vasicek (1977), but not Cox et al. (1985).

Under the par bond assumption, $V(0, T_n) = 1$ and $y_n = c_n$ and hence (20) can be written as:

$$\begin{aligned} & \frac{1 - \sum_{i=1}^n P(0, T_i) Q(0, T_i) h y_n - P(0, T_n) Q(0, T_n)}{1 - \sum_{i=1}^{n-1} P(0, T_i) Q(0, T_i) h y_{n-1} - P(0, T_{n-1}) Q(0, T_{n-1})} \\ &= \frac{1 - N_n^+}{1 - N_{n-1}^+} = \theta_n \end{aligned} \quad (21)$$

Note the following identity:

$$1 = \sum_{i=1}^n P(0, T_i) Q(0, T_i) h c_n^0 + P(0, T_n) Q(0, T_n) \quad (22)$$

where $c_n^0 = y_n^0$ is the coupon of a zero-recovery risky par bond. Hence, (17) can be simplified as follows:

$$\frac{\sum_{i=1}^n P(0, T_i) Q(0, T_i) (y_n^0 - y_n)}{\sum_{i=1}^{n-1} P(0, T_i) Q(0, T_i) (y_{n-1}^0 - y_{n-1})} = \theta_n \quad (23)$$

The extended Merton model is usually categorized as a structural model, because of its endogenous recovery assumption and the use of asset value. However, default is defined as the asset value crossing an external barrier. This could cause negative equity value. To see that, we can look at the payoffs at time T_{n-1} :

$$\begin{aligned} & A(T_{n-1}) > X_{n-1} \\ \Rightarrow & \begin{cases} D(T_{n-1}, T_{n-1}) = X_{n-1} \\ D(T_{n-1}, T_n) = P(T_{n-1}, T_n) E_{n-1}^E [\min \{A(T_n), X_n\}] \\ E(T_{n-1}) = P(T_{n-1}, T_n) E_{n-1}^F [\max \{A(T_n) - X_n, 0\}] - X_{n-1} \end{cases} \\ & A(T_{n-1}) \leq X_{n-1} \\ \Rightarrow & \begin{cases} D(T_{n-1}, T_{n-1}) = A(T_{n-1}) \\ D(T_{n-1}, T_n) = 0 \\ E(T_{n-1}) = 0 \end{cases} \end{aligned}$$

When $A(T_{n-1})$ is small, there is no guarantee that the equity value, $E(T_{n-1})$, can exceed X_{n-1} since X_{n-1} can be arbitrary. To keep the continuity assumption of the asset value at time T_{n-1} , we need to issue new equity when it is negative. In other words, we allow the company to raise new equity when it is already in bankruptcy. Clearly this is not possible in reality. There are three approaches to avoid such a problem. The first is to set the default boundary at equity value, not asset value, equal to X_{n-1} . This is the Geske-Johnson model that we will discuss in the next sub-section. Second, we should treat the underlying asset as an unobservable state variable and specify recover value separately (e.g. Longstaff and Schwartz (1995) and Zhou (2001)). But doing so effectively transforms the structural model into

reduced form in that both defaults and recovery are exogenously specified. It differs from the reduce form approach only by different default process, one assumes a Poisson process and the other assumes a diffusion variable crossing a barrier. Third, we can simplify the debt structure so that an endogenous barrier can be solved (e.g. Leland 1994; Leland and Toft 1996).

75.3.4 The Geske-Johnson Model

A true structural model is Geske (1977) and Geske and Johnson (1984) in which internal strikes are solved to guarantee positive equity value. We extend the Geske-Johnson model of an n period risky debt to incorporate random interest rates.^{12,13} The T_n -maturity zero coupon bond can be written as follows.

$$D(0, T_n) = \sum_{i=1}^n P(0, T_i) X_i [\Pi_i^-(K_{1n}, \dots, K_{in}) - \Pi_i^-(K_{1n-1}, \dots, K_{in-1})] + A(0) [\Pi_{n-1}^+(K_{1n-1}, \dots, K_{n-1n-1}) - \Pi_n^+(K_{1n}, \dots, K_{nn})] \quad (24)$$

where¹⁴

$$\begin{aligned} \Pi_i^\pm(K_{1j}, K_{2j}, \dots, K_{ij}) = & \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} N_i(h_1^\pm(K_{1j}(r)), h_2^\pm(K_{2j}(r)) \\ & \dots, h_i^\pm(K_{ij}(r))) \varphi(r(T_1), \\ & r(T_2), \dots, r(T_i)) \\ & dr(T_1) dr(T_2), \dots, dr(T_i) \end{aligned}$$

for $n \geq j \geq i$ where φ is the joint density function of various interest rate levels observed at different times under the forward measure. Note that $h_j^\pm(K_{ij})$, for $i < j$, is to plug into (18) K_{ij} for the strike and K_{ij} is the internal solution to:

$$A(T_i) = \sum_{k=i}^j D(T_i, T_k) + X_i$$

¹²The formulas provided by Geske (1977) are incorrect and corrected by Geske and Johnson (1984). However, Geske and Johnson only present formulas for $n = 2$. Here, we generalize their formulas to an arbitrary n .

¹³Later on, for calibration, we also augment the model to include non-constant volatility.

¹⁴Note that the implementation of (24) does not need multi-variate integrals. The easiest way to implement it is to construct a bi-variate lattice. Eom et al. (2002), for example, use a one-dimension binomial model to implement the deterministic Geske-Johnson model.

which is a function of the interest rate at time T_i , and $K_{ji} = X_i$. All strikes are solved internally. Note that since interest rates are random, the internally solved strike, K_{ij} , is a function of r under the forward measure. If interest rates are deterministic, then $\Pi_i^\pm = N_i(\cdot \cdot \cdot)$ the standard multi-variate normal probability function. If we further assume that default points are equal to cash obligations, i.e. $K_{ij} = X_i$ for all j , then $\Pi_i^\pm = N_i^\pm$ defined in (18).

Although each bond is computed by a complicated formula, the coupon bond is not:

$$\begin{aligned} V_{GJ}(0, T_n) &= \sum_{i=1}^n D(0, T_i) \\ &= A(0) [1 - \Pi_n^+(K_{1n}, K_{2n}, \dots, K_{nn})] \\ &\quad + \sum_{i=1}^n P(0, T_i) X_i \Pi_i^-(K_{1n}, \dots, K_{in}) \\ &= R_n(0) + \sum_{i=1}^n P(0, T_i) Q(0, T_i) hc_n \\ &\quad + P(0, T_n) Q(0, T_n) \end{aligned} \quad (25)$$

where $X_i = hc_n$ for $i < n$ and $X_i = 1 + c_n h$ for $i = n$. This equation is extremely similar to (19) except that the probabilities are defined differently due to different strikes. Hence, by observation, the recovery must be $R_n(0) = A(0) \times [1 - \Pi_n^+(K_{1n}, K_{2n}, \dots, K_{nn})]$. It is interesting to see that the Geske-Johnson model satisfies the condition $Q(0, T_i) > Q(0, T_{i+1})$.

Note again that $\Pi_n^-(K_{1n}, K_{2n}, \dots, K_{nn})$ is the total survival probability (under the forward measure) because the asset value, $A(t)$ needs to stay above its default boundaries, K_{ij} at all times. Hence, the total (cumulative) default probability is $[1 - \Pi_n^-(K_{1n}, K_{2n}, \dots, K_{nn})]$. To see it, we know that the total default probability can be derived directly from summing the default probability of each period:

$$\begin{aligned} &\int_0^{K_{1n}} \varphi(A_1) dA_1 + \int_{K_{1n}}^\infty \int_0^{K_{2n}} \varphi(A_1, A_2) dA_2 dA_1 + \dots \\ &+ \int_{K_{1n}}^\infty \dots \int_{K_{n-1n}}^\infty \int_0^{K_{nn}} \varphi(A_1, \dots, A_n) dA_n \dots dA_1 \\ &= 1 - \int_{K_{1n}}^\infty \dots \int_{K_{n-1n}}^\infty \int_{K_{nn}}^\infty \varphi(A_1, \dots, A_n) dA_n \dots dA_1 \\ &= 1 - \Pi_n^-(K_{1n}, \dots, K_{nn}) \end{aligned} \quad (26)$$

where $A_i = A(T_i)$ is a short-hand notation. This is analogous to $\int_0^T -dQ(t) = 1 - Q(T)$. The recovery is to consider the cash amount received upon default:

$$\begin{aligned}
& P(0, T_1) \int_0^{K_{1n}} A_1 \varphi(A_1) dA_1 + P(0, T_2) \int_{K_{1n}}^\infty \int_0^{K_{2n}} A_2 \varphi(A_1, A_2) dA_2 dA_1 \\
& + \cdots + P(0, T_n) \int_{K_{1n}}^\infty \cdots \int_{K_{n-1n}}^\infty \int_0^{K_{nn}} A_n \varphi(A_1, \dots, A_n) dA_n \cdots dA_1 \\
& = A_0 \left[1 - \int_{K_{1n}}^\infty \cdots \int_{K_{n-1n}}^\infty \int_{K_{nn}}^\infty \varphi^+(A_1, \dots, A_n) dA_n \cdots dA_1 \right] \\
& = A_0 [1 - \Pi_n^+(K_{1n}, \dots, K_{nn})]
\end{aligned} \tag{27}$$

The change of measure can be found in an appendix.

In this unified framework, we can see that the difference in the Geske-Johnson model differs from Jarrow-Turnbull model is that Jarrow and Turnbull assume a fixed recovery value at maturity while Geske and Johnson assume a fixed recovery value at current time.

75.4 Calibration and Model Comparison

In this section, we demonstrate how different models can calibrate to the same market data and imply different parameter values. Equation 8 represents a general formula for all risky bond pricing models, reduced form and structural models included. It is seen that the difference only lies in the recovery assumption: recovery of the face value yields the Jarrow-Turnbull model; recovery of the market value yields the Duffie-Singleton model, and recovery of the asset value yields the Geske-Johnson model.

We shall first use a two-period model as an example to demonstrate the computational details. Then we provide analysis in a multi-period setting. The Vasicek model (1977) for the risk free term structure of interest rates is considered.

75.4.1 A Two-Period Example

We need three pieces of information to complete the calibration: risk free zero yield curve, a set of risky bond prices, and a recovery assumption. In the case of structural models, the recovery assumption is replaced by the volatility curve for the set of bond prices.

To demonstrate the calibration procedures for both reduced form and structural models, we use a two-period example. The following table describes the base case:

Time	1	2
Coupon	10	10
Face	100	100
Bond price	100	100
Yield curve	5%	5%

The Jarrow-Turnbull model can be calibrated as follows. From (11), we obtain the 1 year bond formula:

$$V_{JT}(0, 1) = P(0, 1)[Q(0, 1)(1 + c_1) + (1 - Q(0, 1))w_1]$$

We assume a fixed recovery rate of 0.4 of the principal and accrued interest. In this 1-year example, the recovery amount is \$44 if default occurs. Given coupon $c_1 = \$10/\$100 = 10\%$ and 1-year discount $P(0, 1) = e^{-5\%} = 0.9512$, we can solve for the survival probability to be $Q(0, 1) = 0.9262$. Again, from (11), for the 2-year bond:

$$V_{JT}(0, 2) = P(0, 1)Q(0, 1)c_2 + P(0, 2)Q(0, 2)(1 + c_2) \\ + P(0, 1)[1 - Q(0, 1)]w_2 + P(0, 2)[Q(0, 1) - Q(0, 2)]w_2$$

With the knowledge of $Q(0, 1)$, together with $P(0, 2) = e^{-10\%} = 0.9048$, we can then solve for the second period survival probability to be $Q(0, 2) = 0.8578$.

The Duffie-Singleton model can be calibrated as follows. From (13), we have:

$$V_{DS}(0, 1) = P(0, 1)Q^*(0, 1)(1 + c_1)$$

for the 1-year bond and

$$V_{DS}(0, 2) = P(0, 1)Q^*(0, 1)c_2 + P(0, 2)Q^*(0, 2)(1 + c_2)$$

for the 2-year bond. Hence, we solve for $Q^*(0, 1) = 0.9557$ and $Q^*(0, 2) = 0.9134$. From (14), we know that $Q^*(0, t) > Q(0, t)$ always due to non-negative recovery. By assuming a recovery rate of 0.4, we get $Q(0, 1) = 0.8929$ and $Q(0, 2) = 0.7973$, which are both lower than the survival probabilities calculated by the Jarrow-Turnbull model. Note that in both models, the recovery present values for 1 and 2-year bonds are 3.09 and 5.81 for Jarrow-Turnbull and 6.57 and 12.15 for Duffie-Singleton, respectively. It is seen that the recovery amounts for Duffie-Singleton are higher, and hence to maintain the same the bond values, the survival (default) probabilities of Duffie-Singleton have to be lower (higher) to balance it out.

In both the Jarrow-Turnbull model and the Duffie-Singleton model, given that there is no other random factor other than the interest rate, there is no need to identify a specific term structure model, given that survival and default probabilities are computed under the forward measure. However, in the Geske-Johnson model, in addition to random interest rates, there is a random “asset price” state variable. As a result, a specific term structure model needs to be specified in order to carry out survival and default probabilities.

To simplify the calculation and without any loss of generality, we assume a deterministic yield curve in this section. The Vasicek term structure model is

assumed in the next sub-section. In the Geske-Johnson model, the recovery amount is random and endogenous. Under deterministic interest rates, the one-period Geske-Johnson model is a Black-Scholes-Merton solution:

$$V_{GJ}(0, 1) = D(0, 1) = P(0, 1)X_1N(h_1^-(X_1)) + A(0)[1 - N(h_1^+(X_1))] \quad (28)$$

where $h_1^\pm$ is defined in (18). Since interest rates are non-stochastic, $P(0, 1) = \Lambda(0, 1)$. Equation 28 is identical to (18) when $\sigma_P = 0$ and $T_n = T_1 = 1$. For the 2-year bond, i.e. $T_n = T_2 = 2$ and $T_1 = 1$, we have two zero bond components:

$$D(0, 1) = P(0, 1)X_1N(h_1^-(X_1)) + A(0)[1 - N(h_1^+(X_1))] \quad (29)$$

and

$$\begin{aligned} D(0, 2) &= P(0, 1)X_1[N_1(h_1^-(K_{12})) - N_1(h_1^-(X_1))] \\ &\quad + P(0, 2)X_2N_2(h_1^-(K_{12}), h_2^-(X_2); \sqrt{1/2}) \\ &\quad + A(0)[N_1(h_1^+(X_1)) - N_2(h_1^+(K_{12}), h_2^+(X_2); \sqrt{1/2})] \end{aligned} \quad (30)$$

where $h_i^\pm$ for $i = 1, 2$ is defined in (18), $X_1 = c_2$, $X_2 = 1 + c_2$. Recall that K_{12} is the solution to $A(1) = D(1, 2) + X_1$ where $D(1, 2)$ is a bond price at $t = 1$. Finally, the 2-year coupon bond value is the sum of (29) and (30):

$$\begin{aligned} V_{GJ}(0, 2) &= D(0, 1) + D(0, 2) \\ &= P(0, 1)X_1N(h_1^-(X_1)) + P(0, 2)X_2N_2(h_1^-(K_{12}), h_2^-(X_2)) \\ &\quad + A_0[1 - N_2(h_1^+(K_{12}), h_2^+(X_2); \sqrt{1/2})] \end{aligned} \quad (31)$$

In the equation, we need to evaluate three probabilities. The first one is $N(h_1^-)$ which has already been evaluated. The second one is a bivariate normal probability with two separate strikes, K_{12} that has to be internally solved and X_2 that is the face and coupon value at maturity.

Note that X_1 is the first cash flow of the company, hence $X_1 = 10 + 110 = 120$. The value of $D(0, 1)$ hence contains the cash flow of the first bond and the coupon amount of the second bond. Here, we assume that the split of $D(0, 1)$ is proportional. That is the value of the 1-year bond is $\frac{110}{120}D(0, 1)$, and the value of the 2-year bond is $\frac{10}{120}D(0, 1) + D(0, 2)$.

In the original Geske-Johnson model, the volatility is assumed flat (as in Black-Scholes 1973). Unfortunately under this condition, the calibration of the second bond becomes impossible. Hence, we extend the model to include a volatility curve, i.e. $v(0, 2)^2 = v(0, 1)^2 + v(1, 2)^2$. This flexibility allows us to calibrate the model to the 2-year bond price. The results are $A(0) = 2351.65$, $v(0, 1) = 1.5$, and $v(1, 2) = 0.69$. Under such results, the survival probabilities are $Q(0, 1) = N_1^-(K_{12}) = 0.9426$ and $Q(0, 2) = N_2^-(K_{12}, X_2) = 0.8592$ respectively. And the recovery values for the two bonds are computed by subtracting the coupon value

from the corresponding discount debt value. For example, $D(0, 1) = 109.09$ which is split into two parts – the 1-year bond of \$100 and the coupon of the 2-year bond of \$9.09. The 1-year bond has a coupon portion of $110 \times Q(0, 1) \times P(0, 1) = 110 \times 0.9426 \times 0.9512 = 98.63$, and hence has a recovery value of $100 - 98.63 = 1.37$. A similar calculation gives the recovery value of the 2-year bond as 5.52.¹⁵

For easy comparison, we put together all the numbers in the following table. We observe that the Duffie-Singleton (DS) model has the lowest survival probabilities and therefore should have the highest recovery values, due to the fact that they both contribute positively to the bond price. The Geske-Johnson (GJ) model has the highest survival probabilities and lowest recovery values. The Jarrow-Turnbull (JT) model is in between. Since the bond price is traded at par, higher survival probabilities need to be balanced by lower recovery values.

	JT	DS	GJ
$Q(0,1)$	0.9262	0.8929	0.9426
$Q(0,2)$	0.8578	0.7923	0.8592
Total recovery value (i.e. $R(0)$)	8.90	18.68	6.89
Recovery of first bond	3.09	6.53	1.37
Recovery of second bond	5.81	12.15	5.52

75.4.2 Multi-period Analysis

In this section, we examine the multi-period behavior of reduced form models, namely Jarrow-Turnbull and Duffie-Singleton and the structural model of Geske-Johnson. We examine the default and recovery implication under an n -period setting. We also incorporate stochastic interest rates in our analysis. We replace the interest rate process in (16) by the following Ornstein-Uhlenbeck process:

$$dr(t) = \alpha \left(\mu - \frac{\delta q}{\alpha} - r(t) \right) dt + \delta dW_r^Q(t) \quad (32)$$

where the parameter values are given for flat (constant) and upward sloping yield curves as follows.

Vasicek model parameters		
	Flat	Upward
α (reverting speed)	∞	0.40
μ (reverting level)	0.05	0.08
δ (volatility)	0.00	0.05
q (mkt. price of risk)	0.00	-0.10
$r(0)$ (initial rate)	0.05	0.05

¹⁵ Note that the total recovery value needs to be 6.89 by (31).

We first examine flat yield curve. Then we use the upward sloping parameter values to construct the Vasicek model. The two sets of results are similar and we shall present the flat yield curve result and the other one is available upon request.

We first examine the case of extremely low coupons. This is the case where we can see the fundamental difference between the structural model of Geske-Johnson and the reduced form models of Jarrow-Turnbull and Duffie-Singleton. Note that the Jarrow-Turnbull model is (11) and the Duffie-Singleton model is (13) and (14), both with $c_n = 0$. The Geske-Johnson model is (25) with $X_i = 0$ for $i < n$. In all the models, the zero coupon bond price, $P(t, T)$, should follow the Vasicek model (formula given in an appendix.) The face value of debt is 110. We run the Geske-Johnson model with an asset value of $A(0) = 184$ and various volatility levels: 0.4, 0.6, 1.0, and 1.6. The results computed are summarized as follows.

GJ Model				
Volatility	0.4	0.6	1.0	1.6
Equity value	169.25	177.92	183.49	183.94
Debt value	14.74	6.08	0.51	0.06
Recovery	4.06	2.08	0.19	0.00
JT Model				
Recovery rate	3.69%	1.89%	0.17%	0.00%
Intensity	1.79%	4.85%	13.19%	20.00%

As the volatility goes up, the equity value in the Geske-Johnson model goes up (i.e. call option value goes up.) Since the asset value is fixed at 184, the debt value goes down. The survival probability curves under various volatility scenarios of the Geske-Johnson model are plotted in Fig. 1; and the default probability curves (unconditional, i.e. $Q(T_{i-1}) - Q(T_i)$) are plotted in Fig. 2. We observe several results. First, as the risk of default becomes eminent (i.e. high volatility and low debt value), the likelihood of default shifts from far term (peak at year 30 for volatility = 0.4) to near term (peak at year 5 for volatility = 1.6). Second, it is seen that the asset volatility has a huge impact on the shape of the survival probability curve. The Geske-Johnson model is able to generate humped default probability curve, often observed empirically. Third, these differently shaped probability curves are generated by one single debt, something not possible reduced form models. Both the Jarrow-Turnbull and Duffie-Single models cannot generate such probability curves with one single bond, due to the lack of information of intermediate cash flows. Corresponding to the recovery amounts under the Geske-Johnson model, we set the fixed recovery rate of the Jarrow-Turnbull model as shown in the above table. Given that one bond can only imply one intensity parameter value, we set it (under each scenario) so that the zero coupon bond price generated by the Geske-Johnson model is matched. As shown in the above table, the intensity rate goes from 1.79% per annum to 20% per annum. Note that flat intensity value is equivalent to a flat *conditional* default probability curve. To visualize the difference this flat conditional default probability curve of the Jarrow-Turnbull model with the non-flat curve generated by the Geske-Johnson model, we plot in Fig. 3 the case of volatility = 1.6. The conditional default probabilities are calculated as $\frac{Q(T_{i-1}) - Q(T_i)}{Q(T_{i-1})}$.

Note: Figure 1 illustrates the survival probability curves under various asset volatility scenarios of the 30-year zero coupon bond under the Geske-Johnson model. The Asset value is set to be \$184. The bond has no coupon and a face value of \$110. The yield curve is flat at 5%

Fig. 1 The GJ model: zero coupon bond (Note: Fig. 1 illustrates the survival probability curves under various asset volatility scenarios of the 30-year zero coupon bond under the Geske-Johnson model. The asset value is set to be \$184. The bond has no coupon and a face value of \$110. The yield curve is flat at 5%)

Note: Figure 1a illustrates the default probability curve. All parameters are identical to those in Figure 1.

Fig. 2 The GJ model: zero coupon bond (Note: Fig. 2 illustrates the default probability curve. All parameters are identical to those in Fig. 1)

Note: Figure 1b illustrates the default probability curves under GJ and JT models for the volatility level of 1.6. All parameters are identical to those in Figure 1.

Fig. 3 Comparison of GJ and JT models: zero coupon bond (Note: Fig. 3 illustrates the default probability curves under GJ and JT models for the volatility level of 1.6. All parameters are identical to those in Fig. 1)

Our next analysis is to keep bond value fixed, so that we can examine the default probability curve with the risk of the bond controlled. We assume that the company issues only one coupon bond at 10%. At the volatility level of 0.4, the asset value is \$123, at 0.6, it is \$290, at 1.0, it is \$15,000. Figures 4 and 5 demonstrate the Geske-Johnson model for various volatility levels but keep the bond at par. We can see that for the same par bond, the default and survival probability curves are drastically different as the asset/volatility combination changes. This is a feature not captured by either the Duffie-Singleton or the Jarrow-Turnbull model.

To compare to the Jarrow-Turnbull and Duffie-Turnbull models, we keep the case where the volatility level is 0.6 and asset value is 290. The recover rates of both Jarrow-Turnbull and Duffie-Singleton models are assumed to be 0.4. Figures 6 and 7 show the survival and default probability curves of the three models. The flat conditional forward default probability for the Jarrow-Turnbull model is solved to be 7.60% (or equivalently the intensity rate is 7.74%.) The conditional forward default probabilities for the Duffie-Singleton model are certainly non-constant. The “recovery-adjusted” continuously compounded discount rate is 9.52%. From the survival probability curves (Fig. 6), it is seen that the Geske-Johnson and Jarrow-Turnbull models can be close. But the default probability curves (Fig. 7) demonstrate that the default pattern can be quite different.

75.5 Conclusion

In this chapter, we provide a general framework that brings consistency between the reduced form and structural models. The structural models we consider in this chapter is not those of the “barrier-type” that assumes exogenous barriers but the Geske-Johnson model that allows the default points (strike price) to be endogenously computed. We show that the “true structural” model of Geske-Johnson can be simplified to barrier-type (extended Merton) if the endogenous default points are not internally solved for but exogenously given.

In a discrete time binomial framework, we show that any set of risky cash flows and recovery can be priced by a simple formula. This formula is same for both structural and reduced form models. This formula allows us to compare various models because they only differ in the recovery computation. Different recovery assumptions result in different survival and default probabilities. In calibration, the differences in recovery amounts and in probabilities balance each other out, as we demonstrate, because each model price is made to match the market price. However, these different recovery values and probabilities should result in large differences in derivatives prices. We demonstrate that large differences exist even for the simplest credit derivative contract – credit default swaps.

Finally, In order to compare the “true structural” Geske-Johnson model with the reduced form models represented by Jarrow and Turnbull (1995) and Duffie and Singleton (1997, 1999), we extend the Geske-Johnson model to incorporate random interest rates and a non-flat volatility curve. In a series of appendices, we demonstrate how to implement the Geske-Johnson model with random interest rates and a volatility curve.

Note: Figure 2 illustrates the survival probability curves under various asset volatility scenarios of the 30-year Geske-Johnson model. The Asset values are 123, 290, 15,000 for volatility levels of 0.4, 0.6, and 1.0 respectively. The bond has a coupon of \$10 and price of par.

Fig. 4 The GJ model: 10% coupon bond (Note: Fig. 4 illustrates the survival probability curves under various asset volatility scenarios of the 30-year Geske-Johnson model. The asset values are 123, 290, 15,000 for volatility levels of 0.4, 0.6, and 1.0 respectively. The bond has a coupon of \$10 and price of par)

Note: Figure 2a illustrates the default probability curves under various asset volatility scenarios of the 30-year Geske-Johnson model. The Asset values are 123, 290, 15,000 for volatility levels of 0.4, 0.6, and 1.0 respectively. The bond has a coupon of \$10 and price of par. All parameters are identical to those in Figure 2.

Fig. 5 The GJ model: 10% coupon bond (Note: Fig. 5 illustrates the default probability curves under various asset volatility scenarios of the 30-year Geske-Johnson model. The asset values are 123, 290, 15,000 for volatility levels of 0.4, 0.6, and 1.0 respectively. The bond has a coupon of \$10 and price of par. All parameters are identical to those in Fig. 4)

Note: Figure 3 illustrates the survival probability curves under the 30-year Geske-Johnson, Duffie-Singleton with 0.4 recovery ratio, and Jarrow-Turnbull with 0.4 recovery ratio models. The Asset value is set to be \$290 and volatility 0.6 so that the bond is priced at par. The bond has \$10 coupon and a face value of \$110.

Fig. 6 Comparison of the GJ, DS and JT models: par coupon bond (Note: Fig. 6 illustrates the survival probability curves under the 30-year Geske-Johnson, Duffie-Singleton with 0.4 recovery ratio, and Jarrow-Turnbull with 0.4 recovery ratio models. The asset value is set to be \$290 and volatility 0.6 so that the bond is priced at par. The bond has \$10 coupon and a face value of \$110)

Note: Figure 3a illustrates that under a 10% coupon bond, the Geske-Johnson model can generate desired default probability curve. All parameters are identical to those in Figure 3.

Fig. 7 Comparison of the GJ, DS and JT models: par coupon bond (Note: Fig. 7 illustrates that under a 10% coupon bond, the Geske-Johnson model can generate desired default probability curve. All parameters are identical to those in Fig. 6)

Appendix: Derivation of (18)

We shall derive (18) by induction. A T_1 -maturity zero coupon bond with a barrier X_1 is:

$$\begin{aligned} D(0, T_1) &= E_0^Q \left[e^{-\int_0^{T_1} r(u) du} \min \{A(T_1), X_1\} \right] \\ &= P(0, T_1) E_0^{F_1} [\min \{A(T_1), X_1\}] \\ &= A(0) [1 - N(h_1^+(X_1))] + P(0, T_1) X_1 N(h_1^-(X_1)) \end{aligned} \quad (33)$$

where $h_1^\pm(X_1)$ is defined in the text. A T_2 -maturity zero coupon bond with a barrier X_2 has the following value at T_1 :

$$\begin{cases} E_{T_1}^Q \left[e^{-\int_{T_1}^{T_2} r(u) du} \min \{A(T_2), X_2\} \right] & A(T_1) > X_1 \\ 0 & A(T_1) \leq X_1 \end{cases} \quad (34)$$

Hence, it has the following value today:

$$\begin{aligned} D(0, T_2) &= E_0^Q \left[e^{-\int_0^{T_1} r(u) du} E_{T_1}^Q \left[e^{-\int_{T_1}^{T_2} r(u) du} \min \{A(T_2), X_2\} \right] I_{\{A(T_1) > X_1\}} \right] \\ &= E_0^Q \left[E_{T_1}^Q \left[e^{-\int_0^{T_2} r(u) du} (A(T_2) I_{\{A(T_2) < X_2\}} + X_2 I_{\{A(T_2) > X_2\}}) \right] I_{\{A(T_1) > X_1\}} \right] \\ &= P(0, T_2) E_0^{F_n} [A(T_2) I_{\{A(T_2) < X_2 \wedge A(T_1) > X_1\}} + X_2 I_{\{A(T_2) > X_2 \wedge A(T_1) > X_1\}}] \\ &= P(0, T_2) E_0^{F_n} [A(T_2) (I_{\{A(T_1) > X_1\}} - I_{\{A(T_2) > X_2 \wedge A(T_1) > X_1\}}) + X_2 I_{\{A(T_2) > X_2 \wedge A(T_1) > X_1\}}] \\ &= A(0) [N_1^+ - N_2^+] + P(0, 2) X_2 N_2^- \end{aligned} \quad (35)$$

where the second to last line is obtained by appropriately dividing the integration region. Carrying out the expectation using the standard log normal results should yield the result desired. Similar procedure is applied to any arbitrary T_n .

N_n^+ and N_n^-

In this appendix, we show that N_n^+ and N_n^- are both survival probabilities, but under different probability measures. For the ease of composition, we use $N_1^\pm = N(h_1^\pm(X_1))$ where $N(\cdot)$ is a standard univariate normal probability

function, as an example. The general case, while tedious algebraically, is straightforward.

To simplify notation, we drop “1” from $h_1^\pm$, X_1 , T_1 , and measure F_1 . Note that:

$$\begin{aligned} N(h^+) &= \frac{P(0, T)}{A(0)} E_0^F [A(T) I_{\{A(T) > X\}}] \\ N(h^-) &= E_0^F [I_{\{A(T) > X\}}] \end{aligned} \quad (36)$$

Equation 36 can be written as:

$$\begin{aligned} E_0^F [A(T) I_{\{A(T) > X\}}] &= E_0^F [A(T)] E_0^{F*} [I_{\{A(T) > X\}}] \\ &= \frac{A(0)}{P(0, T)} E_0^{F*} [I_{\{A(T) > X\}}] \end{aligned} \quad (37)$$

The change of measure from F to F* is done as follows:

$$\frac{dF^*}{dF} = \frac{A(T)}{E_0^F [A(T)]} \quad (38)$$

Given that A is a log normal process, we immediately obtain that the above derivative as a change of measure of $\sqrt{\text{var}[\ln(A(T))]}$ under the F measure. In the following, we sketch the basic math of forward measure.

Assume an interest rate process under the Q measure generally as:

$$dr(t) = \alpha(r, t)dt + \sigma(r, t)dW^Q(t) \quad (39)$$

Then, by (3), we have the Radon-Nykodym derivative defined as follows:

$$\eta(t, T) = \frac{\Lambda(t, T)}{P(t, T)} \quad (40)$$

Applying Ito's lemma on the bond price:

$$\begin{aligned} 0 &= \ln P(T, T) \\ &= \ln P(t, T) + \int_t^T \frac{1}{P(u, T)} \left[P_u(u, T)du + P_r(u, T)dr + \frac{1}{2} P_{rr}(u, T)(dr)^2 \right] dW^Q(u) \\ &\quad - \int_t^T \frac{1}{2} \left[\frac{\sigma(r, u)P_r(u, T)}{P(u, T)} \right]^2 du \end{aligned}$$

$$\begin{aligned}
&= \ln P(t, T) + \int_t^T \frac{1}{P(u, T)} [P_u(u, T) du + P_r(u, T) \widehat{\mu}(r, u) \\
&\quad + \frac{1}{2} P_{rr}(u, T) \sigma(r, u)^2] du + \int_t^T \frac{1}{P(u, T)} P_r(u, T) \sigma(r, u) dW^Q(u) \\
&\quad - \int_t^T \frac{1}{2} \left[\frac{\sigma(r, u) P_r(u, T)}{P(u, T)} \right]^2 du \quad (41) \\
&= \ln P(t, T) + \int_t^T r(u) du + \int_t^T \frac{1}{P(u, T)} P_r(u, T) \sigma(r, u) dW^Q(u) \\
&\quad - \int_t^T \frac{1}{2} \left[\frac{\sigma(r, u) P_r(u, T)}{P(u, T)} \right]^2 du
\end{aligned}$$

Letting:

$$\theta(t, T) = \frac{\sigma(r, t) P_r(t, T)}{P(t, T)} \quad (42)$$

and moving the first two terms to the left:

$$\begin{aligned}
&-\int_t^T r(u) du - \ln P(t, T) = \int_t^T \theta(u, T) dW^Q(u) - \int_t^T \frac{1}{2} \theta(u, T)^2 du \\
&\frac{\Lambda(t, T)}{P(t, T)} = \eta(t, T) = \exp \left(\int_t^T \theta(u, T) dW^Q(u) - \int_t^T \frac{1}{2} \theta(u, T)^2 du \right) \quad (43)
\end{aligned}$$

This implies the Girsanov transformation of the following:

$$W^Q(t) = W^{F_T}(t) + \int_t^T \sigma(r, u) \frac{P_r(u, T)}{P(u, T)} du \quad (44)$$

The interest rate process under the forward measure henceforth becomes:

$$dr(t) = \left[\alpha(r, t) + \sigma(r, t)^2 \frac{P_r(t, T)}{P(t, T)} \right] dt + \sigma(r, t) dW^{F_T}(t) \quad (45)$$

Note that the forward measure derived above is quite general. It does not depend on any specific assumption on the interest rate process. In the following, “random

equity and random interest rate,” we do need normally distributed interest rates, or there is no solution to option pricing.

$$\begin{aligned} \begin{bmatrix} \frac{dA(t)}{A(t)} \\ dr(t) \end{bmatrix} &= \begin{bmatrix} r(t) \\ \alpha(r, t) \end{bmatrix} dt + \begin{bmatrix} \sigma_A & 0 \\ 0 & \sigma_r(r, t) \end{bmatrix} \\ &\quad \times \begin{bmatrix} \sqrt{1-\rho^2} & \rho \\ 0 & 1 \end{bmatrix} \times \begin{bmatrix} dW_S^Q(t) \\ dW_r^Q(t) \end{bmatrix} \end{aligned} \quad (46)$$

Using the forward measure, we get:

$$\begin{aligned} \begin{bmatrix} \frac{dA(t)}{A(t)} \\ dr(t) \end{bmatrix} &= \begin{bmatrix} r(t) + \rho\sigma_A\sigma_r(r, t) \frac{P_r(t, T)}{P(t, T)} \\ \alpha(r, t) + \sigma_r(r, t)^2 \frac{P_r(t, T)}{P(t, T)} \end{bmatrix} dt \\ &\quad + \begin{bmatrix} \sigma_A & 0 \\ 0 & \sigma_r(r, t) \end{bmatrix} \times \begin{bmatrix} \sqrt{1-\rho^2} & \rho \\ 0 & 1 \end{bmatrix} \times \begin{bmatrix} dW_S^Q(t) \\ dW_r^{F_T}(t) \end{bmatrix} \end{aligned} \quad (47)$$

$$\begin{aligned} A(T) &= A(t) \exp \left(\int_t^T \left[r(u) + \rho\sigma_A\sigma_r(r, t) \frac{P_r(u, T)}{P(u, T)} \right] du \right. \\ &\quad \left. + \int_t^T \sigma dW^{F_T}(u) - \frac{1}{2} \int_t^T \sigma^2 du \right) \end{aligned} \quad (48)$$

where

$$dW^{F_T}(t) = \sqrt{1-\rho^2} dW_S^Q(t) + \rho dW_r^{F_T}(t)$$

From the result of Ito's lemma, we can then arrive at the following result:

$$\begin{aligned} A(T) &= \frac{A(t)}{P(t, T)} \exp \left(\int_t^T \left[-\frac{1}{2} \left[\sigma_r(r, t) \frac{P_r(u, T)}{P(u, T)} \right]^2 \right. \right. \\ &\quad \left. \left. + \rho\sigma_A\sigma_r(r, t) \frac{P_r(u, T)}{P(u, T)} - \frac{1}{2} \sigma^2 \right] du \right. \\ &\quad \left. - \int_t^T \sigma_r(r, t) \frac{P_r(u, T)}{P(u, T)} dW_r^{F_T}(u) + \int_t^T \sigma_A dW^{F_T}(u) \right) \end{aligned} \quad (49)$$

Hence,

$$\begin{aligned} E_t^{F_T}[\ln S(T)] &= \ln S(t) - \ln P(t, T) + \frac{1}{2}v(t, T)^2 \\ \text{var}_t^{F_T}[\ln S(T)] &= v(t, T)^2 \end{aligned} \quad (50)$$

where

$$v(t, T)^2 = \int_t^T \left[\left[\sigma_r(r, t) \frac{P_r(u, T)}{P(u, T)} \right]^2 - 2\rho\sigma_A\sigma_r(r, t) \frac{P_r(u, T)}{P(u, T)} + \sigma_A^2 \right] du$$

Derivation of (24)

The Geske-Johnson model is usually written as the multi-variate normal probability format. As a result, the final solution looks more complex than it really is. Once, we understand the recursive relationship in zero coupon bond formulas, the final result is very straightforward to recognize. Hence, in this appendix, we provide a simple three period example to demonstrate how we can easily derive and streamline the Geske-Johnson model. The rest can be obtained by induction.

For the 1-year zero, it is identical to the Merton-Rabinovitch model:

$$\begin{aligned} D(0, T_1) &= V_{\text{GJ}}(0, T_1) = P(0, T_1)K_{11} [N_1(h_1^-(K_{11})) - 0] \\ &\quad + A(0)[1 - N_1(h_1^+(K_{11}))] \\ &= P(0, T_1)K_{11}\Pi_1^-(K_{11}) + A(0)[1 - \Pi_1^+(K_{11})] \end{aligned} \quad (51)$$

Note that $K_{11} = X_1$, the first coupon. The second line of the above equation is merely a notation change. The simpler notation allows to more easily label high dimension normal probabilities with different strikes.

For the 2-year zero, we need to solve for an internal solution K_{12} that equates

$$A(T_1) = D(T_1, T_2) + X_1 \quad (52)$$

where

$$\begin{aligned} D(T_1, T_2) &= E_{T_1}^Q[\Lambda(T_1, T_2) \min\{A(T_2), X_2\}] \\ &= P(T_1, T_2)N(d_-) + A(T_1)[1 - N(d_+)] \end{aligned} \quad (53)$$

and

$$d_{\pm} = \frac{\ln A(T_1) - \ln P(T_1, T_2) - \ln X_2 \pm \frac{1}{2}v^2(T_1, T_2)}{v(T_1, T_2)} \quad (54)$$

is a Merton-Rabinovitch result again. Note that $v^2(\cdot, \cdot)$ is defined in (18). We should note that since $P(T_1, T_2)$ is a function of the interest rate at time T_1 , i.e. $r(T_1)$. As a result, K_{12} is also a function of $r(T_1)$. For the convenience of later derivation, we rewrite (66) in its original integral form as follows. Also for notational convenience, we shorten the following notation: $D(T_i, T_j) = D_{ij}$, $P(T_i, T_j) = P_{ij}$, $A(T_i) = A_i$ and $r(T_i) = r_i$.

$$D_{12} = \int_{-\infty}^{\infty} \int_{X_2}^{\infty} \Lambda_{12} X_2 \varphi(A_2, r_2) dA_2 dr_2 + \int_{-\infty}^{\infty} \int_0^{X_2} A_{12} A_2 \varphi(A_2, r_2) dA_2 dr_2 \quad (53a)$$

This expression allows us to easily integrate with other integrals. The value of the 2-year zero price at T_1 is:

$$\begin{cases} D_{12} & A_1 > K_{12} \\ A_1 - X_1 & X_1 < A_1 \leq K_{12} \\ 0 & A_1 \leq X_1 \end{cases} \quad (55)$$

To obtain the current value of the 2-year zero, we simply integrate these payoffs at its corresponding region. Note that K_{12} is a function of the interest rate.

$$\begin{aligned} D(0, 2) = & \underbrace{\int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{0,1} E[\Lambda_{1,2} \min \{A_2, F_2\}] \varphi(A_1, r_1) dA_1 dr_1}_{\Delta_1} \\ & + \underbrace{\int_{-\infty}^{\infty} \int_{X_1}^{K_{12}} \Lambda_{0,1} (A_1 - F_1) \varphi(A_1, r_1) dA_1 dr_1}_{\Delta_2} \end{aligned} \quad (56)$$

The second term can be shown as:

$$\begin{aligned} \Delta_2 = & \int_{-\infty}^{\infty} \int_{K_{11}}^{\infty} \Lambda_{01} (V_1 - F_1) \varphi(V_1, r_1) dV_1 dr_1 \\ & - \int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{01} (V_1 - F_1) \varphi(V_1, r_1) dV_1 dr_1 \\ = & V_0 [\Pi_1^+(K_{11}) - \Pi_1^+(K_{12})] - P_{01} X_1 [\Pi_1^-(K_{11}) - \Pi_1^-(K_{12})] \end{aligned} \quad (57)$$

The first term can be valued as:

$$\begin{aligned}
\Delta_1 &= \int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{01} \left[\int_{-\infty}^{\infty} \int_0^{K_{22}} \Lambda_{12} A_2 \varphi(A_2, r_2 | A_1, r_1) dA_2 dr_2 \right] \\
&\quad \varphi(A_1, r_1) dA_1 dr_1 \\
&\quad + \int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{01} \left[\int_{-\infty}^{\infty} \int_{K_{22}}^{\infty} \Lambda_{12} X_2 \varphi(A_2, r_2 | A_1, r_1) dA_2 dr_2 \right] \\
&\quad \varphi(A_1, r_1) dA_1 dr_1 \\
&= \int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{0,1} \left[\int_{-\infty}^{\infty} \int_0^{\infty} \Lambda_{12} A_2 \varphi(A_2, r_2 | A_1, r_1) dA_2 dr_2 \right] \\
&\quad \varphi(A_1, r_1) dA_1 dr_1 \\
&\quad - \int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{01} \left[\int_{-\infty}^{\infty} \int_{K_{22}}^{\infty} \Lambda_{12} A_2 \varphi(A_2, r_2 | A_1, r_1) dA_2 dr_2 \right] \\
&\quad \varphi(A_1, r_1) dA_1 dr_1 \\
&\quad + \int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{01} \left[\int_{-\infty}^{\infty} \int_{K_{22}}^{\infty} \Lambda_{12} X_2 \varphi(A_2, r_2 | A_1, r_1) dA_2 dr_2 \right] \\
&\quad \varphi(A_1, r_1) dA_1 dr_1 \\
&= A_0 \Pi_1^+(K_{12}) - A_0 \Pi_2^+(K_{12}, K_{22}) + P_{02} X_2 \Pi_2^-(K_{12}, K_{22})
\end{aligned} \tag{58}$$

Hence, the 2-year coupon bond, returning to the original notation, is:

$$\begin{aligned}
V_{\text{GJ}}(0, T_2) &= D(0, T_1) + D(0, T_2) \\
&= D(0, T_1) + \Delta_1 + \Delta_2 \\
&= P(0, T_1) X_1 \Pi_1^-(X_1) + P(0, T_2) X_2 \Pi_2^-(K_{12}, X_2) \\
&\quad + A_0 [1 - \Pi_2^+(K_{12}, X_2)]
\end{aligned} \tag{59}$$

where

$$\begin{aligned}
\Pi_1^{\pm}(K) &= \int_{-\infty}^{\infty} \int_K^{\infty} \varphi^{\pm}(A_1, r_1) dA_1 dr_1 \\
\Pi_2^{\pm}(K_1, K_2) &= \int_{-\infty}^{\infty} \int_{K_1}^{\infty} \int_{K_2}^{\infty} \varphi^{\pm}(A_1, A_2, r_1) dA_2 dA_1 dr_1
\end{aligned} \tag{60}$$

It is shown in Appendix A that the last two integrals in the above equation can be written as:

$$\int_K^\infty A_1 \varphi^-(A_1|r_1) dA_1 = A_0 \int_K^\infty \varphi^+(A_1|r_1) dA_1 \quad (61)$$

and

$$\int_{K_1}^\infty \int_{K_2}^\infty A_2 \varphi^-(A_1, A_2|r_1) dA_2 dA_1 = A_0 \int_{K_1}^\infty \int_{K_2}^\infty \varphi^+(A_1, A_2|r_1) dA_2 dA_1 \quad (62)$$

where the density is adjusted by the volatility.

Following the same procedure, although tedious, we can derive the 3-year zero as:

$$\begin{aligned} D(0, T_3) = & P(0, T_1) X_1 [\Pi_1^-(K_{13}) - \Pi_1^-(K_{12})] \\ & + P(0, T_2) X_2 [\Pi_2^-(K_{13}, K_{23}) - \Pi_2^-(K_{12}, K_{22})] \\ & + P(0, T_3) X_3 \Pi_3^-(K_{13}, K_{23}, K_{33}) \\ & + A(0) [\Pi_2^+(K_{12}, K_{22}) - \Pi_3^+(K_{13}, K_{23}, K_{33})] \end{aligned} \quad (63)$$

Now, we should observe a pattern for the zero coupon bond prices, which gives (24).

Implementation of (24)

The closed form Geske-Johnson model (with constant volatility and constant interest rates) can be computed efficiently only when $n \leq 2$. When $n > 2$, then the multivariate normal probability functions can not be implemented efficiently, particularly in high dimensions. We use the standard equity binomial model with various payoffs to pick up the survival probabilities, zero bond values, and the equity (compound option) value.¹⁶ Note that in the binomial model, there is no need to solve for the implied strike price, K_{ij} . The (compound) option value is directly computed off the actual strikes, X_i .

In (24), we have both volatility and interest rate to be non-constant. We allow volatility to be a deterministic function of time (for calibration) and interest rates to be random (to capture interest rate risk). We shall sketch briefly in this appendix how (24) is implemented.

¹⁶We learned via private conversation that the implementation of the Geske-Johnson model in Eom et al. (2002) is computed using the binomial model.

First, the deterministic volatility function is handled by changing time interval, suggested by Amin (1991). In the binomial model, the up and down sizes are determined by:

$$\begin{aligned} u &= e^{\sigma\sqrt{\Delta t}} \\ d &= e^{-\sigma\sqrt{\Delta t}} \end{aligned} \quad (64)$$

If the volatility is changing over time, we simply adjust Δt so that $\sigma\sqrt{\Delta t}$ is constant. In this case, both u and d are constants over time and the tree recombines.

To incorporate stochastic interest rates, we first build a lattice for a “risk-neutral” bivariate Brownian motion process:

$$\begin{aligned} \begin{bmatrix} d \ln A \\ dr \end{bmatrix} &= \begin{bmatrix} r - \sigma^2/2 \\ \alpha(\mu - r) \end{bmatrix} dt + \begin{bmatrix} \sigma & 0 \\ 0 & \delta \end{bmatrix} \\ &\quad \times \begin{bmatrix} \sqrt{1 - \rho^2} & \rho \\ 0 & 1 \end{bmatrix} \times \begin{bmatrix} dW_1 \\ dW_2 \end{bmatrix} \end{aligned} \quad (65)$$

where $E[dW_1 dW_2] = 0$. We then set up a binomial lattice as follows:

$$\begin{array}{c} \sqrt{\Delta t} \\ 0 \\ -\sqrt{\Delta t} \end{array}$$

We label asset value and interest rate at various nodes as follows:

$$\begin{array}{ccc} & & < \ln A_{22}, r_{22} > \\ & < \ln A_{11}, r_{11} > & \\ < \ln A_{00}, r_{00} > & < \ln A_{21}, r_{21} > \\ & < \ln A_{10}, r_{10} > & \\ & & < \ln A_{20}, r_{20} > \end{array}$$

Then we first show that the asset values recombine. Given that:

$$\begin{aligned} \ln A_{11} &= \ln A_0 + (r_0 - \sigma^2/2)\Delta t + \sigma\sqrt{\Delta t} \\ \ln A_{10} &= \ln A_0 + (r_0 - \sigma^2/2)\Delta t - \sigma\sqrt{\Delta t} \end{aligned} \quad (66)$$

It is straightforward that:

$$\begin{aligned} \ln A_{21} &= \ln A_{10} + (r_0 - \sigma^2/2)\Delta t + \sigma\sqrt{\Delta t} \\ &= \ln A_{11} + (r_0 - \sigma^2/2)\Delta t - \sigma\sqrt{\Delta t} \end{aligned} \quad (67)$$

We now show that the interest rate lattice recombines approximately. Note that:

$$\begin{aligned} r_{11} &= r_0(1 - \alpha\Delta t) + \alpha\mu\Delta t + \delta\sqrt{\Delta t} \\ r_{10} &= r_0(1 - \alpha\Delta t) + \alpha\mu\Delta t - \delta\sqrt{\Delta t} \end{aligned} \quad (68)$$

Hence,

$$\begin{aligned} r_{21} &= r_{10}(1 - \alpha\Delta t) + \alpha\mu\Delta t + \delta\sqrt{\Delta t} \\ &= \left[r_0(1 - \alpha\Delta t) + \alpha\mu\Delta t - \delta\sqrt{\Delta t} \right] (1 - \alpha\Delta t) \\ &\quad + \alpha\mu\Delta t + \delta\sqrt{\Delta t} \\ &= r_0(1 - 2\alpha\Delta t) + 2\alpha\mu\Delta t \\ &= r_{11}(1 - \alpha\Delta t) + \alpha\mu\Delta t - \delta\sqrt{\Delta t} \end{aligned} \quad (69)$$

This result is an approximated one because higher order terms are ignored.¹⁷

Closed Form Solution for $v(0, T_i)$: Rabinovitch

Following the interest rate model defined in Appendix D (i.e. the Vasicek model), the zero coupon bond price satisfies the following closed form equation (Rabinovitch 1989):

$$P(0, t) = e^{-rF(0, t) - G(0, t)} \quad (70)$$

where

$$\begin{aligned} F(0, t) &= \frac{1 - e^{-\alpha t}}{\alpha} \\ G(0, t) &= (t - F(0, t)) \left(\mu - \frac{\delta^2}{2\alpha} \right) + \frac{\delta^2 F(0, t)^2}{4\alpha} \end{aligned}$$

Hence, by Ito's lemma we have,

$$\sigma_P^2(t, T_i) = \left[\frac{\partial P(t, T_i)}{\partial r} \delta \right]^2 = F(t, T_i)^2 \delta^2 \quad (71)$$

and

¹⁷ If higher order terms are not ignored, then the lattice does not combine. In the case where the lattice does not recombine, we take the average of two non-recombining values at each node and proceed. We discover that this method produces extremely close results when we compare the zero coupon bond price against the Vasicek closed form model. We use the same technique with both deterministic volatility function and random interest rate are used. Note that in here, since Δt is different period by period, the interest rate dimension of the lattice does not recombine.

$$\int_0^t \sigma_p^2(u, T_i) du = \int_0^t F(u, T_i)^2 \delta^2 du = \delta^2 t + \left((t - 2F(0, t)) + \frac{1 - e^{-2\alpha t}}{2\alpha} \right) \left(\frac{\delta}{\alpha} \right)^2 \quad (72)$$

Bankruptcy Prediction Studies Across Countries Using Multiple Criteria Linear Programming (MCLP) and Other Data Mining Approaches

76

Wikil Kwak and Yong Shi

Abstract

In this study, we want to show the usefulness of Multiple Criteria Linear Programming (MCLP) data mining approach to predict bankruptcy across countries such as Japan, Korea, and China compared with those of US studies. Bankruptcy studies are interesting to investors, managers, regulators, and other external users, but traditionally we used logit or probit types of statistical methods to predict firm bankruptcy. Recently, data mining has proven to be a useful tool in accounting and finance for various prediction and classification studies. Many applications have been used in accounting and finance areas where accountants deal with large amounts of computerized operational and financial databases. Eighty-two percent of these studies are predictive studies based on recent survey (Amani, F. A. and A. M. Fadlalla, *International Journal of Accounting Information Systems* 24:32–58, 2017). Segal (*Economics and Business Review* 2:45–64, 2016) proposes more applications of data mining in fraud detection and prevention as advanced technologies in the current information environment. There are higher potential payoffs for data mining applications in these areas. The purpose of this study is to propose an MCLP data mining approach as comparable to other data mining methods for bankruptcy prediction. This approach has proven to be robust and powerful even for a large sample size using a huge financial database. The results of the MCLP approach in a bankruptcy prediction study are promising as this approach performs better than traditional multiple discriminant analysis or logit

analysis using financial data. Similar approaches can be applied to other accounting areas such as auditor changes, internal control weakness prediction, hedging, forecasting stock performance, detection of tax evasion, and an audit-planning tool using financial variables (see Kwak, W., S. Eldridge, S. Yong, and K. Gang, *Journal of Applied Business Research* 25:105–118, 2009, Kwak, W., S. Eldridge, S. Yong, and K. Gang, *Journal of Applied Business Research* 27:73–84, 2011, and Sam, R., J. Osleeb, and K. Si, *International Regional Science Review* 39:77, 2016 for examples).

76.1 Introduction

Data mining tools are widely used in business applications such as credit card default prediction, a customer's buying behavior analysis, product promotion analysis, and online sales support as more online business are booming because of the pandemic. Recently, more applications in finance and accounting such as bankruptcy prediction, fraud detection, forecasting stock returns, auditor change prediction, and internal control weakness prediction have increased as accounting deals with huge amount of financial data and computational costs are cheaper.

The purpose of this study is to introduce a multiple criteria linear programming (MCLP) approach and other data mining approach for bankruptcy prediction across countries from our previous studies (Kwak et al. 2006a, b, 2012, 2014). Data mining is a tool that can be used to analyze data to generate descriptive or predictive models to solve business problems (Berry and Linoff 1997; Chan and Lewis 2002; Witten and Frank 2000). According to Shi et al. (2002), data mining also can be classified based on its process, methodology, and mathematical tools. From the process view, data mining consists of the following stages: (1) cleaning, (2) integration, (3) selection, (4) transformation (5) data mining, and (6) pattern evaluation or interpreting, see Han and Kamber (2001). Data cleaning is required to remove noise and inconsistent data. Data integration may be needed where multiple data sources are used. Selecting and transforming data for achieving business goals is known as data warehousing. Pattern evaluation or interpretation provides the analysis of mined data for use in business decision making by managers. From the methodological view, data mining can be achieved by association, classification, clustering, and predictions. From the mathematical point of view, the algorithms of data mining can be implemented by binary, induction decision tree, statistics, neural networks, etc. (Shi et al. 2002).

Mousavi and Ouenniche (2018) used statistical models using macroeconomic indicators to predict financial distress using UK data. In contrast, Support Vector Machine methods are found to be highly potential in predicting bankruptcy studies using Korean data (Kim et al. 2018). Klepac and Hampel (2018) also suggested that decision tree approaches are better than support vector machine methods in predicting bankruptcy using EU data. Recently, Batena and Asghari (2020) used logit and genetic algorithm (GA) models to predict bankruptcy and found GA methods to be superior. However, MCLP approach can be comparable to other data mining methods as we have been using these methods in bankruptcy studies across countries.

The challenges may come from creating optimal cost-benefit trade-off mapping between the benefits of quantifying or discrediting financial data and the cost of information loss in the process of granulating financial data for detecting bankruptcy. In computer security detection, the discretization problem may be less severe because of the binary nature of a computer virus or security breach that the detectors deal with, whereas financial data are decimal.

On the other hand, as of now, an MCLP data mining approach has been recently applied to credit card portfolio management. This approach has proven to be robust and powerful for even a large sample size using a huge financial database. The results of the MCLP approach in our bankruptcy prediction study are promising as this approach performs better than traditional multiple discriminant analysis or logistic regression analysis using financial data.

Our study is organized as follows: The next section presents the background of bankruptcy studies. The third section presents an MCLP data mining model. The fourth section describes data collection procedures and reports our empirical results of different countries. The last section concludes with a summary of our findings and future research avenues.

76.2 Background

Altman (1968) proposed a seminal work in the bankruptcy prediction study and used multiple discriminant analysis (MDA) by using five financial ratios to predict a bankruptcy model. Altman et al. (1977) later proposed the ZETA model, but their assumptions of data being normally distributed can be a problem when applying this model. Beaver (1966) used cash flow variables to predict bankruptcy and later studies compared financial ratios with cash flow variables and confirmed that cash flow variables are also useful to predict bankruptcy.

Ohlson (1980) used a logit model, which does not require any assumptions about the prior probability of bankruptcy or the distribution of predictor variables, see Nanda and Pendharkar (2001). The assumptions about the knowledge of prior probabilities and group distributions make both of the above techniques very restrictive in bankruptcy prediction studies. In addition, hold-out sample tests are potentially upwardly biased according to Grice and Dugan (2001) and Platt and Platt

(1990), the differences in the macroeconomic factors are sensitive to specific time periods. Typical finance and accounting bankruptcy studies use financial ratios and other macroeconomic variables to predict bankruptcy and the advantage of these approaches is finding out which variable has significant impact to a firm's bankruptcy. However, if we focus on prediction accuracy rates, data mining methods could be more attractive. Especially the Multiple Criteria Linear Programming data mining method is a promising method compared with other data mining methods.

Korol (2020) proposed long-term trajectories of bankrupt firms using traditional multivariate discriminant analysis and logit models and find that these models are still valid to evaluate long-term growth and early bankruptcy risk beforehand using 17 years of data. Mousavi and Ouenniche (2018) proposed that statistical models using macroeconomic indicators to predict financial distress using 2005–2014 UK data show that their revised statistical methods are still valid. In contrast, Support Vector Machine (SVM) methods are found to be higher potential to predicting bankruptcy studies using 2000–2013 Korean data (Kim et al. 2018). Horak et al. (2020) also proposed that the SVM method show a relatively high accuracy with Czech Republic data. Klepac and Hampel (2018), however, suggested that decision tree approaches are better than support vector machine methods to predict bankruptcy using 2011–2013 EU data. Recently, Batena and Asghari (2020) used logit and genetic algorithm (GA) models to predict bankruptcy and found GA methods to be superior.

The focus of our study is the bankruptcy prediction accuracy rate using past financial data and other variables as other previous studies have used these approaches. Therefore, we propose the MCLP method as comparable to other data mining methods.

76.3 Models of Multiple Criteria Linear Programming Classification

From the aspect of mathematical tools of data mining, the algorithms of data mining can be implemented by many different types of mathematical techniques. For example, Shi et al. (2002) state classification or prediction methods can be constructed by decision trees, statistics, and neural networks as previous bankruptcy studies have used.

Based on Freed and Glover's (1986) linear programming (LP) model, Kou et al. (2003) developed a general problem of data classification by using MCLP. The basic concept of the formulation can be shown as follows:

Given a set of r variables about the bankrupt or non-bankrupt sample firms in the database $\mathbf{a} = (a_1, \dots, a_r)$, let $\mathbf{A}_i = (A_{i1}, \dots, A_{ir}) \in \mathbf{R}^r$ be the sample observations of data for the variables, where $i = 1, \dots, n$ and n is the sample size. We want to determine the coefficients of the variables, denoted by $\mathbf{X} = (x_1, \dots, x_r)^T$, and a boundary value of b to separate two classes: B(Bankrupt) and N (Non-bankrupt); that is,

(a) $A_i X \leq b, A_i \in B$ (Bankrupt) and $A_i X > b, A_i \in N$ (Non-bankrupt).

Now consider two kinds of measurements for better separation of Bankrupt and Non-bankrupt firms. Let α_i be the overlapping degree with respect to A_i , and β_i be the distance from A_i to its adjusted boundary. We also define α to be the maximum overlapping of a two-class boundary for all cases A_i ($\alpha_i < \alpha$) and β to be the minimum distance for all cases A_i from its adjusted boundary ($\beta_i > \beta$).

We use ($\star$) to represent A_i of Non-bankrupt and ($\bullet$) to represent A_i of Bankrupt, then Fig. 1 shows that our goal is to minimize the sum of α_i and maximize the sum of β_i simultaneously. By adding α_i into (a), we have:

(b) $A_i X \leq b + \alpha_i, A_i \in B$ and $A_i X > b - \alpha_i, A_i \in N$.

However, by considering β_i , we can rewrite (b) as

(c) $A_i X = b + \alpha_i - \beta_i, A_i \in B$ and $A_i X = b - \alpha_i + \beta_i, A_i \in N$.

Our two-criterion linear programming model is stated as

(d) Minimize $\sum_i \alpha_i$ and Maximize $\sum_i \beta_i$
Subject to

$$A_i X = b + \alpha_i - \beta_i, A_i \in B,$$

$$A_i X = b - \alpha_i + \beta_i, A_i \in N,$$

Where A_i is given, X and b are unrestricted, α_i and $\beta_i \geq 0$, see Shi et al. (2001, p. 429).

Fig. 1 A Two-class MCLP Model

Fig. 2 Compromise formulation

The above MCLP model can be solved in many different ways. One method is to use the compromise solution approach as Shi and Yu (1989) and Shi (2001) did, to reform model (d) by systematically identifying the best trade-offs between $-\sum_i \alpha_i$ and $\sum_i \beta_i$. To show this graphically, we assume the ideal value of $-\sum_i \alpha_i$ is $\alpha^* > 0$ and the ideal value of $\sum_i \beta_i$ is $\beta^* > 0$. Then, if $-\sum_i \alpha_i > \alpha^*$, we define the regret measure as $-d_{\alpha}^+ = \sum_i \alpha_i + \alpha^*$; otherwise, it is 0. If $-\sum_i \alpha_i < \alpha^*$, the regret measure is defined as $d_{\alpha}^- = \alpha^* + \sum_i \alpha_i$; otherwise, it is 0. Thus, we have (i) $\alpha^* + \sum_i \alpha_i = d_{\alpha}^- - d_{\alpha}^+$, (ii) $|\alpha^* + \sum_i \alpha_i| = d_{\alpha}^- - d_{\alpha}^+$, and (iii) $d_{\alpha}^-, -d_{\alpha}^+ \geq 0$. Similarly, we derive $\beta^* - \sum_i \beta_i = d_{\beta}^- - d_{\beta}^+$, $|\beta^* - \sum_i \beta_i| = d_{\beta}^- + d_{\beta}^+$, and $d_{\beta}^-, d_{\beta}^+ \geq 0$ (see Fig. 2). An MCLP model has been gradually evolved as

(e) Minimize $d_{\alpha}^- + d_{\alpha}^+ + d_{\beta}^- + d_{\beta}^+$
Subject to

$$\alpha^* + \sum_i \alpha_i = d_{\alpha}^- - d_{\alpha}^+,$$

$$\beta^* - \sum_i \beta_i = d_{\beta}^- - d_{\beta}^+,$$

$$A_i X = b + \alpha_i - \beta_i, A_i \in B,$$

$$A_i X = b - \alpha_i + \beta_i, A_i \in N,$$

Where A_i , α^* , and β^* are given, X and b are unrestricted, α_i , β_i , d_{α}^- , d_{α}^+ , d_{β}^- , $d_{\beta}^+ \geq 0$.

The data separation of the MCLP classification method is determined by solving the above problem. Two versions of actual software have been developed to implement the MCLP method on large-scale databases. The first version is based on the well-known commercial SAS platform (SAS/OR 1990). In this software, the SAS

codes, including the SAS linear programming procedure, are used to solve (e) and produce the data separation. The second version of the software is written by C++ language running on a Linux platform (Kou and Shi 2002).

The reason for developing a Linux version of the MCLP classification software is that the majority of database vendors, such as IBM are aggressively moving to Linux-based system development. This Linux version follows the trend of information technology. Because many large companies currently use an SAS system for data analysis, the SAS version is also useful to conduct data mining analysis under the SAS environment.

76.4 Data Collection and Research Design

In this, study we present the MCLP approach for our bankruptcy study (Kwak et al. 2006a) for illustration purpose and later we will report the summary of other countries' studies from our previous studies. We collected bankrupt firms from 1992 to 1998 and an average of 5.84 times more than the number of matching firms by the size and industry to emulate a real-world bankruptcy situation. We collected financial data from Research Insight (RI) and selected companies listed in three major stock exchanges: New York Stock Exchange, American Stock Exchange, and NASDAQ. We checked other sources such as the Wall Street Journal to make sure we include all bankrupt firms around this time.

We include in our sample companies only up to and including 1998 data from 1992 as there were not enough bankrupt companies after 1998 with all the data available. We ran our model every year since the time period is a factor unless our research design controls all macroeconomic factors.

We used Altman's (1968) original variables and Ohlson's (1980) variables for bankruptcy prediction. Altman (1968) used five ratio variables in his study and Ohlson (1980) used nine variables in his study. We can include more macroeconomic variables later without difficulty in our model.

We first ran our MCLP data mining model using five variables for each year as Altman (1968) did in his original study. We wanted to compare the results of our study with the results of Altman's (1968) study to show the prediction accuracy of our study. Then we ran our MCLP data mining model using nine variables as Ohlson (1980) did in his study. Our goal is to show the effectiveness of our model compared with Altman's (1968) and Ohlson's (1980).

Table 1 shows the descriptive statistics that are similar to Altman's (1968) and Ohlson's (1980) previous studies. As you can see in Panel B, all variables between bankrupt and non-bankrupt firms are significantly different except for the size and market value of equity/book value of total debt variables. The size variable is not significantly different since we matched the control firms based on the size and industry. The market value of equity/book value of total debt is marginally significant. However, the size and changes in net income variables are significantly different compared with Ohlson's (1980) original study and our study because of different time periods. Both variables are significantly negative in our study. We used

Variable descriptions:

Size = Log (Total Assets/Gross Domestic Products)

TL/TA = Total Liabilities/Total Assets

WCA/TA = Working Capital Divided by Total Assets

CL/CA = Total Current Liabilities/Total Current Assets

OENEG = if $TL/TA > 1$ then $OENEG = 1$; else $OENEG = 0$

NI/TA = Net Income/Total Assets

FUTL = Funds from Operations/Total Liabilities

INTWO = if $Net\ Income < 0$ or $lag(Net\ Income) < 0$ then $INTWO = 1$; else $INTWO = 0$

CHIN = $(Net\ Income - lag(Net\ Income)) / [absolute(Net\ Income) + absolute(lag\ Net\ Income)]$

WCATA = Working Capital/Total Assets

RE/AT = Retained Earnings/Total Assets

EBIT/AT = Earnings Before Interest and Taxes/Total Assets

MKVAL/TL = Market Value of Equity/Book Value of Total Debt

SALE/TA = Sales/Total Assets

the gross domestic product of each year instead of the GNP price-level index as a deflator, with a base value of 100 for 1968 as did the Ohlson (1980) study.

Compared with Altman's (1968) study, the signs of working capital/total assets, retained earnings/total assets, and earnings before interest and taxes variables are the same for the bankrupt firms of our study, but directions are mixed in non-bankrupt firms. Since the time period is quite different, this comparison cannot be meaningful.

Table 2 presents our MCLP model results using Altman's (1968) five variables by each year and overall years. In our study, we tried the MCLP data mining approach using Altman's (1968) five variables with more numbers of control firms since

Table 2 Predictability of the MCLP model using Altman's five variables

One year prior to bankruptcy				
1992	N	Number correct	Percent correct	Percent error
Type-I	21	12	57.14	42.86
Type-II	70	68	97.14	2.86
Overall prediction rate			87.91	12.09
1993	N	Number correct	Percent correct	Percent error
Type-I	15	11	73.33	26.67

Overall prediction rate			92.68	7.32
1998	N	Number correct	Percent correct	Percent error
Type-I	9	4	44.44	55.56
Type-II	89	86	96.63	3.37
Overall prediction rate			91.84	8.16
All years	N	Number correct	Percent correct	Percent error
Type-I	91	42	46.15	53.85
Type-II	521	500	95.97	4.03
Overall prediction rate			88.56	11.44

Table 3 Type-I and Type-II errors for re-estimated Ohlson’s Model using 1990s data

Likelihood ratio	Year	Percent correct	Percent error
38.47	1992	92.5%	7.4%
39.77	1993	96.1	3.7
35.03	1994	98.3	1.7
44.10	1995	100.0	0.0
32.34	1996	93.6	6.1
29.41	1997	94.5	5.5
20.07	1998	93.3	6.7
109.04	All years	79.6	19.7

Altman’s (1968) approach of using the same number of control firms is criticized by Ohlson and others for an upward bias of the prediction error rate. For the overall prediction rate, the lowest prediction rate was 87.91% in 1992 by combining the Type I and Type II errors as Altman (1968) reported. The highest prediction rate was 97.30% in 1996. The overall prediction rate for all years was 88.56%. Altman (1968) reported a 95% prediction rate in his original study, but this rate dropped to 78.4% in the 1980s holdout sample according to Begley et al. (1996). From these results, our MCLP model shows that our approach is a lot more efficient and effective in bankruptcy prediction with current financial data. There are some variations by each year in terms of the Type-I error rate. However, Type-II error rates are very consistent and high (average of 95.67%). In the case of bankruptcy prediction, Type-I error is more costly as we discussed before. From the results of Table 2, we can conclude that the correct prediction rate in relation to Type-I error is very time-sensitive, which means bankruptcy prediction 1 year prior to bankruptcy depends on the specific year or other macroeconomic factors. We may need to extend this study using current bankruptcy firm data to verify our findings.

Table 3 reports overall prediction rates of the logit model based on Type-I and Type-II errors using Ohlson’s (1980) nine variables model with an equal number of bankrupt firms and control firms for each year and overall years. The lowest prediction rate was 92.5% in 1992 and the highest rate was 100% in 1995. However, the overall prediction rate for all years was 79.6%, which is similar to other previous studies. Begley et al. (1996) reported similar results when the re-estimated Ohlson (1980) model is applied to the 1980s holdout sample. This table is presented here to compare with the results of our MCLP data mining model.

We applied the MCLP data mining approach using Ohlson’s (1980) nine variables with their original research design of a higher number of control firms and their results are reported in Table 4. We tried Altman’s (1968) five variables model with an equal number of control firms as they did in the original study and their results are reported in Table 4 for comparison purposes.

Table 4 reports Type I and Type II error rates of both models. If we consider that the costs of Type I errors outweigh the costs of Type II errors in a bankruptcy situation, our focus of prediction error rate should be on Type I errors. The prediction rate of Type I errors is increasing and the prediction rate of Type II errors is

Table 4 MCLP data mining model

Year		Altman Model			Ohlson Model		
		N	Number correct	Percent correct (%)	N	Number correct	Percent correct (%)
1992	Type-I	21	15	71	21	11	52
	Type-II	21	17	81	70	66	94
1993	Type-I	15	13	87	15	13	87
	Type-II	15	13	87	74	72	97
1994	Type-I	12	8	67	12	9	75
	Type-II	12	10	83	63	62	98
1995	Type-I	8	8	100	8	6	75
	Type-II	8	8	100	58	57	98
1996	Type-I	15	14	93	15	8	53
	Type-II	15	14	93	96	93	97
1997	Type-I	12	10	83	12	7	58
	Type-II	12	11	92	70	69	99
1998	Type-I	9	7	78	9	4	44
	Type-II	9	8	89	89	87	98
All data	Type-I	126	109	87	91	39	43
	Type-II	91	62	68	521	492	94

decreasing in Altman's (1968) model compared with the model with more numbers of control firms. This is an interesting result that suggests Altman's (1968) original model could be upward biased and he should use more control firms to represent the real-world situation of bankruptcy. However, in the case of Ohlson's (1980) nine variables model, the Type I error prediction rate is decreasing, and the Type II error prediction rate is increasing in our MCLP approach. From the results of the overall prediction rate, Ohlson's (1980) model is similar to Altman's (1968) model (86.76% vs. 88.56%) using more control firms, but our MCLP model using Ohlson's (1980) nine variables is better than the overall prediction rate of the logit model (79.6%). This sustains our findings in this study. From the above results, our MCLP data mining approach performs better than Altman's (1968) model but provides similar or better results to Ohlson's (1980) nine variables model.

Figure 3 presents the cumulative distribution of bankrupt and non-bankrupt firms for all years using Ohlson's (1980) model. The picture is presented to visualize the results of bankruptcy prediction. As you can see from Fig. 3, our MCLP data mining approach is stable about 43% for the Type I prediction rate, but the Type II prediction rate is more than 90% for the overall years.

In our other paper, we used Japanese data using the MCLP data mining approach to predict bankruptcy during 1989–1999 (Kwak et al. 2006a). Although our overall prediction rate using the MCLP approach is somewhat less than that reported by Kwak et al. (2006b), the primary difference between Japanese study and that of Kwak et al. (2006b) is that the difference between Japanese data and US data.

Fig. 3 Cumulative distribution of bankrupt and non-bankrupt firms

Differences in the predication rates may be caused by accounting systems and its information environment of the two countries.

Kwak et al. (2012) also used the MCLP data mining approach to predict bankruptcy using 1997–2003 financial data of Korean bankrupt firms. Overall, the prediction rates in Korean study show 88.7%. Therefore, our MCLP data mining model is very efficient and prediction rates are reasonably good compared to other models.

tWe used other data mining models and the logit model to predict bankruptcy in China (Kwak et al. 2014). Using 1999–2007 Chinese bankruptcy data, our results suggest that Chinese firms with current liquidity problems and firms experiencing a decline in profits are more likely to file for bankruptcy. Overall prediction rates are lower than those of previous USA, Japanese, or Korean bankruptcy studies as shown in our previous studies. China’s capital market has become more dynamic and diverse. We may need to incorporate productivity enhancement and effective strategy implementation for Chinese firms to improve bankruptcy prediction rates (Bryan et al. 2013). In addition, we may use time-series data as suggested by Shumway (2001) and macroeconomic factors to improve our bankruptcy model (Nam et al. 2008).

76.5 Summary and Conclusions

In this chapter, we present empirically the usefulness of Multiple Criteria Linear Programming (MCLP) data mining approaches to predict bankruptcy across countries such as Japan, Korea, and China compared with those of US study. Data mining has proven to be a useful tool in accounting and finance for various prediction and classification studies by several researchers. By using traditional financial ratios and other financial variables such as Altman’s (1968) five variables, using MCLP data mining for bankruptcy studies generally shows better prediction rates than using

traditional logit or probit analysis. However, US data empirically show better prediction rates than Japanese, Korean, and Chinese data around similar time periods. This could be a more reliable information environment in the USA.

Our next research will compare our MCLP data mining approach with other current data mining approaches with current data. We may also include nonfinancial data such as stock market return, qualified audit opinions, internal control weakness data, and other macroeconomic data to improve bankruptcy prediction rates.

Application of Difference-in-Differences Strategies in Finance: The Case of Natural Disasters and Bank Responses

77

James R. Barth, Kang Bok Lee, Xuan Shen, and Yeo Song Yoon

Abstract

Natural disasters are negative shocks that can severely disrupt the communities in which they occur. Disasters like hurricanes, tornados, floods, wildfires, and earthquakes, moreover, can cause severe property damage, including damages to homes, businesses, and automobiles. An important issue that arises is whether branches of banks in communities affected by natural disasters raise deposit rates to attract additional deposits in response to any deposit withdrawals and to meet any increase in loan demand for the rebuilding that takes place. Studies of the responses of banks to natural disasters increasingly find it useful to rely on a difference-in-differences (DID) identification strategy. The contribution of our entry is to examine how different choices that can be made affect the empirical results. Importantly, as our empirical results indicate, the discretion that a researcher uses in terms of the choices made at different stages do indeed produce different conclusions about the impact of natural disasters on bank deposit rates. If we do not match branches of branches affected by natural disasters with those

in adjacent communities not affected the results indicate that natural disasters have a statistically negative effect on deposit rates without matching and with a low degree of matching. However, when we use a medium or a high degree of matching there is no statistically significant effect. Moreover, when we use two different matching methods, the results differ. In the case of PSM, we find a statistically significant effect, but no effect in the case of CEM.

77.1 Introduction

Natural disasters are negative shocks that can severely disrupt the communities in which they occur. Such disasters, moreover, are not rare events. Indeed, since the 1990s, there has been a clear acceleration in disasters, averaging more than 300 county-level events per year over the period 2000–2013. Furthermore, disasters like hurricanes, tornados, floods, wildfires, and earthquakes can cause severe property damage, including damages to homes, businesses, and automobiles. Although insurance and government support cover some of the reconstruction and replacement costs, individuals and business owners suffering damages may withdraw deposits at banks and apply for loans to help cover all the costs.

An interesting and important issue that arises is the impact of natural disasters on banks. For example, do individuals and business owners withdraw deposits in response to such disasters to obtain funds to cover expenses associated with recovery efforts? And do branches of banks in communities affected by natural disasters raise deposit rates to attract additional deposits in response to any deposit withdrawals and to meet any increase in loan demand for the rebuilding that takes place? Studies of the responses of banks to natural disasters, and other credibly exogenous sources of variation, increasingly find it useful to rely on a difference-in-differences (DID) identification strategy. The reason is that such a strategy provides a stronger foundation to achieve the identification of causal relationships rather than simply correlations.¹ However, when using such a strategy one assumes there is a good match between the treatment group (e.g., bank branches in communities affected by disasters) and the control group (e.g., bank branches in communities not affected by them). The purpose of a good match is to reduce potential confounding by improving the comparability of units (e.g., bank branches) in the treatment and

¹ Angrist and Pischke (2010, p. 14) state that DID is “... probably the most widely applicable design-based estimator.”

control groups. One also assumes that there is a common trend (e.g., in deposit rates) for the two groups before the treatment.

The contribution of our entry is to analyze the effect of natural disasters on the deposit rates of banks. However, for a nonexperimental method, like DID that we will be using, there are several stages in the research process where a researcher may exercise discretion (Brodeur et al. 2020). We, therefore, examine how different choices that can be made affect the empirical results. This is important due to the concern that a researcher might engage in *p*-hacking, which refers to the practice used to generate “better” *p*-values, perhaps, though not necessarily, in response to a publication bias or the difficulty of publishing statistically insignificant results (Brodeur et al. 2020).² Specifically, we show there are choices regarding the matching of branches and the type of matching method employed when using DID. Thus, we compare the results from estimating a basic model of deposit rate responses to natural disasters using a DID identification strategy based on several different choices made. The choices we make are with and without matching of bank branches as well as using “poor” and “good” matches, adjectives that are defined later. We also choose different matching methods to determine whether they produce the same or different results. Lastly, we choose a sample with a pre-disaster common trend in deposit rates in counties experiencing natural disasters and those in adjacent counties not experiencing them as well as a subsample with no pre-disaster common trend. Importantly, as our empirical results indicate, the discretion that a researcher uses in terms of the choices made at different stages do indeed produce different conclusions about the impact of natural disasters on bank deposit rates. Indeed, some choices could be considered as *p*-hacking. Yet, the most reliable results indicate that natural disasters have no statistically significant effect on bank deposit rates. This finding might produce publication bias, whereby the lack of statistical significance lowers the probability of publication (Brodeur et al. 2020).

The remainder of the entry proceeds as follows. In the next section, we describe the motivation for our study. The third section explains the data, and its various sources, used in the empirical work. This is followed in the fourth section with a discussion of matching methods and the quality of the methods using an imbalance measure. The fifth section explains our research design. The basic model to be estimated as well as the empirical results are presented and discussed in the sixth section. The seventh and last section contains the conclusions.

77.2 Motivation

Our study of the effect of natural disasters on bank deposit rates is motivated in part by a recent paper by Dlugosz et al. (2020). They use a DID identification strategy to examine whether branches of banks in communities affected by natural disasters can set deposit rates locally and thereby be in a position to raise those rates to attract additional deposits to meet an increase in loan demand for the reconstruction and replacement efforts that

²Brodeur et al. (2020, p. 3658), moreover, state that “. . . papers using IV and DID are identified as particularly problematic with respect to *p*-hacking and publication bias problems.”

take place after such disasters. They find that branches that set rates locally do increase deposit rates more in counties affected by natural disasters than branches in adjacent counties not experiencing them. We adopt a similar approach to analyzing the response of deposit rates at branches in counties suffering natural disasters, including their model specification, data sources, and sample period. However, they chose to implement a triple DID strategy and rely on a single matching method, while we choose to employ a DID strategy and rely on two matching methods.

Also, our study, in contrast to Dlugosz et al. (2020), is partly motivated by the discretion a researcher can exercise at different stages in the implementation of the DID identification strategy (Brodeur et al. 2020). We therefore compare and contrast the results from the different choices that one can make, including choosing with and without matching, and poor and better matching, of bank branches in counties with natural disasters and those in adjacent counties without them. Also, we consider the effect on the results of matching banks when one can choose between two different matching methods. Lastly, we examine whether there is a difference in results for rates when one can choose either with or without a common trend for the two groups of branches before the occurrence of natural disasters. Importantly, we find that the empirical results do indeed differ depending upon the research design when using DID to determine whether bank deposit rates are different for banks in counties experiencing natural disasters and those in adjacent counties not experiencing them. Our findings have important implications for the degree to which one can rely upon different DID strategies for not only a study like that of Dlugosz et al. (2020), but also other studies using DID techniques to access the response of a bank, or another firm, to various types of exogenous shocks.

77.3 Data

The data for our study combines several datasets covering the period 1999 to 2014, which is the same period used by Dlugosz et al. (2020). These include information on natural disasters, deposit rates for each bank branch, bank balance-sheet variables, and branch location. We now describe in more detail the construction of the data used in the empirical work.

77.3.1 Natural Disasters

The data on natural disasters are from the Federal Emergency Management Agency (FEMA).³ FEMA provides the declaration date of the disaster, location (county and state), and type of disaster. We include the following types of disasters in the analysis: fires, floods, hurricanes, snow, severe storms, tornados, and other disasters. We exclude disasters in territories such as Puerto Rico. The total number of disasters from 1999 to 2013 is 4,287, ranging from a low of 60 in 1999 to a high of 482 in

³See <https://www.fema.gov/data-sets>

2007. This translates into 24,688 natural disasters in counties for our sample period. This number is reduced to 14,751 disasters in counties once we remove counties with multiple disasters in the same month and those suffering any other disaster in a 7-month window other than but including the disaster month (i.e., 3 months before and 3 months after a disaster as well as the month of the disaster). For analyzing the impact of disasters, we form a cohort including a disaster-affected county and its adjacent non-affected counties to compare the deposit-rate responses of the branches within each of the counties. Our treatment group consists of the branches within a disaster-affected county and the control group consists of the branches within its adjacent non-affected counties. We keep those cohorts for which there are at least one affected and one unaffected county. This further reduces the sample to 7,894 counties with natural disasters and adjacent counties without disasters.

77.3.2 Deposit Rates

We obtain deposit rate data from RateWatch, a firm that provides weekly branch-level data for such rates. Information is available for the location of branches (county and state), unique branch IDs assigned by the Federal Deposit Insurance Corporation (FDIC), and type of deposit products. We use the deposit rates of each branch for 12-month certificates of deposit requiring a minimum balance of \$10,000 (CDs). Since the deposit rate data are weekly, we use the monthly average deposit rate for each branch in our analysis.

77.3.3 Deposit Data

Deposit data at the branch-level are available from the Summary of Deposits (SOD), FDIC. SOD provides an annual survey of branch deposits as of June 30, from 1999 to 2013. The data also includes geographic information (county and state) of branches and bank headquarters as well as unique branch IDs assigned by the FDIC. We keep the cohorts within which at least one affected and at least one unaffected county exists and drop those branches if for any month within the event window they are missing.

77.3.4 Bank Variables

The data for the bank variables are available from the quarterly Call Reports and the Statistics on Depository Institutions (SDI), FDIC. The following three bank control variables, also used by Dlugosz et al. (2020), are used in our estimation: (1) 1 if a bank is a community bank (*Small*),⁴ 0 otherwise, (2) 1 if a bank has more than 65%

⁴ Actually, Dlugosz et al. (2020) define *Small* to be a dummy variable that equals 1 if a bank has less than \$2 billion in assets

of its deposits from a single county (*Local*), 0 otherwise, and (3) 1 if a county is in the top quartile of deposits among the counties in which a bank has branches (*Important Market*), 0 otherwise. The values of the control variables are determined at the end of the quarter before the month of the natural disaster. The bank control variables are transformed into monthly values by interpolating their quarterly values.

With the unique branch IDs and geographic information, we can match and merge SOD data with both RateWatch deposit rates and FEMA natural disaster data at the county level. In the next section, we discuss the matching techniques and imbalance measure used in our empirical work.

77.4 Matching Methods and Imbalance Measure

Matching Methods. Random assignment is required to construct a valid causal inference, as it provides a perfect balance in covariates between treatment and control groups. With observational datasets, obtaining valid causal inference is a challenge due to the difference between the treatment and control groups (Heckman et al. 1998). Thus, in the absence of random assignment, the goal of matching is to reduce the observable differences, or, the imbalance between the two groups (Stuart 2010; Iacus et al. 2012). A better balance is achieved when there is a similar distribution of covariates between the two groups. Previous research has shown that large deviations in the distribution of covariates between groups can lead to a bias in estimating the treatment effect (Cochran and Rubin 1973; Rubin 1973; Rubin and Thomas 2000). A matching method can be used to obtain a well-matched sample that reduces statistical bias in estimating the treatment effect and thereby improving the estimation of causal effects (Ho et al. 2007; Stuart 2010; Iacus et al. 2012). In this regard, we employ two matching methods: Coarsened Exact Matching (CEM) and Propensity Score Matching (PSM) to estimate the DID parameter after matching the branches. The first method, CEM, is one of a new generalized class of matching methods called the monotonic imbalance bounding (MIB) method. This involves preprocessing data by coarsening variables, implementing one-to-one exact matching, and reducing multivariate imbalance measures (Blackwell et al. 2009; Iacus et al. 2011, 2012). The second method, PSM, is one of the most widely used matching methods for causal inference and for analyzing the causal effect of treatments specifically. PSM⁵ was introduced by Rosenbaum and Rubin (1983) and has been implemented in numerous empirical research studies in statistics, economics, finance, and other fields. By implementing parametric models, such as logit or probit models based on the matching variables, the propensity score, which is the likelihood of receiving treatment, is estimated to compute the causal effect.

Imbalance Measure. When using the two matching techniques, one can determine the quality (i.e., good versus poor) of the match of variables for the two groups by calculating a multivariate imbalance measure. Specifically, we can determine which covariate balance based on different matches of variables between the treatment (i.e.,

⁵PSM is a member of the class of matching methods called equal percent bias reducing (Rubin and Thomas 1992; Rubin and Stuart 2006).

branches in counties suffering natural disasters) and control (i.e., branches in counties in adjacent counties not suffering them) groups is most appropriate for the DID estimation. To gauge the difference in the multivariate distributions between the treatment and control groups, one calculates the multivariate imbalance measure ($\mathcal{L}_1$) (Iacus et al. 2012). $\mathcal{L}_1$ falls between 0 and 1; $\mathcal{L}_1 = 0$ if the distributions perfectly overlap, and $\mathcal{L}_1 = 1$ if the distributions are completely separated. For example, if $\mathcal{L}_1 = 0.4$, then 60% of the two groups overlap. Thus, the lower the imbalance measure, $\mathcal{L}_1$, the better the match.⁶ In our study, a low degree of matching of bank branches is defined as a low reduction (i.e., a decrease of less than 0.02, no reduction, or even an increase) in the multivariate imbalance measure after matching when the measure after matching remains higher than 0.65. In contrast, a high degree of matching is defined as a high reduction (i.e., a decrease of more than 0.6) in the multivariate imbalance measure after matching when the measure after matching is lower than 0.20. For example, when the imbalance measures based on before matching (using the full dataset) and after matching are 0.9 and 0.2, respectively, we classify the case as a high reduction (0.7 is greater than 0.6 and the decrease is more than 0.6). The degree of matching is considered medium when the imbalance measure and the magnitude of reduction after matching remain between the values of the low and high degrees of matching.

Common Trend Assumption. In the empirical DID literature, the common trend assumption is a key identifying assumption because the DID estimator requires that, in the absence of treatment, the differences in the average outcomes between the treatment and the control groups would be constant in the post and pretreatment periods (Angrist and Pischke 2008; Lechner 2011; Mora and Reggio 2019⁷).⁸ Given the purpose of our study, we estimate parameters in our models in which the pre-disaster common trend is satisfied as well as not satisfied for the matched branches. Based on the work of Mora and Reggio (2015), we test the common trend assumption using the `didq` command in STATA.⁹ This test enables us to determine whether our samples satisfy the common trend assumption for using the DID model when several pretreatment periods exist.

77.5 Research Design

Given one of the main purposes of this study, we estimate several variations of a basic DID model. More specifically, we estimate DID models for samples both with and without matching bank branches in counties experiencing natural disasters as well as in adjacent counties not experiencing natural disasters. We also

⁶For more details, see [Appendix 1](#).

⁷Mora and Reggio (2015, p. 1) state that “When there is only one pretreatment period, this assumption is the parallel paths assumption. When there are several pretreatment periods, the assumption is usually referred to as common trends.”

⁸For more details, see [Appendix 2](#).

⁹When using this command, if the *p-value* is over some threshold, such as 0.05, then one cannot reject the null hypothesis that there are common trends.

estimate DID models based on different sets of matching variables for the branches in the two types of counties. Lastly, we estimate DID models in which the pre-disaster common trend is satisfied as well as not satisfied for the matched branches in a similar manner.

Tables 1 and 2 show the basic approach to our empirical estimation. In Table 1, there are six question marks, indicating our objective to determine whether common trends and matching affect the impact of natural disasters on bank deposit rates. We also examine whether there is a difference in the results (Δ Imbalance Measure¹⁰) for low, medium, and high degrees of matching, based on the imbalance measure as described in the previous section. This type of exercise is not typically performed in empirical studies, which raises the question of whether the use of DID is dependent upon the underlying matching of treatment and control groups used and a common trend assumption commonly made to produce reliable results.

Table 2 is quite similar to Table 1. The only difference is that, in the former table, two different matching methods (PSM and CEM) are employed when estimating the models.

The next section discusses the empirical DID models used in estimating the treatment effect and the empirical results.

77.6 Models and Empirical Results

77.6.1 Base Scenario – DID Model Without a Matching Method

We use a DID model to estimate the average treatment effect without any matching method. To examine the impact of natural disasters on branch deposit rates, we focus on a 7-month event window (i.e., 3 months before and 3 months after a disaster) centered on the month in which a natural disaster occurred. This is a period that encompasses the occurrence of an external shock (Dlugosz et al. 2020). Given this situation, we postulate the following hypothesis:

Hypothesis: *When a natural disaster occurs, branches within disaster-affected counties are more likely to experience an increase in deposit rates than branches within unaffected adjacent counties.*

To test this hypothesis, we use the following basic regression model:

$$\text{Deposit rate}_{ijct} = \beta_0 + \delta_0 \text{Post}_t + \beta_1 \text{Treated}_{ijc} + \delta_1 \text{Post}_t \times \text{Treated}_{ijc} + \mathbf{X}'_{bj} \mathbf{\Lambda} + e_c + \varepsilon_{ijct} \quad (1)$$

where i, j, c, b , and t denote a branch, a county, a cohort, a bank that owns branch i , and time ($t = 0, 1$), respectively. A cohort, c , is formed when a disaster-affected county is combined with its adjacent non-affected counties. The cohort, c , is added to compare the deposit responses of affected and non-affected branches within a cohort. The $\text{Deposit rate}_{ijct}$ denotes the average deposit rate for branch i within county j in cohort c at time t , where the rate is defined as the average deposit rate for the 4 months after the disaster (including the disaster month; $t = 1$) and the 3 months before the disaster ($t = 0$); Post_t equals 1 for the 4 months after the disaster ($t = 1$) and 0 for the 3 months before the disaster ($t = 0$) (i.e., $\text{event month} = -3, -2, -1, 0, +1, +2, +3$ where $\text{disaster} = 0$. $\text{Post}_t = 1$ if $\text{event month} \geq \text{disaster month}$); Treated_{ijc} equals 1 if branch i is within a disaster-affected county in cohort c ; $\mathbf{X}'_{bj} \mathbf{\Lambda}$ is a vector of bank control variables, as noted earlier; e_c indicates cohort fixed effects; and ε_{ijct} is an idiosyncratic error term. Standard errors are clustered (Cluster SE) at the bank level. In the following sections, subscripts are often omitted for simplicity when their omission does not create any confusion.

Following Bertrand et al.'s (2004) suggestion to mitigate serial correlation, the dataset is aggregated into one observation for the pretreatment period and one for the posttreatment period by taking the average value of all the variables for each branch in a cohort (i.e., $\text{Deposit rate}_{ijct}$). Our control variables include a small bank dummy (*Small*), a local bank dummy (*Local*), and an important market dummy (*Important Market*), representing factors that might affect branch deposit behavior (Dlugosz et al. 2020). The coefficient of interest, δ_1 , denotes the DID estimator and measures the effect of a natural disaster on the deposit rate, which may be positive, negative, or zero.

Table 3 Summary statistics

	<i>N</i>	Mean	SD	25th	Median	75th

Small (dummy)	35,766	0.78	0.42	1.00	1.00	1.00
Local (dummy)	35,766	0.63	0.48	0.00	1.00	1.00

To examine whether the empirical results differ with and without a common trend for the two sets of branches, we construct a subset¹¹ of observations in which the pretreatment common trend is not satisfied. In other words, we determine whether our coefficient of interest is affected by the common trend assumption. By testing the common trend assumption (Mora and Reggio 2015), our subset sample is formed with the branch cohorts that are affected by more than three disasters between 1999 and 2013. Using this particular sample, we also estimate the same specification as in Eq. (1) to determine whether the results change.

Table 3 provides a summary of the statistics of our full dataset and subset samples. As can be seen, apart from the difference in sample size, the values of the variables themselves are quite similar in magnitude when measured in the different ways indicated.

77.6.2 Imbalance Measure, Common Trend Assumption, and DID Estimator

To estimate the causal effect of the treatment, we employ CEM as our first matching method and then use the matched branches to estimate the same specification given by Eq. (1). As mentioned earlier, CEM is part of a new generalized class of matching methods called the MIB method, which involves preprocessing data by coarsening

¹¹This subset is obtained from our full sample used to estimate Eq. (1). We test the common trend assumption before aggregating the data and find that the full dataset satisfies the common trend assumption.

variables, implementing one-to-one exact matching, and reducing multivariate imbalance measures (Blackwell et al. 2009; Iacus et al. 2011, 2012). This is the reason we employ CEM, first because this method has desirable statistical properties and second it shows the improvement of the multivariate imbalance measure compare to other existing matching methods (Iacus et al. 2012). We will discuss PSM in Section C.

CEM is performed *before* the average of observations in the 4 months after a disaster and the 3 months before a disaster (i.e., 7 event months) is calculated. We match the same event month in the treatment and control groups (e.g., we match event month 2 in the treatment group with event month 2 in the control group). Performing CEM involves three steps: (1) select the matching variables and calculate the imbalance measure, (2) coarsen variables using coarsening methods (automated or by user), and (3) ensure the imbalance measure is reduced after CEM is performed to find the set of variables yielding best-matched branches. Our matching strategy is to apply three matching variable sets and show how multivariate imbalance measures are reduced after matching using CEM. The three matching variable sets consist of (1) poor or low degree matching variables, (2) poor matching variables plus good or medium degree matching variables A, and (3) poor matching variables plus good matching variables A plus good or high degree matching variables B, as shown in Table 4.

Table 4 Matching variables sets

Δ Imbalance measure		
Low	Medium	High

	Year ^a	Consumer – loan ratio
	Month ^a	Year ^a
		Month ^a
		Small
		Branch ratio ^b

^aYear and month in the event window

^bFraction of branch of the bank within the county

Poor matching variables (low degree of matching) refer to matching variables that minimally reduce the imbalance measures. Good matching variables (high degree of matching) refer to matching variables that substantially reduce imbalance measures. As shown in Sets 1, 2, and 3, the matching procedure increasingly includes more variables, and changes in the imbalance measures moving from one set to the next are calculated. The three-match samples are then used with the same specification to estimate the parameters for the variables in Eq. (1). By adding good matching variables A and B to produce Set 3, we obtain the biggest reduction in the imbalance measure of the three sets. This enables us to determine how the results from the different estimations are affected by different imbalance measures. Also, by matching the same three matching sets for the subset sample when the pretreatment common trend is not satisfied, we can determine whether the common trend assumption matters for the effect of natural disasters on deposit rates. Accordingly, the first research question to be answered is as follows:

Research Question 1: *Do different sets of matching variables and whether a common trend assumption is satisfied change the estimation results?*

To answer this question, Table 5 presents changes in the imbalance measures (i.e., the imbalance measures from the before matching minus the imbalance measures from after matching) for three sets of matching variables of the two groups of branches for each of the 7 months in the event window, as described earlier, but with a common trend for the treatment and control groups before treatment. As can be seen, there is an increasingly larger improvement in the imbalance measures when more good matching variables are included. Indeed, Set 3 shows a far better match than either of the other two sets of variables when all good matching variables are included.

Table 6 presents the same information as Table 5, but the treatment and control groups do not share a common trend before treatment. Once again, there is an

Table 5 Imbalance measure changes for different matching variables with a common trend

Months before, during, and after disaster	Poor matching variables	Poor matching variables + good matching variables A	Poor matching variables + good matching variables A + good matching variables B
	<i>Set 1</i>	<i>Set 2</i>	<i>Set 3</i>

-3	-0.019	0.413	0.775
-2	0.011	0.402	0.801
-1	-0.013	0.402	0.832
0	0.016	0.402	0.830
1	-0.022	0.429	0.853
2	0.001	0.636	0.868
3	0.002	0.605	0.892

increasingly larger improvement in the imbalance measures when more good matching variables are included. Set 3 provides the best match among the three sets due to the largest reduction in the imbalance measure.

Given the difference in the goodness of matching the two groups of branches with and without a common trend, does the degree of matching and the presence of a common trend matter for deposit rates? The answer is provided in Table 7. Panel A shows the results with a common trend, while Panel B shows the results without a common trend. As can be seen in Panel A, branches in counties struck by natural disasters experience a significant negative impact on deposit rates as compared to branches in unaffected adjacent counties without matching and with poor matching variables (Set 1). However, when good and all good matching variables are included (Sets 2 and 3), the results are quite different. In this case, there is no significant relationship between deposit rates and natural disasters. In other words, matching matters, but only when it occurs when there is a substantial improvement in the imbalance measure, as shown in 5.

The analysis is repeated with the two groups of branches that do not have a common trend before the occurrence of natural disasters. The results reported in Panel B are essentially the same as those reported in Panel A. In this case, however, the presence of a pretreatment common trend in the two groups of branches does not matter for the empirical results.

Table 8 summarizes our findings for the three different matching sets, with and without pretreatment a common trend. Importantly, the results for no matching and poor or low matching, and good or medium and high matching, are quite different. However, the lack of a common trend in the treatment and control groups does not affect the empirical results. In short, matching and the degree of matching based on the imbalance measure matter, but the violation of a common trend assumption does not matter for our sample of branches and study period.

Table 7 Difference-in-differences results. *Post* = 1 for 4 months after a disaster, including the disaster month (*event month* = +3, +2, +1, 0); *Post* = 0 for 3 months before the disaster (*event month* = −1, −2, −3). The deposit rate is the average of the 4 months after the disaster and the average of the 3 months before the disaster.

77.6.3 Different Matching Methods (PSM and CEM), Common Trend Assumption, and DID Estimator

In this section, we investigate our second research question:

Research Question 2: *Do different matching methods and whether a common trend assumption is satisfied change the estimation results?*

To address this question, we employ another matching technique, PSM, which is one of the most widely used matching methods for causal inferences, to analyze the

causal effect of disasters on bank deposit rates. PSM was introduced by Rosenbaum and Rubin (1983) and has been implemented in numerous empirical studies in finance, among other fields of study. Using estimated propensity scores calculated from observed covariates, one can stratify the propensity scores and then use a matching method (e.g., nearest neighbor or radius matching) to calculate the causal effect (Li 2013). However, PSM has an important limitation: it provides a misleading conclusion regarding causal inference. The reason for this is that a true propensity score obtained from the perfect overlap of distributions of the pretreatment variables for the treatment and control groups cannot be identified (Imai et al. 2008; Imai and Ratkovic 2014). Yet, a perfect overlap can be obtained from a true propensity score. This is called the propensity score tautology. Since we implement the estimated propensity score on matching (Diamond and Sekhon 2013), it may not be possible to have a perfect overlap that would enable one to estimate the causal effect. In contrast, Iacus et al. (2012) explain that CEM has more favorable statistical properties: it outperforms other existing matching methods in reducing imbalance, model dependency, estimation error, and bias. Indeed, CEM is a nonparametric model that considerably reduces potential bias and model dependency in comparison to parametric models, such as PSM (Ho et al. 2007; King and Nielsen 2019). King and Nielsen (2019) contend that PSM increases imbalance, inefficiency, and statistical bias.

Once again, we begin our analysis by showing the improvement in imbalance measures for the two matching methods. PSM is performed in the same way as CEM was performed earlier, but the comparison is now based only on Set 3, the set with the highest degree of matching. We apply the nearest neighbor matching using a caliper width of 0.001. Table 9 clearly shows that the reduction in the imbalance measure when matching with PSM is negligible. In contrast, CEM shows a substantial decrease in the imbalance measure. Thus, CEM allows us to obtain a far better match between branches affected by natural disasters and branches in unaffected adjacent counties when a common trend assumption is satisfied. There is essentially no reduction in the imbalance measure for PSM, whereas there is a substantial reduction in the measure for CEM.

Table 9 Imbalance measures for different matching methods with a common trend

Months before, during, and after disaster	PSM	CEM
	Set 3	Set 3
	Δ Imbalance measure	Δ Imbalance measure
−3	0.013	0.761
−2	0.012	0.798
−1	0.011	0.804
0	0.012	0.802
1	0.012	0.797
2	0.012	0.753
3	0.012	0.781

The same comparison of imbalance measures is performed without a common trend assumption satisfied. The same basic results are presented in Table 10 as in Table 9. CEM provides a far better match for the two groups of branches than PSM in terms of imbalance measure reduction. Indeed, there is hardly any reduction in the case of PSM, while there is a substantial reduction when CEM is used as the matching method.

Given that there is a difference in the goodness of the matching between the two groups of branches with and without a common trend, does the type of matching method and whether there is a common trend matter for the effect of natural disasters on deposit rates? The answer is provided in Table 11. Panel A shows the results with

Table 10 Imbalance measures for different matching methods without a common trend

	PSM	CEM
	Set 3	Set 3

a common trend, while Panel B shows the results without a common trend. As can be seen in Panel A, branches in counties struck by natural disasters experience a significant negative impact on deposit rates as compared to branches in unaffected adjacent counties with and without matching (Set 3) based on PSM. However, when matching with CEM using the same variables (Set 3), the results are quite different. In this case, there is no significant effect of natural disasters on deposit rates. In other words, the matching method matters when the common trends assumption is satisfied.

One concern is that CEM has a smaller sample of matched observations. However, this is not a critical problem because a smaller sample size might indicate that (1) more observations are dropped since well-matched units rarely exist, and (2) heterogeneity between the treatment and control groups is considerably reduced by matching and eliminating observations. This leads to smaller variances in causal estimates and, in turn, a low imbalance measure (Iacus et al. 2011, 2012). Indeed, in observational data, MIB methods may even produce no matched observations (Iacus et al. 2011).

Next, the same type of analysis is performed without a common trend assumption satisfied. The results, in this case, are reported in Panel B and are essentially the same as those in Panel A. Branches in counties struck by natural disasters experience a significant negative impact on deposit rates as compared to branches in unaffected adjacent counties with and without matching (Set 3) based on PSM. However, when matching with CEM using the same variables (Set 3), natural disasters have no significant effect on deposit rates. Thus, once again, the matching method matters even when a common trend assumption is not satisfied. Moreover, the failure of this assumption to be satisfied does not affect the empirical results.

Table 12 summarizes our findings for the two different matching methods, PSM and CEM, using the same set of variables (Set 3) with and without a pretreatment common trend. Importantly, the results are quite different for PSM and CEM. In the former case, deposit rates are significantly affected by natural disasters, whereas in the latter case the rates are not affected. However, the lack of a common trend in the treatment and control groups does not affect the empirical results. In short, matching and the matching method employed matter, but a violation of a common trend assumption does not matter for our sample of branches and study period.

Table 12 Summary of results

<i>HIGH generalizability</i>				
Δ Imbalance measure		Matching methods		
		No matching	PSM	CEM
			Set 3	Set 3
			Low	High
Common trends	Not satisfied	Significant	Significant	Not significant
	Satisfied	Significant	Significant	Not significant

77.7 Conclusions

The contribution of our entry has been twofold. First, we analyzed the effect of natural disasters on the deposit rates of banks. This was done using the DID identification strategy. The basic (i.e., most reliable) finding is that there is no statistically significant response of deposit rates by branches of banks located in counties struck by natural disasters as compared to deposit rates of branches of banks in adjacent counties not so affected. Of course, our focus was only on the rate for 12-month certificates of deposit (CDs) requiring a minimum balance of \$10,000. This finding is consistent with that of Dlugosz et al. (2020), who also use this rate in their analysis and find that there is no statistically significant effect of natural disasters on the rate for branches in counties experiencing them as compared to branches in adjacent counties not experiencing them.¹² However, in their triple DID analysis they find a statistically significant effect for those branches that set rates within the county. More generally, our results are not directly comparable to their results because, as Angrist and Pischke (2010, p. 23) state, “Empirical evidence on any given causal effect is always local, derived from a particular time, place, and research design.”

Second, as noted earlier, there are several steps in conducting our analysis where discretion in how to proceed could be exercised. This involved decisions about whether to match or not and what method to use if matching. Also, a decision had to be made as to whether there was a common trend in the outcome variable before the treatment for both the treatment group and the control group. Our findings indicate that the choices made do indeed affect the empirical results. If we do not match, the results indicate that natural disasters have a statistically negative effect on deposit rates without matching and with a low degree of matching. However, when we use a medium or a high degree of matching there is no statistically significant effect. Moreover, when we use two different matching methods, the results differ. In the case of PSM, we find a statistically significant effect, but no effect in the case of CEM. Lastly, the results do not change whether or not there is a common trend for the treatment group and control group.

Overall, the findings are important not only in terms of assessing the effect of natural disasters on deposit rates of bank branches but in terms of showing that the discretion a researcher possesses can lead to quite different results, whether it be significant or insignificant results, and thereby possibly a publication or not. More importantly, studies with policy implications can be misleading depending on the choices a researcher makes.

¹²Dlugosz et al. (2020) actually use the CD rate following the disaster in the event window minus the rate in the period prior to the disaster in the event window.

Appendices

Appendix 1

The multivariate imbalance measure is calculated as below (Blackwell et al. 2009; Iacus et al. 2011, 2012):

$$\mathcal{L}_1(f, g) = \frac{1}{2} \sum_{\ell_1, \dots, \ell_k \in H(X)} |f_{\ell_1, \dots, \ell_k} - g_{\ell_1, \dots, \ell_k}|$$

Iacus et al. (2012) let $f_{\ell_1, \dots, \ell_k}$ and $g_{\ell_1, \dots, \ell_k}$ denote the k -dimensional relative frequencies of the treatment and the control units, respectively, affiliated with coordinates $\ell_1, \dots, \ell_k$. $H(X)$ denotes the values generated by the multidimensional bins (H) chosen for variable X . f^m and g^m denote the frequencies of matched treatment and control units, respectively, corresponding with the frequencies of nonmatched f and g . Then, when the matching is conducted, a good matching method produces a reduction in the imbalance measure; $\mathcal{L}_1(f^m, g^m) \leq \mathcal{L}_1(f, g)$ (Blackwell et al. 2009; Iacus et al. 2011, 2012).

Appendix 2

Average treatment effect on the treated (ATT), α_{ATT} , of the DID approach is:

$$\alpha_{ATT} = E(Y_t^1 | D = 1, X) - E(Y_t^0 | D = 1, X)$$

where D , Y_t^1 , and Y_t^0 denote the treatment indicator (0 or 1), the potential outcome *with* treatment, and the potential outcome *without* treatment, respectively. $t = 0$ indicates pretreatment period and 1 indicates posttreatment period. The common trend assumption is expressed as follows (Lechner 2011):

$$E(Y_1^0 | D = 1, X) - E(Y_0^0 | D = 1, X) = E(Y_1^0 | D = 0, X) - E(Y_0^0 | D = 0, X)$$

This equation indicates that if there were no treatment, the treated and untreated groups ($D = 1$ and $D = 0$) would show the same time trend given observed covariates X , which are assumed not to vary over time (Lechner 2011). Thus, the difference in the trend between the observed outcomes with treatment and those without treatment would be attributed to the treatment effect, not to the differences in any covariate between the treatment and control groups (Lechner 2011). This is the main idea of the DID approach to attain identification by calculating the difference between the average outcome of treatment and control groups after the treatment and subtracting the difference of the outcomes that existed before the treatment (Lechner 2011).

Financial Panel Data Models, Strict Versus Contemporaneous Exogeneity, and Durbin-Wu-Hausman Specification Tests

78

Robert H. Patrick

Abstract

Panel data, pooling cross-sectional and time series data, is increasingly used in estimating financial models. This chapter presents estimators for pooled, fixed effects (FE), and random effects (RE) linear panel data models, assumptions on which they are based, particularly contemporaneous and strict exogeneity assumptions on the explanatory variables, and model specification testing (DWH and Wooldridge tests). Implications of estimator and specification choice on parameter consistency and standard error efficiency are developed. The relationship between the approaches, choice of approach, and their advantages and disadvantages are discussed. Examples illustrate application of the estimators and tests, applying the concepts and testing specifications to illustrate their use and interpretation.

78.1 Introduction

Omitted variables are a common cause of endogeneity in estimation of empirical finance models (e.g., Giglio and Xiu 2021). Panel data, combining time series on each cross-sectional entity in the sample, presents an opportunity to model unobserved

R. H. Patrick (✉)

Professor Emeritus, Finance and Economics, Rutgers University, Newark, NJ, USA

e-mail: rpatrick@business.rutgers.edu

heterogeneity that may exist across cross section and time, potentially providing approaches to obtain unbiased and/or consistent parameter estimates. Consider CEO compensation for example. An observed variable such as compensation may be correlated with an unobserved (to the econometrician) variable such as effort or ability, which implicitly enters the model through an individual specific effect. Panel data approaches allow us to model such unobserved heterogeneity and reduce or eliminate omitted variables problems. Chang and Lee (1977) provide an early example.

Using panel data, rather than only cross-sectional or time series data, provides a number of additional potential benefits, including a larger sample size (which is also an approach to ameliorating multicollinearity problems and to increase the precision of our estimates). Panel data also allow consideration of two dimensions, time series and cross section, providing greater flexibility in identifying the data generating process (DGP). An example is to distinguish technological change, a time series notion, from economies of scale, a cross-sectional notion. A cross section might inaccurately estimate the effect of increasing capital, while panel time series components can be used to incorporate the impact of technical change. Finally, we can also relax constant parameter assumptions using panel data estimation techniques (as simply as by interacting effects with explanatory variables).

Often maintained, but rarely tested in financial panel data models are the contemporaneous and strict exogeneity assumptions.¹ Violations of either or both of these assumptions imply parameter estimates will be inconsistent, standard errors will be inefficient, and the usual hypothesis tests will no longer be valid. The CEO compensation example above is a contemporaneous issue. In addition, the strict exogeneity concern in financial models is primarily about potential correlation between a current dependent variable and future values of explanatory variables. According to Grieser and Hadlock (2019), the majority of published research applying panel modeling techniques in the top three finance journals use the fixed effects model and only one article (out of 216) provided any test of strict exogeneity.² Although violation of contemporaneous and strict exogeneity may be prevalent in financial panel data estimation, these issues with consistent parameter estimation have largely been implicitly assumed away. This is not to imply that these papers have presented inconsistent estimates, but these assumptions can be tested rather than maintained when there is any question regarding the endogeneity of any of the explanatory variables.

In this chapter, the basic approaches to linear (in parameters) panel data model specification, estimation, and testing are introduced, and examples of their application are provided to show how results are interpreted.³ First, we define exogeneity, strict

¹Any panel data model with a lagged dependent variable as an explanatory variable and cross-sectional unobserved effects will by specification violate strict exogeneity.

²The three journals Grieser and Hadlock (2019) searched were the *Journal of Finance*, *Journal of Financial Economics*, and the *Review of Financial Studies* from 2006 to 2013, with an updated search of the *Journal of Finance* for 2017.

³Linear is used here to imply that parameters to be estimated enter the model linearly, rather than in a nonlinear fashion. The techniques covered here are applicable to nonlinear in variables models, but not nonlinear in parameters models.

exogeneity, and endogeneity, and discuss their implications for unbiased and consistent parameter estimation in the next section. Sections that follow then provide the fundamental assumptions and considerations in estimating and specification testing panel data models. Pooled least squares (LS), fixed effects (FE), and random effects (RE) are considered. Sections following the specification and estimation of panel models provide tests for contemporaneous and strict exogeneity. Durbin-Wu-Hausman (DWH) type tests can accomplish both, but Wooldridge's (2010) strict exogeneity tests are also discussed and applied. Empirical applications are then provided illustrating the modeling issues, valid application, and interpretation of DWH tests, and estimation approaches to address contemporaneous and strict endogeneity issues.

78.2 Exogeneity, Strict Exogeneity, and Endogeneity

Consider a linear (in parameters) panel model

$$y_{it} = X_{it}\beta + \varepsilon_{it}, i = 1, \dots, N, t = 1, \dots, T \quad (1)$$

and

$$\varepsilon_{it} = u_t + v_i + e_{it} \quad (2)$$

where X_{it} is a $1 \times k$ vector of explanatory variables, β is a $k \times 1$ vector of parameters, ε_{it} is the composite error potentially comprised of components u_t for the time effect t , v_i for the cross-sectional effect i , and the common error, e_{it} , that affect cross-section i at time t . It is generally assumed that the u_t , v_i , and e_{it} are independent across all t , i , and it , respectively.

There are a number of potential violations with the specified model. Constant parameters may be overly restrictive, perhaps they should be specified as random variables, or a nonlinear in parameters model may better explain the data generating process. Unless we are working with experimental data (as in Example 1 below), we cannot generally expect all the explanatory variables to be deterministic. In fact we should not expect this with the usual type of data used in most empirical finance and economics models. The issue is that stochastic explanatory variables may be related to the errors, leading to parameter bias and inconsistency.

Any explanatory variable in the model that is contemporaneously correlated with the error is termed endogenous, regardless of the source of the correlation. Sources of endogeneity in econometrics are typically omitted variables, measurement error, simultaneity, and of selection. If there is no correlation between the explanatory variable and the error at any time, then the explanatory variable is (contemporaneously) exogenous. If there is no correlation between the explanatory variable and the error in any other period, $t = 1, \dots, T$, then the variable is strictly exogenous.⁴

⁴See Engle, Hendry, and Richard (1983) for additional detail. Often exogenous is used to imply strict exogeneity (e.g., Davidson and MacKinnon 2004).

More formally, contemporaneous exogeneity implies

$$E(e_{it}|X_{it}, u_t, v_i) = 0 \quad \forall i = 1, \dots, N; t = 1, \dots, T, \quad (3)$$

i.e., the error for cross-section i at time t is not correlated with any contemporaneous explanatory variable or effect. If only the parameters associated with the X explanatory variables are of interest with can drop the cross-sectional and time effects from the conditional. A stronger assumption than (3) is strict exogeneity, which implies

$$E(e_{it}|X_{is}, u_t, v_i) = 0 \quad \forall i = 1, \dots, N, s, t = 1, \dots, T, \quad (4)$$

or, more succinctly in vector/matrix form,

$$E(e|X, u, v) = 0. \quad (5)$$

That is, the error at each point in time is not correlated with any contemporaneous, lead, or lag of any of the explanatory variables, for all observations. This is usually implicitly maintained. This latter assumption, (4), may be violated when, e.g., high (or low) realizations of the dependent variable (e.g., firm performance) at time t have a positive or negative impact on future values of an explanatory variable (e.g., managerial ownership). Correlation between the current y_{it} and future values of explanatory variables is a potentially prevalent strict exogeneity issue in financial panel data modeling that is critical to consistent parameter estimation in these models.⁵

78.3 Linear Panel Data Models and Pooled LS Estimation

Consider the linear (in parameters) population model

$$y_{it} = \beta_0 + X_{it}\beta + e_{it}, i = 1, \dots, N, t = 1, \dots, T \quad (6)$$

where β_0 is the common constant term, X_{it} is a $1 \times k$ vector of explanatory variables, β is a $k \times 1$ vector of parameters associated with the explanatory variables, and e_{it} is the error. Stacking each cross section of time series data and including a common constant term leads to

$$\begin{pmatrix} y_{11} \\ \vdots \\ y_{1T} \\ y_{21} \\ \vdots \\ y_{NT} \end{pmatrix} = \begin{pmatrix} 1 & x_{111} & \cdots & x_{k11} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_{1NT} & \cdots & x_{kNT} \end{pmatrix} \begin{pmatrix} \beta_0 \\ \beta_1 \\ \vdots \\ \beta_k \end{pmatrix} + \begin{pmatrix} e_{11} \\ \vdots \\ e_{NT} \end{pmatrix}. \quad (7)$$

⁵Strict exogeneity may also be an issue in time series models.

Given that the data is ordered so that all observations of the first cross section appear first, etc. for $i = 1, \dots, N$, then the row corresponding to observation it is row $T(i - 1) + t$. Equation (7) implies that there is a common constant term across all cross sections through time, a critical difference in pooled LS compared to FE and RE models. In matrix notation, keeping the constant and slope parameters separate, (7) can be expressed more concisely in vector/matrix notation as

$$y = \beta_0 + X\beta + e, \quad (8)$$

where y and e are NT vectors, X is a $NT \times k$ matrix, β_0 is a constant term common to the entire sample, and β is a $k \times 1$ vector of slope parameters.

The analysis presented here is for a random sample of cross sections of data (e.g., firms, portfolios, individuals, etc.), $i = 1, \dots, N$, over time, $t = 1, \dots, T$, providing NT total observations.⁶ It is assumed for now that the panel is balanced, i.e., there are the same number of time series observations for all cross sections in the sample. Unbalanced panel data is addressed in Sect. 78.7. The econometric methods presented here, unless otherwise stated, are for panel data with a large number of cross sections relative to the number of time series per cross section, i.e., $N > T$. For panel data models, the cross section is assumed to be a random sample, as with cross-sectional data, but, since we should generally expect variables to be correlated over time, correlation across time is relatively unrestricted. Random implies we can collect a sample of independent and identically distributed cross sections of the underlying population of interest.

In addition to the population model and random sampling assumptions above, we need to estimate the parameters and their standard errors. There are four primary pooled LS assumptions that are key to consistent estimation of parameters and efficient estimation of standard errors. These assumptions are also stated in terms of the population model. Some of these pooled LS assumptions apply and some need to be modified for the FE and RE models later in this chapter.

Assumption P1: Strict exogeneity, $E(e_{it}|X_{is}) = 0$ for all i, s , and t .

Another way to state this assumption that may be more informative in the context of financial panel data modeling is

$$E(y_{it}|x_{i1}, \dots, x_{iT}) = E(y_{it}|X_{it}) = \beta_0 + X_{it}\beta, \text{ for } t = 1, \dots, T. \quad (9)$$

because it is easy to see that strict exogeneity implies that, controlling for X_{it} , X_{is} has no effect on y_{it} for all $s \neq t$, $s, t = 1, \dots, T$.

The key assumption for consistent pooled LS parameter estimation is the population moment (or orthogonality) condition

⁶If the error term for cross-sect. i , conditional on the explanatory variables, is independent of being selected into the sample, random can be relaxed (random is actually a stronger assumption than is needed).

$$E(X'e) = 0, \quad (10)$$

i.e., the error has zero mean and is uncorrelated with each of the explanatory variables in the population. If X includes a constant, let $X_1 = 1$, then (10) implies

$$E(X_1e) = E(e) = 0 \text{ and } \text{cov}(X_j, e) = 0 \text{ for all } j = 2, \dots, K. \quad (11)$$

Sufficient but not necessary for (10) and (11) is the zero conditional mean assumption

$$E(e|X) = 0, \quad (12)$$

and the expected error term has a conditional mean of zero. This implies that the unconditional mean of the error term is zero, $E(e) = 0$ (a special case of the Law of Iterated Expectations), and that e is not correlated with any X or function of any X at any time, $t = 1, \dots, T$, the function of being the much stronger of the two.

Example: Suppose our population model is

$$y = \beta_1 + \beta_2 x_2 + \beta_3 x_3 + e, \quad E(e|x_2, x_3) = 0, \quad (13)$$

then

$$E(e) = 0, \text{cov}(X_2, e) = 0, \text{cov}(X_3, e) = 0. \quad (14)$$

Equation (13) includes the strict exogeneity assumption, which implies that e is uncorrelated with any other function of the X variables, e.g., X_2X_3 , X_2^2 , X_3^2 , etc., so that all effects of X_2 and X_3 on the expected value of y are included in estimating the parameters. If (13) holds, then we have consistently measured the partial effects of a variable when we differentiate y with respect to an X variable. For example, if strict exogeneity holds, $E(e|X) = 0$, with the linear in parameters model then, e.g., $\partial E(y|X)/\partial X_2 = \beta_2$. That is, we have an appropriate functional form specification conditional on the X variables included in the specified model. Equation (13) is a stronger assumption than the contemporaneous correlation represented in (14), the latter leaves open the possibility that e is correlated with nonlinear functions of the variables.

Assumption P1 and the additional pooled LS assumptions below assure that we can identify and consistently estimate the pooled model parameters, with efficient standard errors.

Assumption P2: Explanatory variables are nonstochastic or bounded, i.e., the trace norm of X_{it} , $\|X_{it}\| < K < \infty$ or satisfy moment conditions $E\left\|(x_{it} - \bar{x})(x_{js} - \bar{x})'\right\| < K < \infty \forall i, j, s, t$, where $\bar{x} = \sum_{t=1}^T \sum_{N=1}^N x_{it}/NT$. This assumption can be relaxed to include trend or unit root processes. Explanatory variables that are nonstochastic or deterministic will naturally be strictly exogenous.

Assumption P3: The $k \times k$ matrix

$$Q_{P,NT} = \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T (x_{it} - \bar{x})(x_{it} - \bar{x})' \quad (15)$$

is positive definite for all N and T as $N \rightarrow \infty$.⁷ Since $E(X'X)$ is a $k \times k$ symmetric matrix, this is the same as assuming that the rank $[E(X'X)] = k$. Perfect multicollinearity violates this condition. To avoid a violation of this assumption, eliminate any linear combinations of data in X .

Assumption P4: The errors e_{it} are independent cross-sectionally and may be heteroskedastic cross-sectionally and correlated across time,

$$E(e_{it}^2|X) = \sigma_i^2 < K < \infty, \quad (16)$$

$$E(e_{it}e_{js}|X) = 0 \text{ if } i \neq j \forall s, t = 1, \dots, T, \quad (17)$$

and

$$E(e_{it}e_{is}|X) = \sigma_i(s, t), \text{ for } s \neq t, \quad (18)$$

where the bounded error process e_{it} has autocovariances $\sigma_i(s, t)$. If T is fixed and $N > T$, then restrictions on the autocovariances are not necessary.

If $E(e_{it}|X_{it}) = 0$ for all $i = 1, \dots, N$ and $t = 1, \dots, T$ (i.e., assumption P1 holds), then (6) can be estimated by LS, which will be efficient if the e_{it} are independently and identically distributed. The pooled LS parameter estimates are obtained by minimizing the sum of squared errors, $e'e$, to find

$$\hat{\beta}_{LS} = \left[\sum_{t=1}^T \sum_{i=1}^N (X_{it} - \bar{x})(X_{it} - \bar{x})' \right]^{-1} \left[\sum_{t=1}^T \sum_{i=1}^N (X_{it} - \bar{x})(y_{it} - \bar{y})' \right], \quad (19)$$

where the sample means are

$$\bar{y} = \sum_{t=1}^T \sum_{i=1}^N y_{it}/NT \text{ and } \bar{x} = \sum_{t=1}^T \sum_{i=1}^N x_{it}/NT.$$

Using (15), the variance of $\hat{\beta}_{LS}$ is given by

$$\text{var}(\hat{\beta}_{LS}|X) = Q_{P,NT}^{-1} \left[\frac{1}{N^2 T^2} \sum_{i=1}^N \sum_{j=1}^N \sum_{t=1}^T \sum_{s=1}^T E(e_{it}e_{js}|X)(x_{it} - \bar{x})(x_{jt} - \bar{x})' \right] Q_{P,NT}^{-1} \quad (20)$$

⁷More precisely, as N and/or $T \rightarrow \infty$.

Applying Assumption P4 to substitute for $E(e_{it}e_{js}|X)$ in (20), the pooled LS variance can be expressed as

$$\begin{aligned} \text{var}(\hat{\beta}_{LS}|X) &= Q_{P,NT}^{-1} \left[\sum_{i=1}^N \sum_{t=1}^T \sigma_i^2 (x_{it} - \bar{x})(x_{it} - \bar{x})' \right] Q_{P,NT}^{-1} \\ &\quad + Q_{P,NT}^{-1} \left[\sum_{i=1}^N \sum_{t \neq s}^T \sigma_i(s, t) (x_{it} - \bar{x})(x_{it} - \bar{x})' \right] Q_{P,NT}^{-1}, \end{aligned} \quad (21)$$

where $\sigma_i(s, t)$ are the autocovariances for the pooled LS estimator. Although the pooled LS parameter estimates may be consistent, the standard errors will be inefficient and likely underestimated. See Pesaran (2015) for additional detail.

β is identified with Assumptions P1 and P3 in the population model (6).

Consistency implies that, if our sample is large enough, the estimator produces an estimate that is close to the population parameter with high probability. Precisely, with a sample of size N , let $\hat{\beta}_N$ be an estimator of the population β . Then $\hat{\beta}$ is a consistent estimator of β if

$$\lim_{N \rightarrow \infty} P(|\hat{\beta}_N - \beta| < \varepsilon) = 1, \quad (22)$$

where ε is positive and arbitrarily small. So the probability that $\hat{\beta}_N$ falls in the interval $[\beta - \varepsilon, \beta + \varepsilon]$ can be made arbitrarily close to 1 with a sufficiently large sample size, regardless of the smallness of ε . If (22) is true, then the sequence of random variables $\hat{\beta}_N$ converges in probability to β and the probability limit of $\hat{\beta}_N$, abbreviated as

$$\text{plim}(\hat{\beta}) = \beta.$$

To summarize consistency of pooled LS: given a random sample of the population (6), Assumptions P1 and P3 imply that $\text{plim}(\hat{\beta}) = \beta$, i.e., $\hat{\beta}$ is a consistent estimator of β . See Greene (2018) and Pesaran (2015) for additional detail. Under assumptions P1 and P3, pooled LS parameters are identified and parameter estimates are unbiased and consistent if $E(e|X) = 0$, that is, if the X are strictly exogenous. If $E(e|X) \neq 0$, then pooled LS is biased and inconsistent. This will be the case if, e.g., X_{it} contains lagged dependent variables and the e_{it} are autocorrelated, or if y_{it} is correlated with future values of any of the explanatory variables.

Concerning efficiency of the estimator, it is unlikely that the errors are independently and identically distributed given panel data is being analyzed because shocks affecting cross-section i for all $t = 1, \dots, T$ imply correlation between e_{it} and e_{is} for all $t \neq s$, and shocks affecting all cross-sections $i = 1, \dots, N$ at a particular t imply correlation between e_{it} and e_{jt} for all $i \neq j$. So even if strict exogeneity holds and we have consistent parameter estimates, LS applied to panel data (the pooled LS estimator) is likely to produce inefficient standard errors (generally too small) due

to an inconsistent estimate of the covariance matrix. See Example 1 below for an illustration and discussion of these points.

78.4 Unobservable Heterogeneity

To estimate the panel data model, the unobserved heterogeneity, the u_t and v_i , are specified as FE, RE, or mixed. So the effects are captured as explanatory variables or error components. FE parameters on the X variables can be estimated using group dummy variables or by group mean differencing the data and applying least squares (LS). Including the group dummy variables as X variables is required to estimate parameters on the effects. If effects are specified as random, the random effects covariance matrix is specified as functions of the variances of the u_t and/or v_i , and e_{it} . Feasible generalized least squares (FGLS), maximum likelihood (ML), or generalized method of moments (GMM) could be used for estimation.

Joint hypothesis tests of the fixed effects can be carried out with an F-test. For random effects, a large sample test is required so a Wald, Likelihood Ratio (LR), or Lagrange multiplier (LM) test could be applied.

A Durbin, Wu, Hausman (DWH) test can be used to choose between the FE or RE specification of the panel model. If the effects are correlated with the explanatory variables, then RE will be inconsistent. Another form of DWH test can be used to test strict exogeneity, as can some other tests developed in Wooldridge (2010).

78.5 Fixed Effects (FE) Models

While empirical examples below will contain both cross section and time effects, we will mostly abstract from the time effects in the theoretical development. So to simplify the exposition, let $u_t = 0$ in the error components specification (2). This implies that we are considering shocks specific to the cross section but no time-specific shocks for now. The model is then

$$y = X\beta + D\gamma + e = X\beta + \sum_{i=1}^N \gamma_i D_i + e, E(ee') = \sigma_e^2 I_{NT}, \quad (23)$$

where y and e are NT vectors and D is a $NT \times N$ matrix of dummy variables such that the element in the row corresponding to observation it , for $i = 1, \dots, N$ and $t = 1, \dots, T$, and column j , for $j = 1, \dots, N$, is equal to 1 if $i = j$ and 0 otherwise. The parameter vector γ measures the affects of the *fixed effects*, v_i . The N vector γ has typical elements v_i since the NT vector $D\gamma$ has v_i in the row corresponding to observation it . Therefore there is exactly one element of D equal to 1 in each row, implying that the NT vector i with each element equal to 1 is a linear combination of the columns of D . They may be correlated with the X variables but have to be independent of the errors e_{it} .

The FE assumptions for consistent β parameter estimation with efficient standard errors are the same as the pooled LS assumptions P1 and P4, but assumptions P2 and P3 must be revised to account for the panel nature of the data as follows.

Assumption FE2 Explanatory variables are nonstochastic or bounded, i.e., the trace norm of X_{it} , $\|X_{it}\| < K < \infty$ or satisfy moment conditions $E\left\|(x_{it} - \bar{x}_i)(x_{js} - \bar{x}_j)'\right\| < K < \infty \forall i, j, s, t$, where $\bar{x}_i = \sum_{t=1}^T x_{it}/T$.

Assumption FE3

$$Q_{FE,NT} = \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T (x_{it} - \bar{x}_i)(x_{it} - \bar{x}_i)' \quad (24)$$

is a $k \times k$ positive definite matrix for all N and T as $N \rightarrow \infty$.

If the parameters associated with the fixed effects are of interest, consistent estimation of the fixed effects parameters associated with v_i in the FE model, pooled LS assumption P1 would be revised as follows.

Assumption FE1 Strict exogeneity, $E(e_{it}|X_i, v_i) = 0$, for all i, s , and t .

The LS estimator for the FE model is unbiased if X and D are strictly exogenous (if there is no contemporaneous correlation between explanatory variables and the error term). If these assumptions hold, the FE estimator is BLUE (i.e., the Gauss-Markov Theorem holds). Usually these parameters are treated as nuisance parameters. Consistent estimation of the parameters associated with the explanatory variables X is usually the research interest.

The fixed effects model (23), conditionally on γ , satisfy these moment conditions:

$$E(X'_{it}(y_{it} - X_{it}\beta - v_i)) = 0 \text{ and } E(y_{it} - X_{it}\beta - v_i) = 0. \quad (25)$$

From Frisch and Waugh (1933) and Lovell (1963), we have what is known as the Frisch-Waugh-Lovell Theorem, which demonstrate that the FE estimates of β in (23) can be obtained using LS to regress $M_D y$, the errors from a regression of y on D , on $M_D X$, the matrix of errors from regressing each column of X on D . For any NT vector x , the cross-sectional or group mean is $\bar{x}_i = \frac{1}{T} \sum_{t=1}^T x_{it}$. A straightforward check of element it of the matrix $M_D X$ reveals that it is equal to the deviation from the group mean, $x_{it} - \bar{x}_i$. That is, the fixed effects estimates of parameters, β , associated with the explanatory variables X , can be obtained by transforming the data by group-mean differencing, and using the pooled LS estimator in the following regression:

$$\left(y_{it} - \sum_{t=1}^T \frac{y_{it}}{T}\right) = \sum_{h=1}^K \beta_j \left(x_{hit} - \sum_{t=1}^T \frac{x_{hit}}{T}\right) + \left(e_{it} - \sum_{t=1}^T \frac{e_{it}}{T}\right). \quad (26)$$

In the linear (in parameters) FE model, the sufficient statistic is the group mean (a statistic is called sufficient for a parameter if the distribution of the sample given i does not depend on the parameter). This is referred to as the within-groups estimator because it uses only information on the variation around the mean of each of the N groups. The LS FE parameter estimates are then given by

$$\begin{aligned}\hat{\beta}_{FE} &= \left[\sum_{t=1}^T \sum_{i=1}^N (X_{it} - \bar{x}_i)(X_{it} - \bar{x}_i)' \right]^{-1} \left[\sum_{t=1}^T \sum_{i=1}^N (X_{it} - \bar{x}_i)(y_{it} - \bar{y}_i)' \right] \\ &= \left(\sum_{i=1}^N X_i' M_T X_i \right)^{-1} \left(\sum_{i=1}^N X_i' M_T y_i \right)\end{aligned}\quad (27)$$

where the group (cross section) means are $\bar{y}_i = \sum_{t=1}^T y_{it}/T$ and $\bar{x}_i = \sum_{t=1}^T x_{it}/T$, and M_T is a projection matrix defined analogously to M_D above. The fixed effect parameters γ_i can be estimated using the specified model with (27) and the FE assumptions,

$$\hat{\gamma}_i = \bar{y}_i - \bar{\beta}_{FE}' \bar{x}_i. \quad (28)$$

Using assumptions P1 and FE3, it is straightforward to show that the FE LS estimator of $\hat{\beta}$ is unbiased, i.e., $E(\hat{\beta}_{FE}) = \beta$.

The variance of $\hat{\beta}_{FE}$ is given by

$$\text{var}(\hat{\beta}_{FE}|X) = (1/NT) Q_{FE,NT}^{-1} \left[\frac{1}{NT} \sum_{i=1}^N \sum_{j=1}^N X_i' M_T E(e_i e_j' | X) M_T X_j \right] Q_{FE,NT}^{-1}. \quad (29)$$

Equation (29) can be simplified further using assumption P4 to substitute for $E(e_i e_j' | X)$. See Pesaran (2015) for details and the derivation of a number of other results in the literature that can be derived from here.⁸

An advantage of the FE estimator that has made it so popular is that it is relatively easy to compute. If parameters associated with the dummy variables D are not of interest, then there is no need to estimate the fixed effects parameters, all that is needed is to compute the N group means for all variables and transform the data by subtracting the appropriate mean from the observation. That is, specification of the dummy variables for the fixed effects is required only if estimates of $\hat{\gamma}$ are of interest. Multicollinearity may be an issue in precisely separating the individual effects. If the X variables are well explained by the dummy variables in D , then β will not be

⁸These other results in the literature are beyond the scope of this chapter so are not covered further here. Pesaran (2015), Chamberlain (1984), Cameron and Trivedi (2005), Wooldridge (2010), Hsiao (2014), Greene (2018), and Baltagi (2021) provide detail.

precisely estimated with FE, due to the correlation between X and D . Exact multicollinearity prohibits some specifications such as those with explanatory variables that are constant for each cross section since such a variable would be perfectly collinear with the columns of dummy variables, D (see Application 1 below for an example).

78.6 Random Effects (RE) Models

The efficiency of the FE estimator can be improved by applying the RE estimator, but only if the X and v_i are independent. As discussed above, what is required with the FE model is that the e_{it} are independent of X and v_i (and u_t if time effects are also specified in the model). Contrary to the FE model, RE allows estimation of parameters associated with variables that are fixed across the cross section, as discussed in the previous section of this chapter.

The RE assumptions for consistent parameter estimation with efficient standard errors are:

Assumption RE.1 Strict exogeneity implies the error is conditional on the explanatory variables X and the effects, $E(e_{it}|X_i, v_i) = 0$, and the random effects are constant through time and independent of the explanatory variables X_i , $E(v_i|X_i) = 0$, for all i and t .

Assumption RE.2 $E(e_i e_i' | X_i, v_i) = \sigma_e^2 \mathbf{I}_T$ and $E(v_i^2 | X_i) = \sigma_v^2$, for all $i = 1, \dots, N$.

Assumption RE.3 $\sum_{i=1}^N X_i' \Sigma^{-1} X_i$ is a nonsingular matrix for all N and T as $N \rightarrow \infty$.

RE is not consistent if the random effects are correlated with the X variables. For example, consider a panel of observations on CEO pay, an observed variable like compensation may be correlated with an unobserved (to the econometrician) variable such as effort or ability, which implicitly enters the individual specific error v_i . If this individual effect, an error component with RE, is correlated with variables explaining CEO compensation, then their associated parameter estimates will be inconsistent.

If X and v_i are independent then

$$E(e_{it}|X_{it}) = E(v_i + e_{it}|X_{it}) = 0 \quad (30)$$

since e_{it} is also independent of X . Condition (30) implies that the pooled LS model, (6), provides unbiased parameter estimates (see Example 1 below). However, LS estimation of the pooled panel model is unlikely to be efficient because the e_{it} are not independently and identically distributed. The covariance matrix of the e_{it} can be computed if the v_i are $iid(0, \sigma_v^2)$, so the name “random effects.” From the error

components, $\varepsilon_{it} = u_t + v_i + e_{it}$, assuming shocks are independent for simplicity and $u_t = 0$, it follows that

$$\begin{aligned}\text{Var}(\varepsilon_{it}) &= \sigma_v^2 + \sigma_e^2 \\ \text{Cov}(\varepsilon_{it}\varepsilon_{jt}) &= \sigma_v^2 \text{ for all } t \text{ and } i \neq j, \\ \text{Cov}(\varepsilon_{it}\varepsilon_{js}) &= 0 \text{ for all } i, j \text{ and } t \neq s,\end{aligned}\quad (31)$$

define the elements of the $NT \times NT$ covariance matrix, Ω , needed for GLS estimation. Assumptions in (31) allow heteroskedasticity and contemporaneous correlation between the errors across the cross sections, but rule out autocorrelation, i.e., there are no lagged correlations between the errors. If the data are ordered by the N cross-sectional units in groups of T observations each (assuming a balanced panel), the matrix has the form

$$\Omega = E(ee') = I_N \otimes \Sigma = \begin{bmatrix} \Sigma_1 & 0 & \cdots & 0 \\ 0 & \Sigma_2 & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & \Sigma_N \end{bmatrix} \quad (32)$$

where

$$\Sigma_i \equiv \begin{bmatrix} \sigma_e^2 + \sigma_v^2 & \sigma_v^2 & \cdots & \sigma_v^2 \\ \sigma_v^2 & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \sigma_v^2 \\ \sigma_v^2 & \cdots & \sigma_v^2 & \sigma_e^2 + \sigma_v^2 \end{bmatrix} = \sigma_e^2 \mathbf{I}_T + \sigma_v^2 \mathbf{i}\mathbf{i}' \quad (33)$$

is a $T \times T$ matrix with $\sigma_e^2 + \sigma_v^2$ on the principal diagonal and σ_v^2 elsewhere, and $\mathbf{i}$ is a T -vector of ones.

Estimation of β using GLS requires Ω to be consistently specified at least to a factor, so a consistent estimate the ratio of σ_e^2 to σ_v^2 in order to obtain a consistent estimate of $\hat{\Omega}$. The feasible GLS parameter estimates are then given by

$$\hat{\beta}_{RE} = \left(\sum_{i=1}^N X_i' \hat{\Omega}^{-1} X_i \right)^{-1} \left(\sum_{i=1}^N X_i' \hat{\Omega}^{-1} y_i \right) = (X' \hat{\Omega}^{-1} X)^{-1} X' \hat{\Omega}^{-1} y \quad (34)$$

with variance

$$\text{var}(\hat{\beta}_{RE}) = \left(\sum_{i=1}^N X_i' \hat{\Omega}^{-1} X_i \right)^{-1} = (X' \hat{\Omega}^{-1} X)^{-1}, \quad (35)$$

where the parameter standard errors are given by the square root of the diagonal elements of (35).

A consistent estimate of σ_e^2 can be found by estimating the FE model (23) because there are NT residuals regardless of how N and T behave as $NT \rightarrow \infty$. Dividing the FE sum of squared errors SSE_{FE} from (23) by $NT - N - K$ provides an unbiased and consistent estimate of σ_e^2 since the error terms for this model are just the e_{it} . But the natural estimator of σ_v^2 , the sample variance of the elements of $\hat{\gamma}$ is not consistent unless $N \rightarrow \infty$.

If $NT \rightarrow \infty$ as $N \rightarrow \infty$, σ_v^2 can be estimated consistently. Start with the regression

$$P_D y = P_D X \beta + \text{residuals}, \quad (36)$$

where $P_D \equiv I - M_D$ and the projection matrix $M_D \equiv I - D(D'D)^{-1}D'$. The between-groups estimator is then

$$\hat{\beta}_{BG} = (X'P_DX)^{-1}X'P_D y, \quad (37)$$

which is based on only N observations since all variables are the same for every observation in each group. It only exists if $N > K$ because the matrix $X'P_DX$ can have at most rank N . It is called the between estimator because it uses only the variation among the group means.

If the assumptions of the random effects model are violated, the $\hat{\beta}_{BG}$ estimator, if it exists, is in general biased and inconsistent. To see this, unbiased and consistent parameter estimates require that the moment condition

$$E((P_DX)'_{it}(y_{it} - X_{it}\beta)) = 0. \quad (38)$$

$(P_DX)_{it}$ is the row labeled it of the $NT \times K$ matrix P_DX . Since $y_{it} - X_{it}\beta = v_i + e_{it}$ and e_{it} are independent of everything else in (38), this condition is equivalent to no correlation between the v_i and elements of the X matrix.

The variance of the error terms in the between group regression, (36), is $\sigma_v^2 + \sigma_e^2/T$. Therefore, if we estimate the regression with N observations, divide the resulting sum of squared errors by $N - K$, and then subtract σ_e^2/T , we obtain a consistent estimate of σ_v^2 . If this estimate is negative, the RE model should probably not be estimated, but Greene (2018), for example, provides detail on alternative methods for estimation the covariance components.

The feasible GLS estimator for the RE parameters is matrix-weighted averages of the within-groups (FE) and the between-groups estimators. Fuller and Battese (1973, 1974) show that the GLS estimator of the RE model can be obtained by using LS with the transformed data, i.e.,

$$(I - \lambda P_D)y = (I - \lambda P_D)X\beta + \text{residuals} \quad (39)$$

where the scalar

$$\lambda \equiv 1 - \left(\frac{T\sigma_v^2}{\sigma_e^2} + 1 \right)^{-1/2} = 1 - \left(\frac{\sigma_e^2}{T\sigma_v^2 + \sigma_e^2} \right)^{1/2} \quad (40)$$

and the consistent variance estimators developed above are used in (40). This provides a convenient way to compare the pooled LS, FE, and RE models. The RE GLS estimator is more efficient than the FE and pooled LS estimators as long as $\lambda \in (0, 1)$. If $\lambda = 0$, then the estimator is equivalent to pooled LS, and if $\lambda = 1$, then the FE (within-groups) estimator. Note that the LS estimator on the pooled data can be expressed as the weighted sum of the between and within estimators developed above, i.e.,

$$\begin{aligned}\hat{\beta} &= (X'X)^{-1}X'Y = (X'X)^{-1}(X'M_DY + X'P_DY) \\ &= (X'X)^{-1}X'(M_DX\hat{\beta}_{FE} + P_DX\hat{\beta}_{BG}).\end{aligned}\quad (41)$$

78.7 Balanced Versus Unbalanced Panel Data

The above developments above assume a balanced panel (each cross section has the same number of time series). The FE model requires no adjustment for unbalanced panels other than the appropriately defined D matrix (i.e., each column of D will no longer have the same number of 1's). However, estimation of the RE model does require more than straightforward revision to account for the unbalanced nature of the data. If the panel is unbalanced, (40) becomes

$$\lambda_i \equiv 1 - \left(\frac{T_i \sigma_v^2}{\sigma_e^2} + 1 \right)^{-1/2} \quad (42)$$

where T_i is the number of observations in the i^{th} cross-section. Naturally, the group means are based on the different numbers of observations in each cross section. LS is then used on this transformed data:

$$\begin{pmatrix} y_1 - \lambda_1 \bar{y}_1 \\ \vdots \\ y_N - \lambda_N \bar{y}_N \end{pmatrix} = \begin{pmatrix} X_1 - \lambda_1 \bar{X}_1 \\ \vdots \\ X_N - \lambda_N \bar{X}_N \end{pmatrix} \begin{pmatrix} \beta_1 \\ \vdots \\ \beta_k \end{pmatrix} + \text{residuals} \quad (43)$$

where $\bar{y}_i$, a vector of size T_i , is the mean of the elements of y_i and $\bar{X}_i$, a $T_i \times k$ matrix whose elements are the mean of the corresponding column X_i . Equation (43) simplifies to (39) if the panel is balanced.

78.8 Durbin-Wu-Hausman (DWH) Tests

Durbin (1954), Wu (1973, 1974), and Hausman (1978) developed specification tests to compare parameters of alternative estimators. These types of tests are used for many purposes, e.g., to choose between alternative estimators of a model (e.g., FE versus RE here), and to test alternative theoretical models (Chermak and Patrick

2001). See, for example, Patrick (2021) for details and examples of alternative applications. Here we are primarily concerned with using a DWH test to choose between the FE and RE models.

The DWH test is based on vectors of contrasts of parameters and variances. In general, consider two estimators providing parameter vectors $\hat{\theta}$ and $\tilde{\theta}$ and testing

$$H_0 : \text{plim}(\hat{\theta} - \tilde{\theta}) = 0 \text{ vs. } H_A : \text{plim}(\hat{\theta} - \tilde{\theta}) \neq 0.$$

Under the null hypothesis, if the difference between the root- T consistent estimators is root- T consistent, then it converges in distribution with mean $\mathbf{0}$ and limit normal distribution

$$\sqrt{T}(\hat{\theta} - \tilde{\theta}) \xrightarrow{d} N[\mathbf{0}, \Omega(\hat{\theta} - \tilde{\theta})],$$

where $\Omega(\hat{\theta} - \tilde{\theta})$ is the contrast in variance-covariance matrices in the limiting distribution. The DWH test statistic is then given by

$$m = (\hat{\theta} - \tilde{\theta})' \left(\frac{\Omega(\hat{\theta} - \tilde{\theta})}{T} \right)^{-1} (\hat{\theta} - \tilde{\theta}) \stackrel{a}{\sim} \chi^2(q). \quad (44)$$

That is, m is asymptotically distributed $\chi^2(q)$ under the null with degrees of freedom q , the number of parameters (associated with potential endogenous variables) being compared across the two models considered. The null hypothesis is rejected if $m > \chi^2_{\alpha}(q)$, where the level of statistical significance is indicated by α .

For example, in the context of instrumental variables, if the original X variables are valid instruments (i.e., not correlated with the contemporaneous error), then the LS estimator is consistent and preferred to the IV estimator with other valid instruments. Since both would then have the same probability limit, both provide consistent parameter estimates so the preference between the estimators is then based on the efficiency of the parameter standard errors (see, e.g., Patrick 2021 for detail and an example). The comparison of FE and RE is analogous.

In general, to carry out the test, we need a consistent estimate of

$$\Omega(\tilde{\theta} - \hat{\theta}) = \text{var}[\hat{\theta}] + \text{var}[\tilde{\theta}] - 2\text{cov}[\hat{\theta}, \tilde{\theta}]. \quad (45)$$

The last term on the right-hand side of this expression is relatively computationally difficult. If the estimator of $\hat{\theta}$ from the null hypothesis model is efficient, then $\text{var}[\hat{\theta}] = \text{cov}[\hat{\theta}, \tilde{\theta}]$ and (45) simplifies to

$$\Omega(\tilde{\theta} - \hat{\theta}) = \text{var}[\tilde{\theta}] - \text{var}[\hat{\theta}]. \quad (46)$$

In estimating the FE and RE models, the effects are specified as either fixed or random as developed above. This implies that the effects are either specified as

X variables or error components. If effects are correlated with the X variables then FE is consistent while RE is not. The FE β parameters are estimated using dummy variables (the so-called LSDV estimator) included as explanatory variables or by group mean differencing the variables and applying LS as shown above. Random effects (RE): the ε_{it} covariance matrix is specified as functions of the variances of the u_i , v_i , and e_{it} , and FGLS, ML, or GMM is used for estimation. Joint hypothesis tests of the effects can be carried out with an F-test (for the FE model) or Wald, LR, or LM test (for the RE model). A Durbin-Wu-Hausman (DWH) type test can be used to choose between the FE and RE estimators, among other things, as will be discussed later in this chapter. Patrick (2021), for example, presents detail on various uses for these types of tests.

For now, we focus on using a DWH test to infer if there is correlation between the effects and the explanatory variables, X . By effects in the discussion in this section, I am referring to effects that are specified as part of the error structure. We may also specify mixed effects models as illustrated in the examples below.

The simplest form of DWH test to compute was developed in Hausman (1978) and can be used to choose between the FE and RE specifications of the model if RE is efficient. If applicable, a relatively easy way to compute the test for the comparing parameter estimates from the alternative estimators. Hausman's procedure for testing independence between the explanatory variables and residuals in a model using any asymptotically efficient estimator and a consistent but asymptotically inefficient estimator is much less computationally burdensome than the statistics developed in Wu (1973, 1974). Applied to compare the FE and RE estimators, if effects are not correlated with X , RE is consistent and efficient under the null hypothesis, and FE is consistent but inefficient. If effects are correlated with X , then FE is consistent and efficient and RE is inconsistent.

Although the DWH test statistic presented in (47) is in the context of the RE and FE panel estimators, this is otherwise a relatively general form of the test. The DWH test for FE versus RE hinges on the correlation of the effects with the common error in the model to be estimated. The test statistic for RE versus FE is given by

$$m = \left(\hat{\beta}_{RE} - \hat{\beta}_{FE} \right)' \left(\hat{\Omega}_{FE} - \hat{\Omega}_{RE} \right)^{-1} \left(\hat{\beta}_{RE} - \hat{\beta}_{FE} \right) \overset{A}{\sim} \chi_k^2, \quad (47)$$

where $\hat{\beta}_{RE}$ is a vector of RE parameter estimates, $\hat{\beta}_{FE}$ is a vector of FE parameter estimates, both of size k , and $\hat{\Omega}_{FE}$ and $\hat{\Omega}_{RE}$ are consistent estimates of the covariance matrices defined above for the FE and RE estimators. The DWH test statistic, m , then has k degrees of freedom under the null hypothesis H_0 : RE residuals, ε , are not correlated with X . Rejecting the null hypothesis implies that FE would be the preferred estimator, because the RE parameter estimates are inconsistent (at least one of the explanatory variables is correlated with the random effects in the error structure). If the null is not rejected, there is no preference between FE and RE in terms of consistency, but RE would be preferred to FE because RE produces relatively efficient standard errors. This is a result of the between information in RE estimation, FE discards this information. Note that we can also include in the test

the parameters associated with effects that are specified as explanatory variables in mixed effects models (see Example 2 below for illustration).

The efficiency of the estimator requirement in the null hypothesis above can be relaxed. For example, if there is reason to use robust standard errors then the estimator is not fully efficient, so the relatively easy to compute form of the DWH test above is not applicable. If the estimator in the null hypothesis is not efficient, then direct estimation using auxiliary regressions (Davidson and MacKinnon 1984, 1987, and 1989, and MacKinnon 1992) or the paired bootstrap (Cameron and Trivedi 2005) can be used to estimate the $\text{var}(\hat{\theta} - \tilde{\theta})$, in particular the last term on the right-hand side of (45).

78.9 Testing Strict Exogeneity

A DWH test, or robust DWH test, could also be used to test strict exogeneity by contrasting β parameters and variances estimated by FE versus first difference (FD). Since strict exogeneity holds in the FD specification, pooled LS estimation of the FD equations yields consistent parameter estimates. However, Wooldridge (2010) provides regression based tests of strict exogeneity that are relatively easy to carry out, which are briefly presented below.⁹

Wooldridge (2010) suggests two equivalent regression approaches to test strict exogeneity. One way, Wooldridge (2010) tests strict exogeneity is by estimating

$$y_{it} = X_{it}\beta + X_{i,t+1}\delta + D_i\gamma + \varepsilon_{it}, \quad (48)$$

and testing the null hypothesis $H_0 : \delta = 0$ versus the alternative $H_1 : \delta \neq 0$.

The same test can also be carried out by using LS to estimate the first-difference (FD) form of the model,

$$\Delta y_{it} = \Delta X_{it}\beta + X_{i,t+1}\delta + \varepsilon_{it}, \quad (49)$$

and testing the same null hypothesis as with (48).

Either of these strict exogeneity tests are straightforward to apply and cost little in effort and computational time, yet the benefits of avoiding parameter bias and inconsistency may be substantial. So there is much to gain and little to lose by applying a test of strict exogeneity.

78.10 Empirical Application

This section provides two examples to illustrate the application of the estimators and specification tests covered above in two very different modeling situations. The first is an economics example using experimental data, providing a unique comparison of

⁹Grieser and Hadlock (2019) use simulations to show that these tests have “substantial” power.

the estimators and concepts above. The second is a financial model for asset pricing, where data is not nearly so nicely behaved as in the first example.

78.10.1 Example 1: Comparison of Pooled LS, Pooled LS with Cluster Robust SE, FE, RE (GLS), and RE (ML) Estimators Using Experimental Data

This example provides a comparison of five panel estimators and their relative consistency and efficiency using experimental data from Chermak et al. (2021). Chermak et al. analyze market, survey, and experimental data to estimate a residential water demand model. Water utility managers are interested in household water demand estimates for planning and operational purposes, including pricing, revenue, and providing an adequate supply of water. The experimental data provides a sample of utility customers' water demand levels as the price of water changes. The experiment is repeated for 10 rounds, providing the time periods for the panel. The market data from the utility and survey of the participants in the experiment data provide fixed characteristics that may be used as explanatory variables in the estimated demand model. The prices the consumers in the experiment face are set independently of any reaction that consumers (participants) have to price, conditional on their fixed household infrastructure and characteristics. Since these explanatory variables are fixed (deterministic or nonstochastic) for the pricing experiment, they are contemporaneously and strictly exogenous. This provides the opportunity to compare a range of basic panel data estimators and tests.

The demand for water by household j during time t (round) estimate is

$$w_{jt} = f_{jt}(p, B, \Phi, \Omega) \\ = \beta_0 + \beta_1 p_t + \beta_2 B_j + \sum_{i=3}^{15} \beta_i (p_t x_{ij}) + \sum_{i=16}^{33} \beta_i x_{ij} + v_j + \varepsilon_{jt} \quad (50)$$

where β_i , $i = 0, \dots, 33$, are the estimated parameters; the price of water at time t is p_t ; B_j is the budget for household j , interaction terms between price and the time effects, between price and household size, and between price and location, x_{ij} , $i = 3, \dots, 15$, and other household characteristics, x_{ij} , $i = 16, \dots, 33$. These control for differences across household water conservation technology (XERIC indicates low water use landscaping, LFTLT1 low-flow toilets, LFDW low-flow dishwasher, and LFWM for low-flow washing machine), quadrants of the city ($x_j = SW, NW, SE$, with the NE as the base), household size (PEOPLE), and other characteristics specified in the estimation results reported in Table 1.

As discussed above, a key feature of this data is that all explanatory variables are deterministic and exogenous to the models. Nineteen of the explanatory variables are constant over time. Given this, the associated parameters and standard errors cannot be estimated with FE because these time constant variables are perfectly correlated with the cross-sectional fixed effects in the model. In Table 1, the FE column labels

the parameters to these specific constant explanatory variables “omitted.” The **bold** numerical values indicate parameter estimates where hypothesis test conclusions are conflicting across the different estimators (in terms of the indicated significance level). The pooled LS estimates provide the largest number of parameters that are indicated to be significant, but the LS standard errors are not efficient. Many Type I errors (rejecting the null hypothesis when it is true) would be made in this case. If one were to adopt the pooled LS model, one would draw many incorrect conclusions based on the indicated significance of the parameters, and be overly optimistic in any forecasts based on the standard error of the forecast.

With the exception of the parameters that could not be estimated with FE, the parameter estimates across all of the estimators are the same (for the decimal places shown). As we move across the estimators in Table 1 from left to right, the efficiency of the estimates increases (from pooled LS to pooled LS with cluster robust standard errors to FE to RE, and from RE estimated with GLS to the most efficient, RE estimated with ML). Based on efficiency of estimated standard errors, using pooled LS with cluster robust standard errors is clearly preferred to pooled LS. But the Type I error caveat discussed above remains, though not as severe. Neither of these models considers any cross-sectional effect and efficiency can be improved with other models.

All but one of the time effect interactions with price terms are highly significant individually (joint tests of these effect interactions are also all highly significant). Cross-sectional effects are also all highly significant, as indicated by the F-test for the FE model and Likelihood ratio (LR) and Lagrange multiplier (LM) tests for the RE ML and GLS estimates, respectively. Since all the parameter estimates are the same, it is clear that the random effects are not correlated with the explanatory variables in the model. There is no point in trying to calculate DWH tests for the common parameter estimates across the models. All of the estimators provide consistent estimates in this example, but the RE ML estimates are consistent and *fully* efficient, so they are naturally preferred in this case.

78.10.2 Example 2: FE and RE, Contemporaneous and Strict Exogeneity, DWH and Wooldridge Tests

Fama and MacBeth (1973) used a two-step estimation process in an early test of CAPM theory. Their first step was to use time series data to estimate separate regressions for each asset, obtaining an estimate of all β_i . Second, for each point in time, cross-sectional data was used to estimate the model

$$R_{it} - R_{ft} = \theta_0 + \theta_1 \beta_i + e_i \quad (51)$$

where $R_{it} - R_{ft} \equiv$ excess return on asset i at time t , β_i is the estimated beta, and θ_0 and θ_1 are the parameters to estimate. Fama and MacBeth estimated this second stage separately for each time period and calculated the average of the parameter estimates

$T = 11$, $N = 178$, $NT = 1958$. This is a balanced panel. 19 of the X variables in (50) are constant through time for each cross section, so they are perfectly correlated with the effects in FE and can't be estimated.

to conduct hypothesis tests. However, a panel data approach could be used to carry out the second stage and directly test the Fama and MacBeth hypotheses.

Lee et al. (2019) point out that both cross section and time effects are of interest in financial analyses. To include time effects, the model in (51) is specified to include time dummies as additional explanatory variables. The corresponding panel data model with firm and time effects (a two-way panel data model) is specified as

$$R_{it} - R_{ft} = \theta_0 + \theta_1 \beta_i + v_i + u_t + e_{it} \quad (52)$$

where the cross-sectional effects v_i and time effects u_t could be specified as fixed, random, or mixed. Specification choice is examined below.

Data from Brooks (2014) on annual returns and estimated betas for 2500 UK firms over 11 years is used to estimate two-way FE and RE specifications of (51) and compare these estimates to those obtained using LS on the pooled data, as well as each other. This is an unbalanced panel data set. A DWH test is used to choose between these alternative specifications, i.e., to infer if effects are contemporaneously correlated with the explanatory variables. Wooldridge (2010) strict exogeneity tests are also performed.

Below are the estimation results (using STATA17) for

1. The pooled LS model
2. The FE model (two-way, firm and time effects)
 - (a) F-test of the effects
 - (b) Test of strict exogeneity.
3. Estimate the RE models (two-way, firm and time effects).
 - (a) Tests of the effects
4. DWH test to choose between FE and RE specifications

While cross-sectional effects are included in the model, parameters for cross-sectional effects are not presented below, but joint tests for cross-sectional effects are provided. The pooled LS estimation results are in Table 2. There are no significant parameter estimates indicated, the model lacks explanatory power. Estimates here may be biased and are most likely inefficient.

FE estimation results, with firm and time effects, are presented in Table 3. Contrary to the pooled LS estimation results, the beta coefficient is now negative and highly significant. Jointly testing the time effects gives the test statistic $F(10,7106) = 63.14$, which implies the joint zero null hypothesis is rejected, so time effects are jointly highly significant. From the reported t-tests, all but two of the time effects are individually significant. Firm effects are also jointly significantly different than zero, as indicated by the F-test presented at the bottom of Table 3.

Using (48), the regression to test strict exogeneity is in Table 4. The coefficient on *lead1beta* is not significantly different than 0, so there is no indication of a violation of strict exogeneity for this model according to Wooldridge’s test. If we had found evidence of a departure from strict exogeneity, then we would try to model the source of endogeneity or eliminate it through model specification. For example, see Wintoki et al. (2012) for an example using a dynamic panel GMM estimator (in a notable exception in the literature, they acknowledge strict exogeneity). See Grieser and Hadlock (2019) for more on strict exogeneity tests and IV estimation in financial

panel models. If valid instruments are available, contemporaneous correlation can be inferred by using IV estimation and a DWH test (see Patrick 2021 for more information and examples).

Next we consider the RE estimator and use a DWH test to choose between FE and RE. If the effects are not correlated with the explanatory variables X , then RE is consistent and more efficient than the FE. RE estimates using GLS are in Table 5.

Contrary to the FE results above, the beta coefficient is now positive but not significant at the usual levels. The Wald test with 11 degrees of freedom is to test the joint zero null for the beta and time effects, Wald(11) = 668.22, so these parameters are jointly highly significant. Table 6 provides a test of the cross-sectional random effect, LM(1) = 4.79 indicates that the random cross-sectional effect is highly significant. Table 7 contains a Wald test of the time fixed effects specified in the RE model, the Wald(10) = 664.98 implies that the fixed time effects are jointly highly significant.

violation, so there is no indication of significant correlation between contemporaneous returns and future values of beta for the asset. The RE results indicate an estimate of the impact of beta that is positive but not significant at the usual levels. Joint tests of the time and cross-sectional effects indicate both are highly significant.

A DWH test is used to choose between the FE and RE specifications, i.e., to infer if effects are contemporaneously correlated with the explanatory variables. If effects are correlated with the explanatory variables, then RE will be inconsistent, so the FE model would be preferred (see the DWH discussion above). The DWH test statistic is presented in Table 8, the $\chi^2(11)$ distributed statistic is 38.90, so the null is rejected. From this we infer that the random effect is correlated with the common error, so RE is inconsistent in this case and we reject the RE model.

78.11 Conclusion

Advantages of panel data relative to a cross-sectional or time series model include increased precision in estimation through increased sample size, greater flexibility in identifying the DGP, amelioration of omitted variables problems, and relaxing the constant parameter assumption.

Statistical properties of panel data estimators depend on the specific model and specification of the cross-sectional unobserved effects. The LS estimator with panel data will typically overstate precision (underestimate the standard errors) because it does not control for likely correlation of regression errors over time for the cross section.

There is the possibility of consistent estimation of the FE model, which allows for unobserved heterogeneity that may be correlated with the explanatory variables. The most commonly used panel data estimator is FE, usually only considering variation in the cross section (or time series, these are one-way models) or both (two-way

models). Much of the literature treats the effects as nuisance (incidental) parameters that can be ignored since primary interest is generally in consistent estimation of the vector β . If the parameters associated with the fixed effects are of interest, they can be estimated by specifying the dummy variables and computing the within (FE) estimator by least squares dummy variable estimation.

Some explanatory variables may have no within group variation because they are only observed at the group level. Such variables will exhibit perfect multicollinearity with group dummies in the FE model and, as a result, the associated parameters will not be identified. However, they may be identified by the RE model since RE take into account between-group variation. That is, FE parameters of time-invariant regressors are not identified in the within model (if $x_{it} = x_i$, then $\bar{x}_i = x_i$ and $x_{it} - \bar{x}_i = 0$). FE with group effects cannot be used in this case because it violates the full rank assumption.

To estimate the effect of time-invariant regressors, we could potentially use pooled LS or random effects (RE) estimators since they allow the time invariant effects to be estimated. The effects are captured in the error for both pooled LS and RE estimators and both will produce inconsistent parameter estimates if the effects are correlated with the explanatory variables. Other FE specifications may still be estimable (e.g., time invariant regressors and time rather than group effects).

Error component (see Chen, et al. (2021), Lee and Jen (2021), Kim (Chapter 82), and Chen, et al. (Chap. 103, “Alternative Errors-in-Variables Models and Their

Applications in Finance Research”)) and clustering models are also relevant for cross section data where subsets of observations are natural groups. For example, consider a cross section of firms from different countries, it may be that the error terms for firms within each country are correlated.

ML and GMM are also commonly used estimators for panel data models. The algebra of the linear panel data estimators will often not generalize to nonlinear panel estimators (see Greene (2018)).

The first-difference (FD) estimator may also be useful with panel data. In short panels, $N > T$, it measures the relationship between individual specific one period changes in the regressor and individual-specific one-period changes in the dependent variable. Consistency requires $E[e_{it} - e_{i, t-1} | X_{it} - X_{i, t-1}] = 0$, less stringent than strong exogeneity (the within estimator), but a stronger condition than $E[e_{it} | X_{it}] = 0$.

There may be endogeneity issues in panel data, so contemporaneous and strict exogeneity should be tested. In theory, endogeneity issues can be corrected using IV methods for each cross section, but valid instruments are necessary. Hausman-Taylor (1981b) and Amemiya and MaCurdy (1986) estimators allow instrumental variables in panel models. On validity of instruments, see Hahn and Hausman (2002) and Hausman et al. (2005).

Accruals and the Asymmetric Timeliness of Earnings: A Decomposition Analysis

79

Wenhsin Hsu

Abstract

Since Basu (*Journal of Accounting and Economics*, 24, 3–37, 1997), the difference between the response of earnings to good news (as proxied by positive stock return) and its response to bad news (as proxied by negative stock return) has been referred to as evidence of asymmetric timeliness in the response of earnings to good and bad news and the difference has been termed a measure of asymmetric timeliness. This measure of asymmetric timeliness has been extensively used in assessing accounting conservatism and its economic consequences. In this study, I seek to contribute to the debate on the sources of asymmetric timeliness by testing for its existence across a range of components of earnings. When clean surplus earnings are decomposed into cash flow and accrual components, I find that asymmetric timeliness in operating cash flow is larger than that in accruals. Moreover, using articulated data, the decomposition across line items also finds little evidence with regard to the application of three prominent standards (i.e., the LCM rule, the impairment tests, and the bad debt provision) that incorporate asymmetric verification criteria. These results call into question whether asymmetric timeliness of earnings is a consequence of accounting conservatism.

79.1 Introduction

Since the seminal paper Basu (1997), the difference between the timeliness of earnings in recognizing good and bad news has been characterized as an indicator of earnings conservatism and the informativeness of accounting numbers. The literature (Basu 1997; Pope and Walker 1999) has documented that accounting earnings generally recognize bad news (proxied by negative returns) more quickly than good news (proxied by positive returns) and has extensively employed this measure, “asymmetric timeliness,” over different governance systems and accounting regimes to compare earnings conservatism and its economic consequences (Ball et al. 2000, 2003; Pope and Walker 1999). Although most empirical evidence supports the role of conservatism in causing asymmetric timeliness, the literature still has not provided conclusive evidence on the sources of asymmetric timeliness of earnings. In particular, Dietrich et al. (2007) have raised concern about the econometric appropriateness of using reverse regression to examine earnings conservatism. They argue that the observed asymmetric timeliness of earnings in Basu (1997) is an econometric effect, not a result of conservatism, as the effect can also be observed in their simulated data where accounting conservatism is by construction absent.

In this chapter, I shed further light on the sources of asymmetric timeliness by providing a comprehensive picture of the pattern of asymmetric timeliness across earning components. Specifically, I seek evidence as to whether or not the incidence of asymmetric timeliness across earnings components is consistent with the theory that asymmetric timeliness is due to accounting conservatism. In order to do this, I decompose earnings across two dimensions: into cash flow and accrual components, and into line items.

If asymmetric timeliness is the direct result of earnings conservatism, the asymmetric timeliness should only be associated with accrual components rather than cash flow components. Therefore, a decomposition analysis of accrual and cash flow components can determine the sources of asymmetric timeliness.

Furthermore, although conservatism is considered a pervasive feature of financial reporting, it is likely to be observed in certain line items more than others. If asymmetric timeliness of earnings is a measure for earnings conservatism, asymmetric timeliness should predominately take place in the components, to which a standard with asymmetric requirement for gains and losses is directly related. I focus on three main standards, LCM rule, impairment tests and bad debt (warranty) provision, and the corresponding components.

One innovative feature of the study is that the asymmetric timeliness in aggregated earnings can be disaggregated into asymmetric timeliness in components. Specifically, in the Basu (1997) model where the “aggregated earnings” are regressed on the news, the proxy of which is stock return, the “timeliness” coefficient for news is determined by the covariance of “aggregated earnings” and stock return, divided by the variance of stock return. If the dependent variable (aggregated earnings) is decomposed into a series of earnings components, given that the denominator (the variance of stock returns) is constant, the “timeliness” coefficients

in each of the subsumed components are additive. Consequently, the asymmetric timeliness of clean surplus earnings is exactly identical to the sum of asymmetric timeliness in the subsumed components. This feature is helpful in depicting the sources of asymmetric timeliness of earnings.

With a unique dataset in which clean surplus earnings are articulated with net dividends and consecutive changes in book value, I seek evidence on earnings components subsumed in clean surplus earnings. The results show that asymmetric timeliness in operating cash flow is larger than that in accruals. The decomposition across line items also finds little evidence with regard to the application of three prominent standards that incorporate asymmetric verification criteria. The LCM rule might be expected to induce accounting conservatism, but no asymmetric timeliness is observed in the component of “change in inventory”; impairment tests might also be expected to induce accounting conservatism but little asymmetric timeliness is observed in special items; the rule of bad debt or warranty provision might be expected to induce accounting conservatism in working capital accruals due to the required recognition of a provision for future liability but not future benefits, but little asymmetric timeliness is observed in “working capital accruals.” These results call into question whether asymmetric timeliness of earnings is a consequence of conservatism.

The chapter is organized as follows. Section 79.2 discusses the theoretical background and hypothesis development. Section 79.3 describes research design, and Sect. 79.4 describes sample selection. Empirical evidence is presented in section 79.5. Section 79.6 presents alternative explanation and some additional tests, and Sect. 79.7 summarizes my finding and their implications.

79.2 Theoretical Background and Hypothesis Developments

79.2.1 Earnings Conservatism in the UK

One main purpose of reporting income is to make management accountable for its efforts on behalf of ownership. Moral hazard¹ is a type of information asymmetry that exists between managers and shareholders as ownership tends to be separated from control in most big entities. Because shareholders (principal) are unable to observe managers’ (agent) behaviors, managers tend to maximize their own benefits at the expense of the shareholders by taking advantage of their position of better information.

Watts (2003) proposes that accounting conservatism is a means of addressing moral hazard problems by constraining managers’ opportunistic behaviors in

¹Moral hazard refers to the tendency of the agent who is imperfectly monitored by the principal to engage in dishonest or otherwise undesirable activities.

reporting accounting measures. This is generally operated through the exercise of higher caution in the recognition of gains than losses. Such an asymmetric verification requirement can curb the enthusiasm of managers who want to maximize the earnings in order to distribute some net asset value to themselves when earnings is used in the compensation contracts.² Unless another efficient technology can be found to address the hazard problems between managers and shareholders, conservatism will continuously serve as a fundamental convention in accounting standards.

Specifically, earnings conservatism has been defined as accountants' tendency to require a higher verification for recognizing good news than bad news³ (Basu 1997; Watts 2003). This can induce asymmetry in the timeliness with which economic news is reflected in reported earnings: accounting earnings tend to recognize concurrent bad news as observed in negative market returns more quickly than good news as observed in positive returns. Basu (1997) terms the excess of the sensitivity of earnings to bad news over good news as "asymmetric timeliness of earnings." A firm is willing to supply the level of asymmetric timeliness of earnings to the extent that the benefits outweigh the costs of lower earnings (Hsu et al. 2017; Zhong and Li 2017; Burke et al. 2020).

Before highlighting the limitation of asymmetric timeliness in estimating earnings conservatism, I summarize some of the standards that incorporate the asymmetric verification requirement for recognizing gains and losses in UK GAAP:

1. *The Lower of Cost or Market Value Rule*

The lower of cost or market value is traditionally applied to stock valuation. SSAP 9 states that,

The amount at which stocks are stated in periodic financial statement should be the total of the lower of cost and net realisable value of the separate item of stock or of groups of similar items. (Para. 26)

While stock values are written down to net realizable value on an item-by-item basis or by reference to groups of similar items, they are not allowed to be written up if the net realizable value is higher than the carrying value. Once an asset is written down, the written-down value becomes the new cost, which cannot be written up again. The recognition of the written-down loss can be reflected in the decrease of inventory.

²Conservatism can also reduce the possibility that management make a liquidating dividend to shareholders at the expense of debt holders by manipulating earnings upwards. Other contracting explanations such as tax, litigation can refer to Watts (2003).

³There are other aspects of earnings conservatism. For example, the historical cost convention does not recognize the excess expected NPV (economic rent) at the time of acquisition; the choice of income-deferring accounting methods (i.e., depreciation or inventory).

2. *The Impairment Test for Tangible Assets, Intangible Assets, and Goodwill*

Another commonly illustrated example for the asymmetric recognition of gains and losses is the impairment test for assets. The ASB has issued a standard, FRS 11⁴ to account for the impairment of fixed assets and goodwill. When the book value of the assets exceeds the recoverable amount,⁵ capital assets should be written down to net recoverable value, but not vice versa if the recoverable amount exceeds the carrying value. The reduction of their carrying values is recorded as an “exceptional item” in the profit and loss account (Para. 67–73).

Nevertheless, one unique feature in UK GAAP is that the revaluation upwards⁶ is allowed for certain fixed assets, particularly the investment property. The revaluation surplus is credited to revaluation reserve as a dirty surplus flow rather than be recorded in the profit and loss account (Para. 65).

3. *Contingent Assets and Liabilities*

Under FRS 12, provisions, contingent liabilities, and contingent assets, companies are not allowed to recognize a contingent asset under any circumstances (Para. 31), but contingent liabilities should be recognized if a present obligation that arises from past events is probable and the amount of the obligation can be measured reliably (Para. 2). Likewise, the recognition of a provision for future economic benefits cannot in general be recognized, but a provision for future liability should be recognized if a reliable estimate can be made for the highly probable obligation. Typical examples are the bad debt provision that is reflected in the decrease of accounts receivable, the warranty liability that is recognized in the increase of accounts payable or the recognition of restructuring cost.

To sum up, it can be seen that the conservative practice with regards to asymmetric verification for gains and losses is an important feature of the UK accounting standards. An early recognition of losses in response to economic news mainly takes the form of asset write-offs or write-downs, and the establishment of loss provisions. The LCM rule applies to “changes in inventory” of current accruals; the impairment test applies to “special items”; and bad debt or warranty provisions apply to “changes in working capital.”

⁴The equivalent international standard is IAS 36 impairment of assets, issued in 1998. The FRS treats intangible assets in much the same way as goodwill while the IAS aligns their treatment to that of tangible assets.

⁵The recoverable amount is determined by the higher of its net realisable value and its value in use. Value in use is to be calculated by discounting the expected future cash flows at an estimate of the rate the market would expect on an equally risky investment.

⁶The Company Act 1985 permits either historical cost accounting or the use of an alternative basis of valuation. The issuance of FRS 15 in 1999 has removed considerable flexibility in the previous revaluation practice. FRS 15 requires companies to revalue the assets on a regular basis and does not permit revaluation of individual assets from same class.

79.2.2 Asymmetric Timeliness of Earnings in Earnings Constructs

79.2.2.1 Limitations of Asymmetric Timeliness

Following Basu (1997), asymmetric timeliness of earnings has been widely used as a measure of total conservatism. Although a great number of studies have exclusively employed the measure to assess the full extent of conservatism over countries and accounting regimes (Ball et al. 2000; Giner and Rees 2001; Pope and Walker 1999), recent studies have started to find that some limitations exist in the measure of “asymmetric timeliness” in estimating the full extent of conservatism. For example, Givoly et al. (2007) have documented that asymmetric timeliness can only capture one dimension of conservatism, and the asymmetric timeliness is on average inversely related to other dimensions of accounting conservatism. In other words, the asymmetric timeliness has difficulty in reflecting some conservatism policies regarding the choice of income-deferring accounting methods (such as straight line depreciation and accelerated depreciation) when the policies are not referenced to concurrent market news. But these conservative policies can inversely affect the asymmetric timeliness effect. This argument is consistent with Pope and Walker (2003) that asymmetric timeliness is a conditional measure that is negatively related to the ex ante conservatism (or balance sheet conservatism). This is because firms with higher capitalization of assets at the start of an accounting period tend to display stronger asymmetric timeliness than those with lower capitalization.

Furthermore, there is also some suspicion with regards to the econometric appropriateness of using reverse regression to examine accounting conservatism. Dietrich et al. (2007) have argued that the asymmetric timeliness of earnings is not a pure conservatism product, but an econometric effect. They argue that the model is mis-specified because the model relies on certain assumptions regarding the earnings-returns relation, and the model is only interpretable when returns cause earnings and not vice versa. Specifically, they point out that the Basu (1997) regression suffers from a sample variance ratio bias arising from the reverse regression when earnings are regressed on returns, and a sample truncation bias induced by splitting the sample by an endogenous variable (returns). Dietrich et al. (2007) argue that the observed asymmetric timeliness in Basu (1997) is completely explained by these econometric problems. To support this argument, Dietrich et al. (2007) also provide evidence that the asymmetric timeliness can be observed in data where, by construction, accounting conservatism is absent.

79.2.3 Hypothesis Developments

Since the literature does not provide conclusive evidence with regard to the sources of asymmetric timeliness of earnings, this study attempts to determine the asymmetric timeliness in all components of earnings. This is crucial in providing further evidence as to whether asymmetric timeliness is purely a consequence of earnings

conservatism. The decomposition analysis for the asymmetric timeliness of earnings is across two dimensions:

1. Cash Flow Versus Accruals

First, I decompose clean surplus earnings into cash flow and accrual components. Asymmetric timeliness of earnings has been hypothesized to be the product of earnings conservatism and the accrual process (Basu 1997). Through the application of earnings conservatism, the accrual process requires higher verification requirement for favorable news than unfavorable news and is expected to generate a differential speed for recognizing good and bad news. If asymmetric timeliness is the direct result of earnings conservatism, the asymmetric timeliness should be associated with accrual components and should not be associated with cash flow components. Therefore I expect that, if it is only earnings conservatism that determines asymmetric timeliness of earnings, asymmetric timeliness is only related to accrual components.

H1a: *Ceteris paribus*, asymmetric timeliness of earnings is completely driven by asymmetric timeliness in accrual components, and no asymmetric timeliness can be found in operating cash flow components.

Rejection of the above hypothesis implies that asymmetric timeliness of earnings is not a pure consequence of earnings conservatism.

2. Line Items

Second, I am also interested in earnings components across line items. It has been suggested that aggregate earnings should be decomposed into line items for a better understanding of the role of earnings in performance measurement or valuation as each component provides information that is complementary to information provided by the aggregate earnings (Lipe 1986). Therefore, earnings conservatism as observed in the asymmetric timeliness is better understood by reference to earnings components than by reference to aggregate earnings above.

Moreover, although conservatism is considered a pervasive feature of financial reporting, the “asymmetric timeliness” cannot capture all types of conservative policies (Givoly et al. 2007). Basu (1997, p. 16) reckons that only the accruals with regards to write-offs are more likely to reflect asymmetric timeliness type of conservatism and are reflected in extraordinary items. In other words, the prominent instances that asymmetric timeliness is expected to capture are the standards with asymmetric requirements for unrealized gains and losses, such as lower of cost or market value for inventories (LCM) or the impairment tests for fixed assets. This suggests that “asymmetric timeliness” is likely to be observed in earnings components where there is a specific standard with asymmetric verification requirements. Consequently, I predict that, if asymmetric timeliness of earnings is representative of earnings conservatism, asymmetric timeliness should predominately take place in the components, to which a standard with asymmetric requirement for gains and losses is directly related. I will focus on three main standards, LCM rule, impairment

tests and bad debt (warranty) provision, and the corresponding components: “working capital accruals,” and “exceptional items,”⁷ etc.

H1b: *Ceteris paribus*, the asymmetric timeliness of earnings components is stronger in the component where a standard exists which explicitly requires asymmetric recognition of gains and losses (i.e., working capital accruals, special items) than other components.

3. Dirty Surplus Flows

Finally, as I seek evidence on earnings components subsumed in clean surplus earnings, my analysis also covers the dirty surplus flows. Dirty surplus flows refer to gains and losses that bypass the profit and loss account. Under the clean surplus relationship, accounting earnings should include all changes in the book value of shareholders' equity during a period except the net contributions by owners. However, UK GAAP has permitted a wide use of dirty surplus flows (violation of clean surplus accounting) which allow that some of the gains and losses are not reflected in the accounting earnings, but are recognized directly in shareholders' equity. The typical example includes “prior-year adjustments,” “currency translation differences,” “goodwill write-offs,” and “revaluations,”⁸ and such treatment has created some concerns in practice.

The main concern⁹ for dirty surplus flows is that the violation of clean surplus accounting is inconsistent with accounting-based valuation models and is more subject to managers' manipulation because dirty surplus flows are more likely to be overlooked by financial users (Robinson 1991; Johnson et al. 1995). Although bad news is more likely to be concealed in dirty surplus flows than good news,

⁷Exceptional are material items which derive from events or transactions that fall within the ordinary activities of the reporting entity and which individually or, if of a similar type, in aggregate, need to be disclosed by virtue of their size or incidence if the financial statements are to give a true and fair view (FRS 3, Para.5). FRS 3 requires the “gains and losses from sales or termination of continued and discontinued operations,” “gains and losses from sales of fixed assets,” and “reorganisation” be separately disclosed as special items after operating profit.

⁸Among all dirty surplus flows, goodwill and revaluation reserve deserve some notice as they constitute the major part of dirty surplus flows. The goodwill treatment that requires the written-off against shareholders' equity in acquisition accounting (SSAP 22: *Accounting for Goodwill*) has long been criticised on the grounds that it overstates earnings and produce other mismeasurement problems. As such, FRS 10 (*Goodwill and Intangible assets*) eliminated dirty surplus treatment of goodwill write-offs in 1998. FRS 10 requires purchased goodwill and intangible assets to be capitalized and amortized through the profit and loss account over their useful economic lives. All goodwill previously eliminated against reserves has been reinstated as an asset on the balance sheet by way of a prior year adjustment.

⁹On the contrary, proponents of dirty surplus accounting argue that reported earnings should abstract from transitory effects to reflect current operating performance, enhancing the predictive ability for valuation purposes (Black 1993) because the inclusion of some unusual items in reported earnings is likely to cause misleading inferences, and managers are in a better position to identify those unusual items.

due to the obscure position in financial statements, I do not expect to observe asymmetric timeliness in dirty surplus flows. One reason is that current empirical evidence finds little evidence that dirty surplus flows are value relevant: the UK evidence by O'Hanlon and Pope (1999) and the USA evidence by Dhaliwal et al. (1999). Isidro et al. (2004) also show that dirty surplus flows except "goodwill flows" do not create bias in value estimates with respect to clean surplus-based value estimates.

Moreover, in 1992, FRS 3 has required the disclosure of dirty surplus flows in the "statement of total recognised gains and losses" and "reconciliation of movement in shareholders' funds" as a supplement to the "profit and loss account." This can create more transparency in dirty surplus flows, and reduce the tendency that bad news is hidden in dirty surplus flows. Therefore, I predict that, with the data from 1992 to 2000, asymmetric timeliness is not pronounced in dirty surplus flows.

H1c: *Ceteris paribus*, asymmetric timeliness cannot be observed in dirty surplus flows.

79.3 Research Design

In this chapter, I employ a decomposition analysis for asymmetric timeliness of earnings. Following Basu (1997), this study employs the asymmetric timeliness model, the intercept and coefficient of which varies with the sign of market returns. I will first introduce two decompositions of clean surplus earnings in Sect. 79.3.1. Section 79.3.2 describes a feature with regard to the equivalence between asymmetric timeliness in clean surplus earnings and the sum of asymmetric timeliness in each component.

79.3.1 Earnings Components

As the decomposition analysis of clean surplus earnings in this study is operated through two dimensions, I decompose clean surplus earnings across line items and across accrual and cash flow components. Exhibit 1 summaries all the disaggregated components in the study: the vertical dimension is related to decomposition across line items, and the horizontal dimension is for the decomposition across accrual and cash flow components. The line items are displayed in the context of the "profit and loss account," the "statement of total recognised gains and losses," and "reconciliation of movements in shareholders' funds" under UK GAAP (In Appendix 1, I extract financial statements of Boots plc to illustrate the format of three financial statements). Thus, the line items start mainly from operating profits, special items, tax, dirty surplus flows to the aggregated clean surplus earnings.

On the other hand, as accounting earnings is composed of accrual and cash flow components, the line item in each row can be decomposed into its accrual and cash

Exhibit 1 Earnings components of clean surplus earnings

Earnings	=	Cash flow	+	Accruals
Operating profit (OP_t)	=	Reported operating cash flows ($ROCF_t$)	+	Operating accruals (OA_t)
				[=working capital ($WCA_t = \Delta AR_t + \Delta INV_t - \Delta AP_t$) + Long-term operating accruals ($LOA_t = DEP_t + OOA_t$)] ^a
+ Special items ($Special_t$)	=	-	+	$Special_t$
[=gains (losses) from sales of fixed assets (Spe_FA_t) + gains(losses) from termination of operation ($Spec_ter_t$) + other special (Spe_oth_t)]				
+ Net interest expense (INT_t)	=	INT_t	+	-
+ Other nonoperating incomes (ONO_t)	=	-	+	ONO_t
= Pretax profits ($Pretax_t$)	=	$ROCF_t + INT_t$	+	$OA_t + Special_t + ONO_t$
+ Taxation (Tax_t)	=	Tax_t	+	-
= Net profit before extra and minority interest (EAR_t)	=	$ROCF_t + INT_t + Tax_t$	+	$OA_t + Special_t + ONO_t$
+ Extraordinary items ($Extra_t$)	=	-	+	$Extra_t$
+ Minority interest and preference dividend ($Minpref_t$)	=	$Minpref_t$	+	-
= Dirty surplus earnings (DSE_t)	=	$ROCF_t + INT_t + Tax_t + Minpref_t$	+	$OA_t + Special_t + ONO_t + Extra_t$
+ Dirty surplus flows (DSF_t)	=	-	+	DSF_t
[=prior year adjustment (PYA_t) + foreign exchange translation (FX_t) + revaluation (REV_t) + goodwill write-offs (GW_t) + other flows (OTH_t)]				
= Clean surplus earnings (CSE_t)	=	Total cash flows (TCF_t) [= $ROCF_t + INT_t + Tax_t + Minpref_t$]	+	Total accruals ($TACC_t$) [= $OA_t + Special_t + ONO_t + Extra_t + DSF_t$]

^a ΔAR_t , change in accounts receivables; ΔINV_t , change in inventory; ΔAP_t , change in accounts payable; DEP_t , depreciation; OOA_t , other operating accruals

flow component. Following the decomposition of each line item into corresponding accrual and cash flow components, those accrual components can sum up to total accruals as shown in the bottom line and all cash flow components can sum up to the aggregated cash flows. These two aggregated figures then add up to clean surplus earnings. Consequently, clean surplus earnings can be decomposed across accrual and cash flow components.

A. Decomposition Across Line Items

Specifically, the decomposition of clean surplus earnings across line items is expressed as:

$$\begin{aligned}
 CSE_t &= \{DSE_t\} + \{DSF_t\} \\
 &= \left\{ \left[\underbrace{(OP_t + Special_t + INT_t + ONO_t)}_{Pretax_t} + Tax_t \right] + Extra_t + Minpref_t \right\} \\
 &\quad + \{PY_t + FX_t + REV_t + GW_t + OTH_t\}
 \end{aligned} \tag{1}$$

Clean surplus earnings (CSE_t) is equal to dirty surplus earnings or the reported bottom-line earnings from the “profit and loss account” (DSE_t) plus dirty surplus flows (DSF_t).

First, DSE_t can be decomposed into a series of line items based on the context of profit and loss account: operating profits (OP_t), special items ($Special_t$), net interest expense (INT_t), other nonoperating incomes (ONO_t), tax expense (Tax_t), extraordinary items ($Extra_t$), and minority interests and preference dividends ($Minpref_t$). The introduction of FRS 3: Reporting Financial Performance in 1992 requires three kinds of exceptional items, “gains and losses on sales of fixed assets of continued and discontinued operations,” “gains and losses on sale or termination of continued and discontinued operations,” and “reorganisation,” be separately disclosed as special items ($Special_t$) after operating profit.

Among these line items in the profit and loss account, the sum of OP_t , $Special_t$, INT_t , and ONO_t is called pretax profits ($Pretax_t$), which does not take account of tax expense, extraordinary items, minority interests, and preference dividends. $EARN_t$ is another subtotal earnings, the after-tax profits but before the recognition of extraordinary items, minority interest and preference dividends. As FRS 3 redefines extraordinary items and effectively eliminates the use of extraordinary items, the value for $Extra_t$ is expected to be very small.

In addition, DSF_t in Eq. (1) consists of five categories: prior year adjustments (PY_t), foreign exchange translations (FX_t), asset revaluations (REV_t), net goodwill write-offs (GW_t), and other recognized gains/losses (OTH_t). GW_t is recorded in the

“reconciliation of movements in shareholders’ funds” and the other four classes are in the “statement of total recognised gains and losses.”

B. Decomposition Across Accrual and Cash Flow Components

For the second decomposition of clean surplus earnings across accrual and cash flow components, each line item earnings needs to be decomposed into its corresponding accrual and cash flow component.

Start from the first line item, operating profits:

$$\begin{aligned} OP_t &= [ROCF_t] + [OA_t] \\ &= [ROCF_t] + [WCA_t + LOA_t] \\ &= [ROCF_t] + [(\Delta AR_t + \Delta INV_t - \Delta AP_t) + (DEP_t + OOA_t)] \end{aligned}$$

Operating profits can first be decomposed into reported operating cash flows ($ROCF_t$) and operating accruals (OA_t) since FRS1 (cash flow statement) requires $ROCF_t$ to be reconciled between OP_t and OA_t . Then, I decompose OA_t into working capital accruals (WCA_t) and long-term operating accruals (LOA_t) based on the liquidity. WCA_t has three components: change in accounts receivable (ΔAR_t), change in inventory (ΔINV_t), and change in accounts payable (ΔAP_t). LOA_t consists of depreciation (DEP_t) and other operating accruals (OOA_t).

For the rest of line items, I assume that special items ($Special_t$) and extraordinary earnings ($Extra_t$) are pure accrual components. Without loss of insight and with the added convenience of illustration, I assume that net interest expense (INT_t), tax (Tax_t), and “minority interest plus preference dividends” are cash flow components.¹⁰ I also assume that other nonoperating incomes (ONO_t) and dirty surplus flows (DSF_t) are purely accrual components. Based on these assumptions, I can derive two aggregate figures for total cash flows (TCF_t) and total accruals ($TACC_t$), the sum of which equals clean surplus earnings.

$$\begin{aligned} CSE_t &= [TCF_t] + [TACC_t] \\ &= [ROCF_t + INT_t + TAX_t + Minpref_t] + \{[WCA_t + LOA_t] + Special_t + ONO_t + Extra_t + DSF_t\} \\ &= [ROCF_t + INT_t + TAX_t + Minpref_t] \\ &\quad + \{[(\Delta AR_t + \Delta INV_t - \Delta AP_t) + (DEP_t + OOA_t)] + Special_t + ONO_t + Extra_t + DSF_t\} \end{aligned} \quad (2)$$

Specifically, total cash flows equal reported operating cash flows ($ROCF_t$) plus net interest (INT_t) minus tax expense (TAX_t); total accrual equals the sum of working

¹⁰ Apart from operating cash flow, FRS1 requires the separate disclosure of cash flow for net interests and tax payments. The possibility that this assumption can double count the two items as cash flow components is minimal, given that the tax and net interest are not included in the operating cash flows.

capital accruals (WCA_t : change in accounts receivables plus change in inventory minus change in accounts payable), long-term operating accruals (LOA_t : depreciation and other operating accruals), special items ($Special_t$), extraordinary items ($Extra_t$), and dirty surplus flows (DSF_t). Clean surplus earnings can thus equal all accrual and cash flow components.

79.3.2 The Asymmetric Timeliness Model for Earnings Components

Following Basu (1997), I use a contemporaneous reverse regression¹¹ to assess the asymmetry and timeliness in incorporating good and bad news in earnings. This reverse regression specifies earnings as the dependent variable and the news measure as the independent variable, and then incorporates asymmetry in accounting income timeliness for negative economic news.

$$X_{i,t} = \alpha_1 + \alpha_2 DUM_{MR,t} + \beta_1 MR_t + \beta_2 MR_t \times DUM_{MR,t} + \varepsilon$$

where $X_{i,t}$ is earnings component i at time t ; MR_t is the cum-dividend dollar returns in year t , the surrogate for economic news. $DUM_{MR,t}$ is a dummy variable that takes the value one where MR_t is negative, and zero otherwise. All variables are scaled by opening market value.

The coefficient β_1 captures the responsiveness of the earnings construct ($X_{i,t}$) to the good news, and the coefficient β_2 captures the incremental responsiveness of the earnings construct to contemporaneous bad news. As conservatism can induce asymmetry in earnings timeliness, β_2 is expected to be significantly positive.

Notice that the “timeliness” coefficient is determined by the covariance of accounting earnings and stock returns, divided by the variance of stock returns.

$$\beta_1^{CSE} = \frac{COV(CSE_t, MR_t)}{\sigma_{MR_t}^2} \quad \text{when } MR_t > 0$$

$$\beta_1^{CSE} + \beta_2^{CSE} = \frac{COV(CSE_t, MR_t)}{\sigma_{MR_t}^2} \quad \text{when } MR_t < 0$$

¹¹ One of the reasons to use a reverse regression is to facilitate the exploration of the extent to which accounting earnings can capture the contemporaneously economic performance. Besides, some econometric benefits arise from this reverse regression. As the measurement error of earnings can bias downwards the coefficient of ERC and the R^2 in the normal price-earnings regression, in the reverse regression, the measurement errors will be placed in the disturbance term rather than in the explanatory term, and thus the coefficient will be measured with less errors.

If the dependent variable (aggregated earnings) is decomposed into a series of earnings components, given that the denominator (the variance of stock returns) is constant, the “timeliness” coefficients in each of the subsumed components are additive. The asymmetric timeliness of earnings in clean surplus earnings can be exactly identical to the sum of asymmetric timeliness of earnings in all subsumed components.

Specifically, for the decomposition of clean surplus earnings across line items, the identical relationship between asymmetric timeliness in clean surplus earnings and the sum of asymmetric timeliness of earnings in all line items can be expressed as:

$$\begin{aligned}\beta_1^{CSE} &= \frac{COV[CSE_t, MR_t]}{\sigma_{MR_t}^2} \\ &= \frac{COV[(DSE_t + DSF_t), MR_t]}{\sigma_{MR_t}^2} \\ &= \frac{COV[(OP_t + Special_t + INT_t + ONO_t + Tax_t + Extra_t + Minpref_t) + [PY_t + FX_t + REV_t + GW_t + OTH_t]), MR_t]}{\sigma_{MR_t}^2} \\ &= [\beta_{1,t}^{OP} + \beta_{1,t}^{Special} + \beta_{1,t}^{INT} + \beta_{1,t}^{ONO} + \beta_{1,t}^{Tax} + \beta_{1,t}^{Extra} + \beta_{1,t}^{Minpref}] + [\beta_{1,t}^{PY} + \beta_{1,t}^{FX} + \beta_{1,t}^{REV} + \beta_{1,t}^{GW} + \beta_{1,t}^{OTH}]\end{aligned}$$

Likewise, β_2^{CSE} can be expanded in the same manner.

$$\begin{aligned}\beta_2^{CSE} &= [\beta_{2,t}^{OP} + \beta_{2,t}^{Special} + \beta_{2,t}^{INT} + \beta_{2,t}^{ONO} + \beta_{2,t}^{Tax} + \beta_{2,t}^{Extra} + \beta_{2,t}^{Minpref}] \\ &\quad + [\beta_{2,t}^{PY} + \beta_{2,t}^{FX} + \beta_{2,t}^{REV} + \beta_{2,t}^{GW} + \beta_{2,t}^{OTH}]\end{aligned}$$

On the other hand, for the decomposition of clean surplus earnings across cash flow and accrual components, the identical relationship between asymmetric timeliness in clean surplus earnings and the sum of asymmetric timeliness of earnings in all line items can be expressed as:

$$\begin{aligned}\beta_1^{CSE} &= [\beta_{1,t}^{ROCF} + \beta_{1,t}^{INT} + \beta_{1,t}^{TAX} + \beta_{1,t}^{Minprf}] \\ &\quad + \left[(\beta_{1,t}^{\Delta AR_t} + \beta_{1,t}^{\Delta INV_t} - \beta_{1,t}^{\Delta AP_t}) + (\beta_{1,t}^{DEP_t} + \beta_{1,t}^{OOA_t}) + \beta_{1,t}^{Special} + \beta_{1,t}^{ONO} + \beta_{1,t}^{Extra} + \beta_{1,t}^{DSF} \right] \\ \beta_2^{CSE} &= [\beta_{2,t}^{ROCF} + \beta_{2,t}^{INT} + \beta_{2,t}^{TAX} + \beta_{2,t}^{Minprf}] \\ &\quad + \left[(\beta_{2,t}^{\Delta AR_t} + \beta_{2,t}^{\Delta INV_t} - \beta_{2,t}^{\Delta AP_t}) + (\beta_{2,t}^{DEP_t} + \beta_{2,t}^{OOA_t}) + \beta_{2,t}^{Special} + \beta_{2,t}^{ONO} + \beta_{2,t}^{Extra} + \beta_{2,t}^{DSF} \right]\end{aligned}$$

To summarize, the asymmetric timeliness in clean surplus earnings can be appropriately disaggregated into a series of asymmetric timeliness across line items and across cash flow and accrual components. This innovation is helpful in investigating the contribution made by each earnings component in the asymmetric timeliness and therefore can determine the sources of asymmetric timeliness of earnings.

79.4 Sample Selection

The data used for the tests consists of all industrial¹² firms based in the UK during 1992–2000. All data in the study is collected mainly from DATASTREAM and supplemented with published financial statements. The reason to set the starting year as 1992 is that the provision of complete components of changes in shareholders' funds in DATASTREAM starts since the introduction of FRS3¹³ in 1992.

Besides, samples extracted from DATASTREAM include both live and dead firms to avoid the survivorship bias. An important feature of my data is that all reported incomes, dirty surplus flows, net dividends, and book values of shareholders' funds should be connected up in a transparent way. This ensures that all accounting flows are considered in the analysis. Thus, I firstly collect the complete components of "Reconciliation of Movements in Shareholders' Funds" from DATASTREAM, including net incomes, dirty surplus flows, and opening (ending) book value of equity. As some discrepancies or gaps on changes in shareholders' funds are observed in some data collected from DATASTREAM, I need to conduct a validation investigation in such discrepancies,¹⁴ by reference to published financial statements, to ensure a fully articulated data on net income, dirty surplus flows, net dividends, and book values. In most cases, the discrepancies can be resolved and corrected satisfactorily. If it is not likely to resolve the discrepancies, I will delete the corresponding firms from the samples. This process results in the loss of 64 firms and 353 firm/year observations, approximately 4% of the initial samples.

Moreover, the study also requires additional data on accrual components, cash flow components, and line items. Exhibit 2 summarize the definition of the earnings components and the corresponding Datastream (or Worldscope) codes drawn from 1992 to 2000.

In order to conduct comparative analysis among earnings components, the sample includes only the observations when all the earnings components are available in DATASTREAM for a particular year, and the sum of all line items equals reported earnings.¹⁵ To mitigate the potential effects of outliers, I also delete observations in the top and bottom 1% of each year's distribution of each variable. Such screening

¹²I exclude financial firms because I expect them to exhibit a significant different association between earnings and market returns than do nonfinancial firms. For example, financial firms usually apply fair value accounting to a greater extent than nonfinancial firms and could result in a higher intensity in applying asset impairment rules.

¹³*Financial Reporting Standards 3: reporting financial performance*. FRS3 requires that the information about change in shareholders' funds should be disclosed in a supplementary statement, "Reconciliation of Movements in Shareholders' Funds."

¹⁴For example, the discrepancy between "ending book value of shareholders' funds" in the previous period and the "opening book value of shareholders' funds" in current period; the discrepancy between "the sum of opening book value of shareholders' funds and current-period movements in shareholders' funds" and "the ending book value of shareholders' funds."

¹⁵The non-missing variables requirements might cause some survivorship bias, but some analysis shows that my sample is economically representative of the population both in terms of the market value distribution and industry composition.

Exhibit 2 Accounting variable collection

Dirty surplus earnings (DSE_t)	DS#1087		
Dirty surplus flows (DSF_t) [=prior year adjustment (PYA_t) + foreign exchange translation (FX_t) + revaluation (REV_t) + goodwill write-offs (GW_t) + other flows (OTH_t)]	$DSF = PYA + DS\#1098 + DS\#1099 + (DS\#1102 - DS\#1103) + (DS\#1100)$		
Clean surplus earnings (CSE_t)	$DS\#1087 + DSF$		

^aThe replacement of DataStream Company Accounts data with the Worldscope standardized Company Accounts set occurred in April 2004. Since then, the Definitions of the Worldscope items have replaced DataStream accounts data items. If items collected after April 2004, it would require the use of Worldscope definitions

Table 1 Sample collection and variables

	Firms	Firm-year observations
Number of firms and firm-year observations		
The initial collection from DATASTREAM (1992–2000)	1704	8917
Less: firms that are difficulty to investigate the discrepancies in the items, and that have unusual items.	(64)	(353)
Less: firms employ merger accounting	(20)	(128)
Initial observations for the estimation	1620	8436
Less: observations with incomplete line items and observations in the top and bottom 1% of each year's distribution of each line items	(117)	(1715)
Total observations for the estimation	1503	6721

processes reduce the firm-year observations from 8430 to 6721 in this chapter. Table 1 displays the details for all the data collected.

79.5 Empirical Results

79.5.1 Summary Statistics

Table 2 contains the descriptive statistics and correlation matrix for the main variables pooled across time. I delete observations in the top and bottom 1% of each year's distribution of each variable to reduce the effects of outliers. I also deflate all variables by the market value of equity in the beginning of the fiscal year in order to reduce heteroscedasticity in the data. The table provides mean, quartiles, and standard deviation for all deflated earnings constructs, across 1992–2000 and also provides the statistics for news measures.

First, as the earnings variables are displayed in the context of the profit and loss accounts, the mean value can add up across all earnings components. For example, the mean value of pretax earnings (Pretax) equals the sum of the mean values of operating profits (OP), special items (Special), net interest expense (INT), and other nonoperating incomes (ONO); the mean value of clean surplus earnings (CSE) equals the sum of the mean value of Pretax, tax, extraordinary items (Extra), minority interest and preference dividends (Minpref), and dirty surplus flows (DSF). In addition, consistent with previous research in conservatism (Basu 1997; Ball et al. 2000), most of the earnings constructs are negatively skewed (all medians exceed means), reflecting a large number of firms reporting large losses. The mean value of OP, Pretax, Earn, DSE, and CSE (0.09, 0.07, 0.043, 0.040, and 0.02) is smaller than the corresponding median value (0.10, 0.10, 0.07, 0.07, and 0.05). This suggests that large one-time negative transitory items lower the mean of earnings variables.

Another point to note is that the extraordinary items are effectively eliminated since FRS3, as 99.9% of firm-year observations are zero.

Table 2 Descriptive statistics and correlations on the variables during 1992–2000

	(<0.01)	(<0.01)	(<0.01)	(<0.01)	(<0.01)	(<0.01)	(<0.01)	(<0.01)	(<0.01)	(<0.01)	(0.11)	(<0.01)	

Where *OP* denotes operating profits; *Special* denotes special items; *NOP* denotes nonoperating incomes (interest expense plus other operating incomes); *Tax* denotes tax expense; *DSE* is dirty surplus flows; *DSF* is dirty surplus flows; *CSE* is the clean surplus earnings; *ROCF* is reported operating cash flow; *WCA* is working capital accruals; *OOA* is other operating accruals; *DEP* is depreciation; *TACC* is total accruals, inclusive of dirty surplus flows; *MR* is money returns

Moreover, for the operating cash flow variable, the difference between the mean (0.094) and median (0.091) in the operating cash flows is not as evident as other earnings components. However, the values of accruals components (i.e., special, WC, OOA, TACC) are not only left-skewed but also negative. For example, the mean value of working capital (WC), other operating accruals (OOA), and total accruals (TACC) are -0.017 , -0.038 , and -0.020 , respectively, on average negative, and are much lower than the corresponding median values, -0.006 , -0.026 , and -0.006 , respectively. This supports the conservative accounting theory that the timely recognition of bad news in earnings is driven by the accrual component rather than the cash flows component of earnings since the negative skewness in the distribution of earnings components indicates accounting conservatism.

Next, inspection of the mean value of total dirty surplus flows (DSF: -0.019) and inspection of the mean value in each dirty surplus flow show that most of the dirty surplus flows tend to be negative and are generally quite small. Nonzero dirty surplus flows are relatively infrequent: PYA occurs in approximately 10% of firm-year observations, FX in 55%, REV in 14%, and GW in 45%. The mean value of goodwill flows is -0.020 . The magnitude relative to other dirty surplus also suggests that it was the main component of UK dirty surplus flows before FRS10 eliminated dirty surplus treatment of goodwill write-off in 1998. As the mean value of revaluation is positive, the upward revaluation to tangible assets is performed across UK firms.

Finally, Panel A also shows that the return measure is positively skewed. The left skewness in earnings constructs and the right skewness in returns suggest the existence of asymmetry for news recognition in earnings components.

Panel B presents the Pearson and Spearman correlation between the key variables. Note that the correlation between returns and all variables except dirty surplus flows and current operating accruals are greater than zero. Operating profits are significantly positively correlated with operating cash flows and negatively correlated with current operating accruals. Also, operating cash flow is negatively correlated with current accruals, other operating accruals, and total accruals.

79.5.2 Tests for H1a: Asymmetric Timeliness in Operating Cash Flow and Accrual Components

To explore the relation between asymmetric timeliness of earnings and earnings conservatism, this section disaggregates earnings into cash flow components and accrual components, and employs those components in the Basu model. The first hypothesis predicts that the asymmetric timeliness can only be observed in accrual components, but not in operating cash flow.

Table 3 presents the results for the pooled cross-sectional regression in the earnings components of clean surplus earnings, with the dummy variables capturing the intercept and slope effects for the bad news sample. The sign of raw returns is used as an indicator of good and bad news.

^a*MR* is the cum-dividend returns in year *t*; *DUM_{MR}* is a dummy variable that takes the value one when *MR* is negative, and zero otherwise. All variables are scaled by opening market value. The data consists of all the UK industrial firms from 1992 to 2000. Observations falling in the top or bottom 1% of clean surplus (dirty surplus) earnings and returns in each year are excluded. All t-statistics are estimated at the 1% confidence level

The vertical order is based on the context of profit and loss accounts, starting progressively from operating profits to dirty surplus earnings (reported earnings), and the context of the statement of total recognized gains and losses that records dirty surplus flows. Clean surplus earnings are the sum of operating profits, special items, net interest, nonoperating income, tax, extraordinary items, minority and preference dividends, and dirty surplus flows. By construction, the intercept and slope coefficients in clean surplus earnings is exactly identical to the sum of the corresponding coefficients in the above line items. For example, β_2 of the clean surplus earnings is 0.290, the sum of β_2 in operating profits (0.216), special items (0.040), net interest (0.017), nonoperating income (0.005), tax (−0.030), extraordinary items (0.00001), minority and preference dividends (−0.003), and dirty surplus flows (0.045).

Likewise, as earnings equal accruals and cash flow, in each row, the intercept and slope coefficient in the “earnings” column should equal the sum of the corresponding coefficients in the “cash flow” column and the “accrual” column. For example, in the bottom-line row, β_2 in clean surplus earnings (0.290) is equal to β_2 in total cash flows (0.154) and total accruals (0.136). This “adding-up” feature applies to all rows and all columns, and can facilitate my analysis of the relative contribution of operating cash flows and accrual components to the observed asymmetric timeliness effects in earnings.

In this chapter, I am mostly interested in the parameter, β_2 , the incremental response of each earnings component to bad news relative to good news. Under conservative reporting, β_2 is expected to be significantly positive over all accrual components but negligible in operating cash flow components.

Inconsistent with my prediction in H1a, the results show that asymmetric timeliness is not only related to accrual components but also predominantly influenced by cash flow components. As FRS1 (cash flow statement) requires reported operating cash flow to be reconciled between operating profits and operating accruals, the inspection in the first row of “operating profits” provides a broad picture of whether operating accruals or operating cash flow constitutes asymmetric timeliness. Counterintuitively, β_2 in operating profits, along with β_2 in corresponding cash flow and accrual component are significantly different from zero. β_2 in operating profits is 0.216, 79% of which comes from operating cash flow (0.170) and 21% from operating accrual (0.046). Since operating cash flows should not be distorted or influenced by GAAP, this result is inconsistent with the conservatism explanation that asymmetric timeliness of earnings is mainly captured by the accruals rather than the cash flow component of earnings. The preponderance of asymmetric timeliness in operating cash flow calls into question the view that asymmetric timeliness is due to earnings conservatism.

Furthermore, as I move from the row of operating profits downwards to the measure of clean surplus earnings, the pattern that the operating cash flow components dominate the accrual components in the observed asymmetric timeliness of earnings is consistently detected. As “net interest cash flows (INTt)” and “tax payments (Taxt)” are separately identified from operating cash flows in the UK cash flow statement, without loss of insight and with the added convenience of

illustration, I assume INTt and Taxt are cash flow components.¹⁶ Also, “preference dividends and minority interests (Minpref)” is taken as a wholly cash flow item and other nonoperating incomes (ONO) along with dirty surplus flows (DSF) are regarded as accrual components. In such case, the asymmetric timeliness in total cash flows (0.154) is derived from the sum of the asymmetric timeliness in operating cash flows (0.170), net interests (0.017), tax (−0.03), and preference dividends (−0.003); the asymmetric timeliness of total accruals (0.136) is equal to the asymmetric timeliness in operating accruals (0.046), special items (0.040), other non-operating incomes (0.005), extraordinary items (0.0001), and dirty surplus flows (0.045). The asymmetric timeliness in the operating cash flow components (0.154) and the accruals (0.136) can add up to the asymmetric timeliness in the clean surplus earnings (0.290). Again, the contribution of accruals to the overall relation between clean surplus earnings and returns (47%) is smaller than the contribution of operating cash flows (53%). The results refute the theory that asymmetric timeliness is an exact result of earnings conservatism.

79.5.3 Tests for H1b: Evaluating the Application of Three Prominent Standards that Incorporate Asymmetric Verification Criteria

This subsection provides evidence on the relative importance of various accrual components. As Basu (1997, p. 16) states that the accruals process with regards to asset write-offs and write-downs is more likely to reflect conservatism than others, asymmetric timeliness is expected to cumulate in the earnings components related to specific standards that have asymmetric verification for gains and losses. My second hypothesis thus explores the consistency between specific standards that have explicit asymmetric requirements and the asymmetric timeliness in corresponding components.

I first examine subsets of operating accruals by decomposing operating accruals (OA) into working capital accruals (WCA) and long-term operating accruals. WCA consists of change in accounts receivable, change in accounts payable, and changes in inventory; LOA consists of depreciation and other operating accruals. Along with special items and dirty surplus flows, Table 4 reports all the accrual components in the clean surplus earnings.

Consistent with the “adding-up” feature in Tables 3 and 4 shows that the intercept and slope coefficients in “total accruals” equal to the sum of corresponding coefficients in “operating accruals,” “special items,” “other non-operating income,” “extraordinary items,” and “dirty surplus flows.” The coefficient in “operating accruals (OA)” is also equal to the corresponding coefficient in working capital accrual (WCA) [or the coefficient in changes in accounts receivable (ΔAR) plus the coefficient in changes in inventory (ΔINV) minus changes in accounts payable

¹⁶The results are qualitatively similar if those two line items are taken exclusively as accrual components.

Table 4 (continued)

Y^a	α_1	α_2	β_1	β_2	Adj. R^2
	(-2.72) **	(2.93) **		(7.91) **	

^a Y is the accrual measures; MR is the cum-dividend returns in year t ; DUM_{MR} is a dummy variable that takes the value one when MR is negative, and zero otherwise. All variables are scaled by opening market value. The data consists of all the UK industrial firms from 1992 to 2000. Observations falling in the top or bottom 1% of clean surplus (dirty surplus) earnings and returns in each year are excluded. All t-statistics are estimated at the 1% confidence level

^bWhere WCA is working capital accruals; ΔAR is change in accounts receivables; ΔAP is change in accounts payable; ΔINV is change in inventory; DEP is depreciation; LOA denotes long-term operating accruals; OOA is other operating accruals; DSF is dirty surplus flows; CSE is the clean surplus earnings

(ΔAP)] and the coefficient in long-term operating accruals (LOA) [or the coefficient in depreciation (DEP) plus the coefficient in other operating accruals (OOA)]. Likewise, the coefficient in “special items” is identical to the sum of the corresponding coefficient in three subcomponents: “gains /losses from termination of operating,” “gains /losses from sale of fixed assets,” and “gains /losses from reorganisation.”

The results in Table 4 indicate that, across all different level of accruals, the R^2 in the accruals are extremely low and the corresponding asymmetric timeliness effects are quite small. For example, the asymmetric timeliness in the three items of working capital accruals (WCA) is only 0.035 and insignificant; the effect of depreciation (DEP) is also insignificantly small. Consistent with the results in Sect. 79.5.2, the low overall effect of asymmetric timeliness in accrual components casts doubt on the representation of “asymmetric timeliness” for earnings conservatism.

Second, I narrow down my analyses on three prominent standards that incorporate asymmetric specification for gains and losses.

1. LCM Rule: Change in Inventory

SSAP 9 stipulates that stock value should be written down to net realizable value if market value is lower than the recorded value, but not vice versa. Such write-down is usually operated through the decrease of inventory. Table 4 shows that asymmetric timeliness in the changes in inventory (ΔINV) is only 0.024 and not significant. This is in contrast with the prediction that LCM rule should accelerate the timely recognition of bad news and delay the recognition of good news.

2. Impairment Test and Contingent Assets and Liabilities: Exceptional Items

FRS11 specifies the impairment test for tangible assets, intangible assets, and goodwill that assets should be written down if the recoverable amount is less than the

book value, but not vice versa. FRS11 requires that the write-downs of asset value be recorded in exceptional items.

In the UK, there are two types of exceptional items: operating exceptional items and special items. “Operating exceptional items” are disclosed above operating profits that are related to operating activities. This belongs to the component of “other operating accruals (OOA)” in this chapter. “Special items” are the exceptional items that are irrelevant to normal activities and FRS3 requires the separate disclosures after operating profits. FRS3 further specifies that “gains/losses on sales of fixed assets of continued and discontinued operations,” “gains/losses on sale or termination of continued and discontinued operations,” and “gains/losses from reorganisation” should be separately disclosed as special items after operating profit. Therefore, I expect asymmetric timeliness is strong in exceptional items, including “other operating accruals (OOA)” or “special items.”

Nevertheless, the results are mixed. Although Table 4 shows that asymmetric timeliness is not significant in “other operating accruals (OOA),” special items with regards to one-time transitory items in “special items” exhibit asymmetric timeliness of earnings. The effect is significant in special items, but the value of asymmetric timeliness (0.042) is not very large, constituting only 16% of asymmetric timeliness in dirty surplus earnings (0.251) or 14% of clean surplus earnings (0.294).

3. Contingent Asset and Liabilities: Change in Accounts Receivable and Changes in Accounts Payable

Finally, FRS12 is the standard for provision and contingent liabilities. Although this standard does not involve the exercise of write-off and write-down, this standard also has an asymmetric verification requirement for unrealized gains and losses. It requires the provision recognition for future losses but not a pre-recognition of future benefits. The typical example is bad debt provision and warranty expense. Thus, for the application of bad debt provision or warranty provisions, I expect asymmetric timeliness to be pronounced in the working capital accruals such as change in accounts receivable or change in payable. However, Table 4 shows that the effect in both of the components is insignificant. I thus cannot find any evidence with regards to asymmetric timeliness in the application of FRS12.

To summarize, I cannot find much evidence showing that asymmetric timeliness is a consequence of earnings conservatism, with reference to the three standards that have explicit asymmetric verification requirements. I only find some support for the impairment tests as evidenced in the “special items,” though the effect is not very large. All of these results suggest that some factors other than conservatism might cause asymmetric timeliness of earnings.

79.5.4 Tests for H1c: The Role of Dirty Surplus Flows in Asymmetric Timeliness

Finally, the last hypothesis relates to the role of dirty surplus flows in asymmetric timeliness. Dirty surplus flows are the gains and losses not included in the profits and

loss accounts. While it has long been argued that the low transparency of dirty surplus flows can create the loophole for managers to hide bad news, the introduction of “statement of total recognised gains and losses” and “reconciliation of movements in shareholders’ funds” by FRS3 requires the disclosure of dirty surplus flows, which can mitigate the manager’s opportunistic behavior. The hypothesis therefore predicts that asymmetric timeliness in dirty surplus flow should not be pronounced after FRS3.

One way to measure the role of dirty surplus flows (DSF) in clean surplus earnings (CSE) is by comparing the decrease in the adjusted R^2 . The adjusted R^2 decreases from 10.77% for dirty surplus earnings to 7.07% for CSE. This result suggests that dirty surplus flows might create some noise in the earnings-news relationship.

The effects of DSF can also be seen by examining the individual asymmetric timeliness of earnings in five classes of DSF, which is reported in Table 5. It is surprising that the effects in each class of dirty surplus flows are very slight. The explanatory power across five classes of flows is nearly zero, and the incremental coefficient is overall insignificant except goodwill. Among the asymmetric timeliness effects in PYA, FX, REV, GW, and Other (0.0005, -0.003 , 0.001, 0.040, and -0.0009 , respectively), only GW is significant at the 1% level. Before the implementation of FRS10 in 1998, SSAP requires goodwill to be written off against shareholders’ equity. The observed asymmetric timeliness of earnings in goodwill may reflect the fact that acquisition is usually perceived as bad news

Table 5 Asymmetric timeliness of dirty surplus flows in a reverse regression

^a Y is the measure for dirty surplus flows; MR is the cum-dividend returns in year t ; DUM_{MR} is a dummy variable that takes the value one when MR is negative, and zero otherwise. *PYA* denotes prior year adjustments; *FX* denotes foreign exchange translations; *REV* denotes asset revaluations; *GW* denotes goodwill write-offs; *OTH* denotes other recognized gains/losses for the year; *DSF* is dirty surplus flows. All variables are scaled by opening market value. The data consists of all the UK industrial firms from 1992 to 2000. Observations falling in the top or bottom 1% of clean surplus (dirty surplus) earnings and returns in each year are excluded. All t-statistics are estimated at the 1% confidence level

for bidder shareholders when the takeover is carried out with stock offer (Bruner 2002).

To sum up, the components of dirty surplus flows are generally quite small in relation to clean surplus earnings. The results indicate that dirty surplus flows might simply add volatility into reported earnings, given that no apparent asymmetric timeliness effects exist in most of dirty surplus flows and the R^2 also reduces in clean surplus earnings as compared to dirty surplus earnings. While it is often argued that dirty surplus accounting in the UK can conceal some value-relevant information, particularly bad news being prioritized, the introduction of FRS3 in 1992, which attempts to achieve full articulation of financial performance earnings by means of the statement of total recognized gains and losses, might constrain managers' incentives to disclose bad news in the reserves if all aspects of earnings information are disclosed with equal prominence.

79.6 Further Analysis of New Measures

To examine whether the results shown in Sect. 79.5 are sensitive to the way news measures are determined, I also use excess value created (EVC) as an additional news proxy. EVC is defined as the excess of money returns over the required returns from shareholders. In other words, EVC incorporates shareholders' cost of capital in determining the performance and is suggested to be a better performance measure than money returns (MR) for shareholders. Table 6 provides the results for the decomposition analysis based on the news proxy, EVC. Cost of equity capital is determined by CAPM: 5% risk premium multiplied by firm-specific beta plus 3-month T-bill rate at time t .

I find that results based on EVC are qualitatively similar to those based on news proxy, MR, as shown in Table 3. I hence conclude that the news benchmark do not substantially influence my results.

79.7 Conclusion

Since Basu (1997), the higher response coefficient of earnings to negative returns than positive returns has been attributed to earnings conservatism, and termed as "asymmetric timeliness of earnings" (Hsu et al. 2011, 2012; Chan and Hsu 2013; Chan et al. 2015; Wang et al. 2017). This measure of asymmetric timeliness has been extensively used in assessing accounting conservatism and its economic consequences. Nevertheless, there is some doubt as to the sources of asymmetric timeliness of earnings. In particular, Dietrich et al. (2007) have argued that Basu's results are completely explained by coefficient bias due to an econometric artefact, as the effect can be observed in the data where, by construction, conservatism does not exist.

^aEVC is the excess of money returns over the cost of equity capital, which is determined by CAPM. 3-month T-bill rate at time t plus firm-specific beta times 5% risk premium t; DUM_{ec} is a dummy variable that takes the value one when EVC is negative, and zero otherwise. All variables are scaled by opening market value. The data consists of all the UK industrial firms from 1992 to 2000. Observations falling in the top or bottom 1% of clean surplus (dirty surplus) earnings and returns in each year are excluded. All t-statistics are estimated at the 1% confidence level

Motivated by the prediction that asymmetric timeliness of earnings due to conservatism ought to be more pronounced in certain earnings components than in others, I measure asymmetric timeliness for components of earnings. The study is the first to employ an innovative decomposition analysis to analyze the source of asymmetric timeliness of earnings across all earnings components. I decompose clean surplus earnings across line items and across accrual and cash flow components, and seek evidence as to whether the incidence of asymmetric timeliness across components is consistent with the theory that such asymmetric timeliness is due to accounting conservatism. The innovative feature of the study is that the asymmetric timeliness in aggregated earnings can be disaggregated into asymmetric timeliness in components. The asymmetric timeliness of clean surplus earnings is exactly identical to the sum of asymmetric timeliness in the subsumed components, the characteristics of which is very helpful in exploring the sources of asymmetric timeliness of earnings.

With articulated dataset, where clean surplus earnings are articulated with net dividends and consecutive changes in book value, the results show that asymmetric timeliness of earnings is not directly related with earnings conservatism. When clean surplus earnings are decomposed into “accrual” components and “cash flow” components, the asymmetric timeliness of earnings in “cash flow” components is substantially higher than the asymmetric timeliness effect in “accrual” components. The explanatory ability of accrual components to reflect contemporaneous good and bad news measures is also extremely low. This is inconsistent with the conservatism proposition that accrual components drive accounting conservatism. The decomposition across line items also finds little evidence with regard to the application of three prominent standards that incorporate asymmetric verification criteria.

These results call into question whether asymmetric timeliness of earnings is a consequence of conservatism. The study provides important implications to accounting researchers who apply the measure in the conservatism study. In particular, the study in the comparison of conservatism across different governance systems and accounting regimes (Ball et al. 2000, 2003) perhaps needs a second look when the interpretation generally given to the governance system or accounting regime with higher asymmetric timeliness of earnings is that the accounting regime is fundamentally more conservative.

Appendix 1 The UK Financial Statements

I extract the financial statements of Boots Plc. as of 1999 to demonstrate the presentation formats of the UK “profit and loss accounts,” the “statement of total recognised gains and losses,” and “reconciliation of movements in shareholders’ funds.”

1. Format of the UK profit and loss accounts

	Notes	Before exceptional items 1999 £m	Exceptional items (note 3) 1999 £m	Total 1999 £m

Note 1: ⊙ denotes the line items covered in this chapter

2. Statement of total recognized gains and losses

It is suggested that the profit and loss account is not sufficient on its own as a report of a company's financial performance. FRS3 introduces the statement of total recognized gains and losses to present details of the other elements making up a company's performance.

Statement of total recognised gains and losses	1999 £m
Profit for the financial year attributable to shareholders	23.9
Deficit on revaluation of properties ☆ ◎	(1.4)
Impairment losses on revalued assets ☆ ◎	(1.7)
Currency translation differences on foreign currency net investments ☆ ◎	3.0
Other gains and losses ☆ ◎	0.4
Total recognised gains and losses for the year	24.2
Prior period adjustment (see note 20) ☆ ◎	12.0
Total gains and losses recognised since last annual report	36.2

3. Reconciliation of movements in shareholders' funds

Reconciliation of Movements in Shareholders' Funds	1999 £m
Total recognised gains and losses for the year	24.2
Dividends	(214.5)
New share capital issued (net of expenses)	8.8
Goodwill relating to acquisitions prior to 1st April 1998 ☆ ◎	(1.4)
Goodwill released on disposal of businesses ☆ ◎	312.2
Scrip dividends	-
Net increase in shareholders' funds	129.3
Opening shareholders' funds	1,650.9
Closing shareholders' funds	1,780.2

Note 1: ◎ denotes the line items covered in this chapter

Note 2: ☆ denotes the five classes of dirty surplus flows. There are five classes of dirty surplus flows: (1) asset revaluation, (2) currency translation, (3) other gains and losses, (4) prior year adjustment, (5) goodwill write-offs and disposition. All dirty surplus flows except goodwill are disclosed in the "statement of total recognised gains and losses." Goodwill acquisition and disposition are recorded in the "reconciliation of movements in shareholders' funds."

Note 3: Financial Reporting Standard 10: *Goodwill and Intangible Assets* requires purchased goodwill and intangible assets to be capitalized and amortized through the profit and loss account over their useful economic lives. FRS10 eliminated this dirty surplus treatment of goodwill write-offs in 1998

Abstract

Securities trading is one of the few business activities where a few seconds processing delay can cost a company a big fortune. The growing competition in the market exacerbates the situation and pushes further toward instantaneous trading even in a split second. The key lies on the performance of the underlying information system. Following the computing evolution in financial services, it was a centralized process to begin with and gradually decentralized into a distribution of actual application logic across service networks. Financial services have a tradition of doing most of its heavy lifting financial analysis in overnight batch cycles. In securities trading, however, it cannot satisfy the need due to its ad hoc nature and requirement of fast response. New computing paradigms, such as grid and cloud computing, aiming at scalable and virtually standardized distributed computing resources, are well suited to the challenge posed by capital market practices. Both have been gaining popularity to serve as a production environment for finance services in recent years, which further leads to the recent rise of big data and the success of large-scale machine learning, impacting on broad and diverse domains, such as finance services. In this entry, the core computing competence for financial services is examined. A comparison of grid and cloud will be briefly described. How the underlying algorithm for financial analysis can take advantage of grid and cloud environment is presented. One of the most popular practiced algorithms Monte Carlo simulation is used in our cases study for option pricing and risk management. The various distributed computational platforms are carefully chosen to demonstrate the performance issue for financial services, which also extends to applications of big data and machine learning.

80.1 Introduction

80.1.1 Information Technology for Financial Services

The finance service industry involves a broad range of organizations such as banks, credit card companies, insurance companies, consumer finance companies, stock brokerages, investment funds, and some government-sponsored enterprises. The industry represents a significant share of the global market. Information technology (IT) in the financial service industry is considered as an indispensable tool for its competitiveness in the market. The IT spending in financial service industry also grows (Calen 2010). In such a scale of market size, the impact directly from the use of advanced IT brings on the financial service industry.

The structure of the industry has changed significantly in the last two decades as companies, which are not traditionally viewed as financial service providers, have taken advantage of opportunities created by technology entering the market. New technology-based services keep emerging. These changes are a direct result of the interaction of technology with the industrial environment, such as economic atmosphere, societal pressures, and the legal/regulatory environment in which the financial service industry operates. The effects of IT on the internal operations, the structure, and the types of services offered by the financial service industry have been particularly profound (Phillips et al. 1984; Hauswald and Marquez 2003; Griffiths and Remenyi 2003). IT technology has been and continues to be both a motivator and facilitator of change in the financial service industry, which ultimately leads to competitiveness of the industry. The change is in particular radical after 1991 when World Wide Web was invented by Tim Berners-Lee and his group for information sharing in the community of high energy physics. It was later introduced to the rest of the world, which subsequently changed the face of how people do business today.

Informational considerations have long been recognized to determine not only the degree of competition but also the pricing and profitability of financial services and instruments. Recent technological progress has dramatically affected the production and availability of information, thereby changing the nature of competition in such informationally sensitive markets. Hauswald and Marquez (2003) investigate how advances in information technology (IT) affect competition in the financial services industry, particularly credit, insurance, and securities markets. Two aspects of improvement in IT are focused – better processing and easier dissemination of information. In other words, two dimensions of technology progress that affects competition in financial services can be defined as advances in the ability to process and evaluate information, and in the ease of obtaining information generated by

competitors. While better technology may result in improved information processing, it might also lead to low-cost or even free access to information through, for example, informational spillovers. They show that in the context of credit screening, better access to information decreases interest rates and the returns from screening. On the other hand, an improved ability to process information increases interest rates and bank profits. Hence, predictions regarding financial claims' pricing hinge on the overall effect ascribed to technological progress. Their results conclude that in general financial markets' informational asymmetries drive profitability.

The viewpoint of Hauswald and Marquez is adopted in this work. Assuming competitors in the dynamics of financial market possess similar capacity, the informational asymmetries can be created sometimes only between seconds and now are possible to be achieved through the outperformance of underlying IT platforms.

80.1.2 Competitiveness Through IT Performance

Following the computing evolution in financial services, it was a centralized process to begin with and gradually decentralized into a distribution of practical trading application logic across service networks. Financial services have a tradition of doing most of its heavy lifting financial analysis in overnight batch cycles. However, in securities trading, it cannot satisfy the need due to its ad hoc nature and requirement of fast response.

New computing paradigms, grid and cloud computing, emerged in the last decade. It was incorporated into the core context of a well-referenced Atkins' report of National Science Board of the USA, namely "Revolutionizing Science and Engineering Through Cyberinfrastructure" (Atkins et al. 2003), which lays down a visionary path for future IT platform development of the world. One way to observe this trend is from statistics of Google Trends in the global search interest over time of key phrases in the finance sector including cluster computing, grid computing, and cloud computing, which represent three main stream computing paradigms in high-performance quantitative analysis, and big data and machine learning, which have been emerging as a major emphasis on data-centric computing with emphasis of insight from data (Fig. 1).

Cluster computing is a group of coupled computers that work closely together so that in many respects they can be viewed as though they are a single computer. They are connected with high-speed local area networks, and the purpose is usually to gain more compute cycles with better cost performance and higher availability. The grid computing aims at virtualizing scalable geographically distributed computing and observatory resources to maximize compute cycles and data transaction rates with minimum cost. Cloud computing is more of a recent development owing to the similar technology used in global information service providers, such as Google, Amazon, etc. The cloud is referred to as a subset of Internet if to be explained in a simplest fashion. Within the cloud, the computers also talk with servers instead of communicating with each other similarly to that of Peer-to-peer computing (Milojicic et al. 2002). There are no definitive definitions for the above terminology.

Fig. 1 The trend history on search interest in the finance sector from Google Trends

However, people tend to view clusters as one of foundational components of grids, or grids as a metaccluster on wide area networks. This is also known as horizontal integration. The cloud virtualizes further the compute, store, and network in a utility sense and provides an interface between users and grids. We refer to Foster et al. (2008) and Yelick et al. (2011) for a comparison. This perspective considers grids as a backbone of Cyberinfrastructure to support the clouds. Similarly, in the early days of development of grids, there is a so called “@HOME” style PC grids (Korpela et al. 2001), which are exactly working on at least ten thousands of PCs, in which owners of PCs donate their CPU times when their machines are idle. The PC grids can be specifically categorized as clouds.

Figure 1 shows that cluster and grid computing are of less interest, which also in turn more mature in financial services. Cloud computing since its introduction in mid-2007 still has momentum to develop further. The new rising technology is big data (Bughin et al. 2010), which implies a paradigm shift from compute-centric, network-centric gradually to data-centric computing and has been growing significantly since then. There is also a dramatical increase of interest in machine learning. The phenomenon is still based on the advance of system performance. Clusters are the major market products, either in supercomputers from big vendors, such as Cray, IBM, and NEC, or from an aggregation of computers in university research laboratories. It should be noted that accelerators, such as graphic process unit (GPU), field programmable gate array (FPGA), also play a crucial role in HPC clusters. The introduction of coprocessor plays a key role, which is not discussed here and considered as part of the above compute paradigms. Figure 1 also implies constant market need for high-performance computing. The performance and security issues are fundamental to general distributed and parallel computing, which also remain as a challenge to cluster, grid, cloud, big data, and machine learning (Lauret et al. 2010; Ghoshal et al. 2011; Ramakrishnan et al. 2011). Performance models in compute-based grid and cloud-enabled environment are adopted in this work. The general definitions of grid and cloud computing will be introduced. To tackle the core

performance issue, grids are chosen to demonstrate how fundamental financial calculations can be improved, hence leverage the financial service.

In this chapter, the core computing competence for financial services will be examined and how underlying algorithms for financial analysis can take advantage of grid, big data, and cloud-enabled environment scrutinized. One of the most popular practiced algorithms is Monte Carlo simulation (MCS), and it will be specifically used in our case studies for calculations of option pricing and for value at risk (VaR) in risk management.

Four grid-, Big Data-, and cloud-enabled platforms are carefully chosen to exploit the performance issue for financial services. The first one is traditional grid platform with heterogeneous and distributed resources. Digital packets are usually connected via optical fibers. For long distance, depending on network traffics, it will produce approximately 150 ~ 300 microseconds (mm) latency across Pacific Ocean. This is the physical constrain of light speed when traveling through the fiber channels. Therefore, even in a split second, packets can still travel to anywhere in the world. The Pacific Rim Applications and Grid Middleware Assembly (PRAGMA) grid is a typical example, which linked with 14 countries and 36 sites. The system is highly heterogeneous. The computer nodes mounted to PRAGMA grid range from usual PC clusters to high-end supercomputers. The second one is a special Linux, or DRBL, PC cluster. It converts a system into a homogenous Linux system and exploits the compute cycles of the cluster. The intention is to provide dynamic and flexible resources to cope better with uncertainty of the traders' cycle demand. A PC grid is chosen to demonstrate finance services that can be effectively conducted through a cloud-enabled computing. The usefulness of PC grid is based on the fact that 90% of CPUs' time of PCs was in idle status. Finally, a state-of-the-art Cloud-enabled hybrid high-performance system is introduced, which allows to conduct big data computing as well as the machine learning in scale.

80.2 Performance Enhancement

In this section, two types of grid systems, compute intensive and data intensive, respectively, are introduced. The classification of the types is based on various grid applications. Traditionally, the grid systems provide a general platform to harvest, or to scavenge if used only in idle status, compute cycles for a collection of resources across boundaries of institutional administration. In the real world, most applications are in fact data centric. For example, in a trading center, it collects tick-by-tick volume data from all related financial markets and is driven by informational flows, hence typical data centric. However, as noted in Sect. 80.3, the core competence still lies on the performance enhancement of the IT system. The following two sub-sections give more details of compute-intensive as well as data-intensive grid systems by a survey of the current development of grids specifically for financial services. In some cases, e.g., high frequency data with real-time analysis, two systems have to work together to get better performance. Our emphasis will be more on compute-intensive grid system.

Grid was coined by Ian Foster (Foster and Kesselman 2004). The definition of grid thus far is well accepted and has been stably used up to now. The virtual organization (VO) has strong implication of community-driven and collaborative sharing of distributed resources. The advance of the development of optical fiber network in recent years plays a critical role of why grids can be a reality. It is also the reason why now the computing paradigm has shifted to distributed/grid computing.

Additionally, perhaps the most generally useful definition is that a grid consists of shared heterogeneous computing and data resources networked across administrative boundaries. Given such a definition, a grid can be thought of as both an access method and a platform, with grid middleware being the critical software that enables grid operation and ease-of-use.

The term “cloud computing” has been used to refer to different concepts, models, and services over the last few years. The definition for cloud computing provided by the National Institute of Standards and Technology (NIST) is well received in the IT community, which defines cloud computing as a model for enabling convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort of service provider interaction (Mell and Grance 2011). The model gains popularity in the industry for its emphasis on pay-as-you-go and elasticity, the ability to quickly expand and collapse the utilized service as demand requires. Thus, new approaches to distributed computing and data analysis have also emerged in conjunction with the growth of cloud computing. These include models like MapReduce (Dean and Ghemawat 2004) and scalable key-value stores like Big Table (Chang et al. 2006). From the high-performance computing perspective, could computing technology allows users to have the ability to get on-demand access to resources to replace or supplement existing systems, as well as the ability to control the software environment? Yet, the core competence still lies on the performance of financial calculation and further of the transactions of financial processes. This work will focus on the core competence in financial calculation based on grid- and cloud-like environment. Grid computing technology will be used to explain how the core financial calculations can be significantly accelerated in various distributed and parallel computing environments. The calculation models in this work can be easily migrated to pure cloud environments.

80.2.1 Compute-Intensive IT Systems

The recent development of computational finance based on grids is hereby scrutinized and remarks given. Our major interest is to see if the split second performance is well justified under the grid architecture. Also, real-time issue with real market-parametric data should be used as input for practical simulation. In addition, issues of inter-system, inter-disciplinary, geographical distribution of resources and the degree of virtualization are crucial to the success of such a grid. The chosen projects are reviewed and discussed as follows:

80.2.1.1 PicsouGrid

This is a French grid project for financial service. It provides a general framework for computation finance and targets on applications of options trading, options pricing, Monte Carlo simulation, aggregation of statistics, etc. (Stokes-Rees et al. 2007). The key for this development is the implementation of the middleware ProActive. ProActive is an in-house Java library for distributed computing developed by INRIA Sophia Antipolis, France. It provides transparent asynchronous distributed method calls and is implemented on top of Java RMI. It is also used in commercial applications. It also provides fault tolerance mechanism. The architecture is shown in Fig. 2, which is very similar to most of grid applications apart from the software stack used. The option pricing was tested in approximately 894 CPUs. The underlying computer systems are heterogeneous. The system is used for metacomputing. As a result, the system has to specifically design to orchestrate and to synchronize and resynchronize whole distributed processes for one calculation. Once the grid system requires synchronization between processes, which imply stronger coupling of algorithm of interest, the performance will be seriously affected. There is no software treatment to solve such problems and should be tackled by physical infrastructure, e.g., optical fiber network with Layer 2 light path.

80.2.1.2 FinGrid

FinGrid stands for financial information grid. Its study includes components of bootstrapping, sentimental analysis, and multiscale analysis, which focus on information integration and analysis, e.g., data mining. It takes advantage of the huge collection of numerical and textual data simultaneously to emphasize the study of societal issues (Amad et al. 2004; Ahmad et al. 2005; Gillam et al. 2005). The architecture of FinGrid is shown in Fig. 3. It is a typical three-tier system, in which the first tier facilitates the client in sending a request to one of the services: text

Fig. 2 Architecture of PicsouGrid for option pricing based on Monte Carlo simulation

Fig. 3 The architecture of financial information grid

processing service or time series service; the second tier facilitates the execution of parallel tasks in the main cluster and is distributed to a set of slave machines (nodes); and the third tier comprises the connection of the slave machines to the data providers. This work focuses on small-scale and dedicated grid system. It pumps in real and live numerical and textual data from say Reuters and performs real-time sophisticated data mining analysis. This is a good prototype for Financial grid. However, it will encounter similar problems as that of PicasouGrid if it is to scale up. The model is more successful in automatically combining real data and the analysis.

- IBM Japan collaborated with life insurance company and adopted the PC grids concept to scavenge more compute cycles (Tanaka 2003):

In this chapter, an integrated risk management system (see Fig. 4) is modified, in which the future scenarios of the red circle of Fig. 4 are sent via grid middleware to a cluster of PCs. According to the size of the given PCs, the number scenarios are then divided in a work-balanced manner for each PC. This is the most typical use of compute-intensive grid systems and a good practice for production system. However, the key issues that were discussed in the above two cases cannot be answered in this chapter. Similar architecture can also be found in EGrid (Leto et al. 2005).

- UK e-Science developed a grid service discovery in the financial market sector focusing on integration of different knowledge flows (Bell and Ludwig 2005).

From application's viewpoint, business and technical architecture of financial service applications may be segmented by product, process, or geographic concerns. Segmented inventories make inter silo reuse difficult. The service integration model is adopted and a loosely coupled inventory – containing differing explicit capability knowledge. Three use-cases were specifically chosen in this work to explore the use of semantic searching:

Use-case 1 – Searching for trades executed with a particular counterparty.

Use-case 2 – Valuing a portfolio of interest rate-derivative products.

Fig. 4 Architecture of integrated risk management system

Use-case 3 – Valuing an option-based product. The use-cases were chosen to provide examples of three distinct patterns of use – aggregation, standard selection, and multiple selection. The architecture (see Fig. 5) is bound specifically with the use-cases. The advantage for grid in this case is that it can be easily tailored into specific user need to integrate different applications, which is a crucial strength of using grid.

80.2.2 Data-Intensive IT Systems

Grid in financial services from the perspective of web services toward financial services industry. The perspective is more on the transactional side. Once the

Fig. 5 The Semantic discovery for grid services architecture

bottleneck of compute cycle is solved, the data-centric nature plays the key role again. The knowledge flows back to the customized business; logic should provide the best path for users to access the live data of interest. There is no strong focus of development on this data-intensive grid system. Even in FinGrid, which claims in streaming live data for real-time analysis, the data issue remains part of compute grids. However, the need for dynamic data management is obvious as mentioned in Amad et al. (2004).

RBNB DataTurbine was used to support global environmental observatory network, which involves linking with tens of thousands of sensors and is able to obtain the observed data online. It meets grid/cyberinfrastructure (CI) requirements with regard to data acquisition, instrument management, and state-of-health monitoring including reliable data capture and transport, persistent monitoring of numerous data channels, automated processing, event detection and analysis, integration across heterogeneous resources and systems, real-time tasking and remote operations, and secure access to system resources. To that end, streaming data middleware provides the framework for application development and integration.

Use cases of RBNB DataTurbine include adaptive sampling rates, failure detection and correction, quality assurance, and simple observation (see Tilak et al. 2007). Real-time data access can be used to generate interest and buy-in from various stakeholders. Real-time streaming data is a natural model for many applications in observing systems, in particular event detection and pattern recognition. Many of these applications involve filters over data values, or more generally, functions over sliding temporal windows. The RBNB DataTurbine middleware provides a modular, scalable, robust environment while providing security, configuration management, routing, and data-archival services. The RBNB DataTurbine system acts as an intermediary between dissimilar data monitoring and analysis devices and applications. As shown in Fig. 6, a modular architecture is used, in which a source or “feeder” program is a Java application that acquires data from an external live data source and feeds it into the RBNB server. Additional modules display and manipulate data fetched from the RBNB server. This allows flexible configuration where RBNB serves as a coupling between relatively simple and “single purpose” suppliers of data and consumers of data, both of which are presented a logical grouping of physical data sources. RBNB supports the modular addition of new sources and sinks with a clear separation of design, coding, and testing. From the perspective of distributed systems, the RBNB DataTurbine is a “black box” from which applications and devices send data and receive data. RBNB DataTurbine handles all data management operations between data sources and sinks, including reliable transport, routing, scheduling, and security. RBNB accomplishes this through the innovative use of memory and file-based ring buffers combined with flexible network objects. Ring buffers are a programmer-configurable mixture of memory and disk, allowing system tuning to meet application-dependent data management requirements. Network bus elements perform data stream multiplexing and routing. These elements combine to support seamless real-time data archiving and distribution over existing local and wide area networks. Ring buffers also connect directly to client applications to provide streaming-related services including data stream subscription, capture, rewind, and replay. This presents clients with a simple, uniform interface to real-time and historical (playback) data.

80.2.3 Cloud-Enabled Big Data and Machine Learning IT Systems

80.2.3.1 Big Data and MapReduce Systems

Big Data emerged as a leading IT technology development in the early 2010s. The main driving force behind can be considered as the disruption of smart phones and the broad use of Internet. The definition of big data is formally given by NIST (Chang and Grady 2015) which consists of extensive datasets, primarily in the characteristics of volume, variety, velocity, and/or variability, that require a scalable architecture for efficient storage, manipulation, and analysis. The most popular big data tool that has been widely adopted is Hadoop (Cutting 2018). It adopts similar map-reduce algorithm that Google search used and is made to be an open source so that the general public can be benefited. The ecosystem of Hadoop has been

Fig. 6 Taiwan system architecture

booming since then. The idea is to cluster distributed storages into a single virtual one. Data is so-called sharded into pieces with multiple copies, usually three copies, scattering in the clustered distributed storages. To take advantage of the architecture, one needs to use map-reduce algorithm. Google search uses page ranking algorithm, which is also one kind of map-reduce realization (Bhawiyuga and Kirana 2016).

80.2.3.2 Cloud-Enabled Hybrid Systems for Big Data and Machine Learning

Alongside with the development of IT systems for big data, there has been a crucial development in coprocessors that are specifically used to accelerate the performance of the original systems. One of the coprocessors in mainstream is the graphic process unit (GPU), which is originally designed to accelerate computer graphics in usual personal computers. The performance of GPU in graphics has been enhanced not

only as exceedingly powerful but also affordable for layman due to its mass market in game industry. NVIDIA is one of the leaderships and the most well received in GPU solutions. It was gradually introduced to and developed for HPC in the 2010s, which leads to the current hybrid system design.

The hybrid system design is currently in mainstream. In the newest TOP 500 list, which ranks the most powerful supercomputers in the world, published in December 2020, six out of the top ten supercomputers adopt NVIDIA acceleration, such as its Tesla V100 and A100 GPUs. For example, Summit, an IBM-built system at the Oak Ridge National Laboratory (ORNL), remains the fastest system in the USA with a performance of 148.8 petaflops. Summit has 4356 nodes, each one housing two 22-core Power9 CPUs and six NVIDIA Tesla V100 GPUs. NVIDIA also introduced GPGPU (general purpose GPU) embedded into supercomputers, which can be used for floating point numerical analysis directly without sacrificing performance significantly.

One of the state-of-the-art systems is Taiwan 2, which is used to conduct our experiments. Taiwan 2 system consists of 252 compute nodes. Each node contains two Intel Gold Xeon CPUs, eight NVIDIA Tesla V100 GPUs, and 768GB memory with a total performance of nine petaflops. OpenStack and Kubernetes are used to virtualize system resources of HPC and OpenShift for pipeline services specifically for data analytics. The system exemplifies how such convergence can be achieved. Due to its capability, the system is also known as artificial intelligence (AI) supercomputer. The general architecture of Taiwan system is shown in Fig. 6.

Finally, data privacy and security are fundamental to big data and machine learning not only specifically to financial services. Most of the current development is based on algorithms with distributed IT systems, e.g., federated learning (Yang et al. 2019; Xian et al. 2020) and differential privacy (Gandhi and Jayanti 2020). There are system level studies specifically on cloud-based hybrid systems, which are beyond the scope of this chapter and worth a separate entry for introduction.

80.3 Distributed and Parallel Financial Simulation

In the previous sections, we addressed issues of incorporating IT technology for financial competitiveness and derive that the core lies on the performance of the IT platform, provided the competitors in the market have similar capacity and are equally informed. Grid technology, as the leading IT development in high-performance computing, is introduced as the cutting edge IT platform to meet our goal. Many companies have adopted similar technology of grids with success as mentioned in Sect. 80.1. There are also increasing research interests, which result in the work discussed in Sect. 80.2. Better performance, however, cannot be achieved by merely using a single architecture as observed in the cases of Sect. 80.2. The architecture obviously has to be specifically chosen for the analysis of interest. Simultaneously, the analysis procedures have to be tailored into the chosen architecture for performance fine tune.

In this section, we will introduce and discuss analysis procedures of financial simulation and how to tailor the analysis procedures into grid architectures by distribution and parallelism. The popular calculations for option pricing and for value at risk (VaR) in trading practice are used to serve the purpose. The calculation is based on Monte Carlo simulation, which is chosen not only because it is a well-received approach due to the absence of straightforward closed form solutions for many financial models, but also a numerical method intrinsically suited to mass distribution and mass parallelism. The success of Monte Carlo simulation lies on the quality of random number generator, which will be discussed in detail at the end of the section.

80.3.1 Financial Simulation

There is a wide variety of sophisticated financial models developed, to name a few, ranging from analysis in time series, fractals, nonlinear dynamics, and agent-based modeling to applications in optional pricing, portfolio management, market risk measure, etc. (Schmidt 2005), in which option pricing and VaR calculations of market risk measure can be considered crucial and one of the most practiced activities in market trading.

80.3.1.1 Option Pricing

An option is an agreement between two parties to buy or sell an asset at a certain time in the future for a certain price. There are two types of options:

Call Option: A call option is a contract that gives the right to its holder (i.e., buyer) without creating an obligation, to buy a prespecified underlying asset at a predetermined price. Usually, this right is created for a specific time period, e.g., 6 months, or more. If the option can be exercised only at its expiration (i.e., the underlying asset can be purchased only at the end of the life of the option), the option is referred to as a European style call option (or European call). If it can be exercised on any date before its maturity, the option is referred to as an American style call option (or American call).

Put option: A put option is a contract that gives its holder the right without creating the obligation, to sell a prespecified underlying asset at a predetermined price. If the option can be exercised only at its expiration (i.e., the underlying asset can be sold only at the end of the life of the option), the option is referred to as a European style put option (or European put). If it can be exercised any date before its maturity, the option is referred to as an American style put option (or American put).

To price options in computational finance, we use the following notation: K is the strike price; T is the time to maturity of the option; S_t is the stock price at time t ; r is the risk-free interest rate; μ is the drift rate of the underlying asset (a measure of the average rate of growth of the asset price); σ is the volatility of the stock; and

V denotes the option value. Here is an example to illustrate the concept of option pricing. Suppose an investor enters into a call option contract to buy a stock at price K after 3 months. After 3 months, the stock price is S_t . If $S_t > K$, then one can exercise one's option by buying the stock at price K and by immediately selling in the market to make a profit of $S_t - K$. On the other hand, if $S_t \leq K$, then one should not exercise the option to buy the stock. Hence, we see a call option to buy the stock at time T at price K will get payoff $(S_T - K)^+$, where $(S_T - K)^+ \equiv \max(S_T - K, 0)$ (Schmidt 2005; Hull 2003).

80.3.1.2 Market Risk Measurement Based on VaR

Market risks are the prospect of financial losses, or gains, due to unexpected changes in market prices and rates. Evaluating the exposure to such risks is nowadays of primary concern to risk managers in financial institutions. Until the late 1980s, market risks were estimated through gap and duration analysis (interest rates), portfolio theory (securities), sensitivity analysis (derivatives), or scenarios analysis. However, all these methods either could be applied only to very specific assets or relied on subjective reasoning.

Since the early 1990s, a commonly used market risk estimation methodology has been the value at risk (VaR). A VaR measure is the highest possible loss L incurred from holding the current portfolio over a certain period of time at a given confidence level (Dowd 2002)

$$P(L > VaR) \leq 1 - c \quad (1)$$

where c is the confidence level, typically 95%, 97.5%, or 99% and P is cumulative distribution function. By convention, $L = -\Delta X(\tau)$, where $\Delta X(\tau)$ is the relative change (return) in portfolio value over the time horizon τ . Hence, large values of L correspond to large losses (or large negative returns).

The VaR figure has two important characteristics: 1) It provides a common consistent measure of risk across different positions and risk factors; and 2) it takes into account the correlations or dependencies between different risk factors. Because of its intuitive appeal and simplicity, it is no surprise that in a few years value at risk has become the standard risk measure used around the world. However, VaR has a few deficiencies, among them the nonsubadditivity – a sum of VaR's two portfolios can be smaller than the VaR of the combined portfolio. To cope with these shortcomings, Artzner et al. proposed an alternative measure that satisfies the assumptions of a coherent risk measure. The expected shortfall (ES), also called expected tail loss (ETL) or conditional VaR, is the expected value of the losses in excess of VaR:

$$ES = E(L|L > VaR) \quad (2)$$

It is interesting to note that although new to the finance industry – expected shortfall has been familiar to insurance practitioners for a long time. It is very similar to the mean excess function which is used to characterize claim size distribution (Cizek et al. 2011).

The essence of the VaR and ES computations is estimation of low quantiles in the portfolio return distributions. Hence, the performance of market risk measurement methods depends on the quality of distribution assumptions on the underlying risk factors. Many of the concepts in theoretical and empirical finance developed over the past decades, including the classical portfolio theory, the Black-Scholes-Merton option pricing model, and even the RiskMetrics variance-covariance approach to VaR, rest upon the assumption that asset returns follow a normal distribution. The assumption is not justified by real market data. Our interest is more on the calculation side. For interested readers, we refer further to Weron (2004).

80.3.2 Monte Carlo Simulation

80.3.2.1 Monte Carlo and Quasi-Monte Carlo Methods

In general, Monte Carlo (MC) and Quasi-Monte Carlo (QMC) methods are applied to estimate the integral of function $f(x)$ over $[0, 1]^d$ unit hypercube where d is the dimension of the hypercube.

$$I = \int_{[0, 1]^d} f(x) dx \quad (3)$$

In MC methods, I is estimated by evaluating $f(x)$ at N independent points randomly chosen from a uniform random distribution over $[0, 1]^d$ and then evaluating the average

$$\hat{I} = \frac{1}{N} \sum_{i=1}^N f(x_i) \quad (4)$$

From the law of large numbers, $\hat{I} \rightarrow I$ as $N \rightarrow \infty$. The standard deviation is

$$\sqrt{\frac{1}{N-1} \sum_{i=1}^N (f(x_i) - I)^2} \quad (5)$$

Therefore, the error of MC methods is proportional to $N^{-1/2}$.

QMC methods compute the above integral based on low-discrepancy (LD) sequences. The elements in a LD sequence are “uniformly” chosen from $[0, 1]^d$ rather than “randomly.” The discrepancy is a measure to evaluate the uniformity of points over $[0, 1]^d$. Let $\{q_n\}$ be a sequence in $[0, 1]^d$, and the discrepancy D_N^* of q_n is defined as follows, using Niederreiter’s notation (Niederreiter 1992):

$$D_N^*(q_n) = \sup_{B \in [0, 1]^d} \left| \frac{A(B, q_n)}{N} - v_d(B) \right| \quad (6)$$

where B is a subcube of $[0, 1]^d$ containing the origin, $A(B, q_n)$ is the number of points in q_n that fall into B , and $v_d(B)$ is the d -dimensional Lebesgue measure of B . The elements of q_n are said to be uniformly distributed if its discrepancy $D_N^* \rightarrow 0$ as $N \rightarrow \infty$. From the theory of uniform distribution sequences (Kuipers and Niederreiter 1974), the estimate of the integral using a uniformly distributed sequence $\{q_n\}$ is $\hat{I} = \frac{1}{N} \sum_{n=1}^N f(q_n)$, as $N \rightarrow \infty$ then $\hat{I} \rightarrow I$. The integration error bound is given by the Koksman-Hlawka inequality:

$$\left| I - \frac{1}{N} \sum_{n=1}^N f(q_n) \right| \leq V(f) D_N^*(q_n) \quad (7)$$

where $V(f)$ is the variation of the function in the sense of Hardy and Krause (see Kuipers and Niederreiter 1974), which is assumed to be finite.

The inequality suggests a smaller error can be obtained by using sequences with smaller discrepancy. The discrepancy of many uniformly distributed sequences satisfies $O((\log N)^d/N)$. These sequences are called lowdiscrepancy (LD) sequences (Chen et al. 2006). Inequality (7) shows that the estimates using a LD sequence satisfy the deterministic error bound $O((\log N)^d/N)$.

80.3.2.2 Monte-Carlo Simulations for Option Pricing

Under the risk-neutral measure, the price of a fairly valued European call option is the expectation of the payoff $E[e^{-rT}(S_T - K)^+]$. In order to compute the expectation, Black and Scholes (Black and Sholes 1973) modeled the stochastic process generating the price of a nondividend-paying stock as geometric Brownian motion:

$$dS_t = \mu S_t dt + \sigma S_t dW_t \quad (8)$$

where W is a standard Wiener process, also known as Brownian motion. Under the risk-neutral measure, the drift μ is set to $\mu = r$.

To simulate the path followed by S , suppose the life of the option has been divided into n short intervals of length Δt ($\Delta t = T/n$), the updating of the stock price at $t + \Delta t$ from t is (Hull 2003):

$$S_{t+\Delta t} - S_t = r S_t \Delta t + \sigma S_t Z \sqrt{\Delta t} \quad (9)$$

where Z is a standard random variable, i.e., $Z \sim (0, 1)$. This enables the value of $S_{\Delta t}$ to be calculated from initial value S_t at time Δt , the value at time $2\Delta t$ to be calculated from $S_{\Delta t}$, and so on. Hence, a completed path for S has been constructed.

In practice, in order to avoid discretization errors, it is usual to simulate $\ln S$ rather than S . From Itô's lemma, the process followed by $\ln S$ is (Bratley and Fox 1988):

$$d \ln S = \left(r - \frac{\sigma^2}{2} \right) dt + \sigma dz \quad (10)$$

so that

$$\ln S_{t+\Delta t} - \ln S_t = \left(r - \frac{\sigma^2}{2}\right)dt + \sigma Z\sqrt{\Delta t} \quad (11)$$

or equivalently:

$$S_{t+\Delta t} = S_t \exp \left[\left(r - \frac{\sigma^2}{2}\right)dt + \sigma Z\sqrt{\Delta t} \right] \quad (12)$$

Substituting independent samples $Z_1, \dots, Z_n$ from the normal distribution into (49.12) yields independent samples $S_T^{(i)}$, $i = 1, \dots, n$, of the stock price at expiry time T . Hence, the option value is given by

$$V = \frac{1}{n} \sum_{i=1}^n V_i = \frac{1}{n} \sum_{i=1}^n e^{-rT} \max \left[S_T^{(i)} - K, 0 \right] \quad (13)$$

The QMC simulations follow the same steps as the MC simulations, except that the pseudorandom numbers are replaced by LD sequences. The basic LD sequences known in literature are Halton (1960), Sobol (1967), and Faure (1982). Niederreiter (1992) proposed a general principle of generating LD sequences. In finance, several examples have shown that the Sobol sequence is superior to others. For example, Galanti and Jung (1997) observed that “the Sobol sequence outperforms the Faure sequence, and the Faure marginally outperforms the Halton sequence.” In this research, we use Sobol sequence in our experiments. The generator used for generating the Sobol sequence comes from the modified algorithm 659 of Joe and Kuo (2003).

80.3.2.3 Monte-Carlo Bootstrap for VaR

Monte Carlo simulation is applicable with virtually any model of changes in risk factors and any mechanism for determining a portfolio’s value in each market scenario. But revaluing a portfolio in each scenario can present a substantial computational burden, and this motivates research into ways of improving the efficiency of Monte Carlo methods for VaR.

The bootstrap (Efron 1981; Efron and Tibshirani 1986) is a simple and straightforward method for calculating approximated biases, standard deviations, confidence intervals, and so forth, in almost any nonparametric estimation problem. Method is a key word here, since little is known about the bootstrap’s theoretical basis, except that (a) it is closely related to the jackknife in statistic inferring; (b) under reasonable condition, it gives asymptotically correct results; and (c) for some simple problems which can be analyzed completely, for example, ordinary linear regression, the bootstrap automatically produces standard solutions.

The bootstrap method is straightforward. Suppose we observe returns $X_i = x_i$, $i = 1, 2, \dots, n$, where the X_i are independent and identically distributed (iid) according to some unknown probability distribution F . The X_i may be real valued, two-dimensional, or take values in a more complicated space. A given parameter $\theta(F)$, perhaps the mean,

median, correlation, and so forth, is to be estimated, and we agree to use the estimate $\hat{\theta} = \theta(\hat{F})$, where $\hat{F}$ is the empirical distribution function putting mass $1/n$ at each observed value x_i . We wish to assign some measure of accuracy to $\hat{\theta}$.

Let $\sigma(F)$ be some measure of accuracy that we would use if F were known, for example, $\sigma(F) = \text{SD}_F(\hat{\theta})$, the standard deviation of $\hat{\theta}$ when $X_1, X_2, \dots, X_n \sim F^{(\text{id})}$.

The bootstrap estimate of accuracy is $\hat{\sigma} = \sigma(\hat{F})$ which is the nonparametric maximum likelihood estimate of $\sigma(F)$. In order to calculate $\hat{\sigma}$, it is usually necessary to employ numerical methods. (a) A bootstrap sample $X_1^*, X_2^*, \dots, X_n^*$ is drawn from $\hat{F}$, in which each X_i^* independently takes value x_j with probability $1/n, j = 1, 2, \dots, n$. In other words, $X_1^*, X_2^*, \dots, X_n^*$ is an independent sample of size n drawn with replacement from the set of observations $\{x_1, x_2, \dots, x_n\}$. (b) This gives a bootstrap empirical distribution function $\hat{F}^*$, the empirical distribution of the n values $X_1^*, X_2^*, \dots, X_n^*$, and a corresponding bootstrap value $\hat{\theta}^* = \theta(\hat{F}^*)$. (c) Steps (a) and (b) are repeated, independently, a large number of times, say N , giving bootstrap values $\hat{\theta}^{*1}, \hat{\theta}^{*2}, \dots, \hat{\theta}^{*N}$. (d) The value of $\hat{\sigma}$ is approximated, in the case where $\sigma(F)$ is the standard deviation by the sample standard deviation of the $\hat{\theta}^*$ values, where

$$\hat{\mu} = \frac{\sum_{j=1}^n \hat{\theta}^{*j}}{N} \quad (14)$$

and

$$\hat{\sigma}^2 = \frac{\sum_{j=1}^n (\hat{\theta}^{*j} - \hat{\mu})^2}{N - 1} \quad (15)$$

80.4 Case Study and Discussions

80.4.1 Case Study

80.4.1.1 Asian Options and Rainbow Options

To demonstrate what the grid computing can contribute to the financial service in a significant manner, two kinds of popular options, Asian options and rainbow options, are chosen for Monte Carlo pricing model. Asian options have payoffs that depend on the average price of the underlying asset such as stocks, commodities, or financial indices. However, there is no exact closed-form formula existing for these popular options. Rainbow options, also known as basket options, are referred to an entire class of options which consist of more than one underlying asset. Rainbow options are usually calls or puts on the best or worst of the underlying assets, or options which pay the best or worst of the assets. They are excellent tools

for hedging risk of multiple assets. The rainbow options are therefore used for our bootstrap calculations of VaR.

80.4.1.2 Parallelization, Distribution, and Message Passing Interface (MPI)

MPI is a library specification for message passing, proposed and developed as a standard by a broadly based committee of vendors, developers, and users (Snir et al. 1996). MPI was designed for high performance on both massively parallel machines and on distributed clusters. The MPI standard is nowadays widely accepted and used in the community of high-performance computing.

The basic MPI functions are point-to-point pair-wise message passing for send and for receive. Collective communications are also provided for ease of use as well as better performance. These communication methods, when used in supercomputers, do facilitate the parallelization of numerical methods that require both heavy compute cycles and stronger dependency between parallel processes.

Recent development of supercomputer, affected by the popularity of cluster computing in PCs, tends to be designed hierarchically scalable. Further extension of clusters of supercomputers can be regarded as an initial concept of grids (see Sect. 80.2). The use of MPI is straightforward in this kind of hardware architecture and interlink of networks. There is always an obvious physical limitation in this architecture, which is also proportional to the limitation of the investment of governmental research funding. People tend to use mass distribution of computers, mostly PCs, which are linked loosely in Internet cloud. The terminology cloud is often used in networking community to show that in Internet there is no specific network path from one computer to another. MPI working in such an environment is expected to be inefficient and unstable, e.g., high network latency-induced packet lost in long distance real-time communication. In the following sections, three specific platforms, including local clusters, geographically distributed large clusters, and PC grids with tens of thousands of PCs connected in the cloud, will be used for the financial calculations to demonstrate benefits in using grids.

80.4.1.3 Empirical Study for Data Grid System

In order to demonstrate the usefulness of grid system, in particular in data-intensive application, the real market data are used, including daily from iShares (Morgan Stanley Capital International), MSCI Taiwan Index (ETF), and Taiwan Stock Exchange Center (TSEC) weighted index, extracted specifically from May 31, 2005, to May 31, 2008, and 30 days tick-by-tick trading data from Taiwan Futures Exchange Center (TAIFEX).

80.4.2 System Platform Tests

The various grid platforms are carefully chosen to demonstrate the performance issue in finance services, which include a big data Hadoop Cluster, Taiwania 2 cloud-enabled AI supercomputer, a small diskless remote boot Linux (DBRL)

PC clusters, large-scale and geographically widely distributed test-bed the Pacific Rim Applications and Grid Middleware Assembly (PRAGMA) compute grid, and a densely distributed at-home style PC grid, which resembles the clouding computing.

80.4.2.1 Artificial Intelligence-Based High-Performance Computing Platform

As introduction in Sect. 80.2, an Apache Hadoop system is employed to tackle and demonstrate big data solutions. The example given here is for fraud detection based on cyclic trading pattern. The original dataset is unified invoices from the Financial Information Agency of Taiwan, collected over a 3-year period from 2010 to 2012 consisting 378,373,684 records. The number of companies involved in the trading process of interest is 1,385,870, excluding the listed companies in stock market. The company is deidentified, and all other information are removed for this study, but the temporal sequence is kept in order. The dataset is used to search long path cycles using brutal force approach.

In the current case, it is more to do with the volume of data. Practically, the raw data is only approximately a few gigabytes. During the calculation, the intermittent data size can reach almost petabytes, which is almost ten orders of magnitude. The calculation is performed on Apache Hadoop in a supercomputer of 4096 cores (16 core CPU), 16.38 TB memory, and 1.5 PB HDFS (Hadoop File System). The platform based on Hadoop allows us to handle a single file in petascale in this case, which is exactly what big data is designed for. For technical details and results, we refer to Lin et al. (2020).

Similar big data cluster can be built in Taiwan 2 system using virtual machines, which is versatile not only for big data but also for general machine learning. The software architecture of Taiwan 2 is shown in Fig. 7. From the cloud terminology, it ranges from infrastructure as a service (IaaS), platform as a service (PaaS), to software as a service (SaaS). The machine learning from various neural networks, such as deep neural networks, recursive neural networks, and reinforcement neural networks, has been developed way beyond its original scope achieving great successes in computer vision, speech and audio, and national language processing. The technology is now well adopted into a broad range of financial services, which use cases include (Financial Stability Board Report 2017):

- To assess credit quality, to price and market insurance contracts, and to automate client interaction by financial institutes and vendors
- To optimizing scarce capital as well as back-testing models and analyzing the market impact of trading large positions by financial institutes
- To find signals for higher (and uncorrelated) returns and optimize trading execution by hedge funds, broker-dealers, and other firms
- For regulatory compliance, surveillance, data quality assessment, and fraud detection by both public and private sector institutes

Fig. 7 The software stack of Taiwania 2 system

Taiwania 2 provides compute capability for traditional modeling based on Monte-Carlo Simulation and then extends to big data and machine learning. In our example, a LSTM- (Hochreiter and Schmidhuber 1997) recursive neural network and reinforcement neural network are used to train models to predict trends of foreign exchange rate and to derive a trading strategy for foreign exchange rate. The data is online streamed from Yahoo Finance for both training/testing and predicting in real time. Taiwania 2 system effectively builds models and predicts as expected using the AI frameworks from Fig. 7.

80.4.2.2 Diskless Remote Boot Linux (DRBL) Cluster

DRBL is an in-house program of National Center for High-Performance Computing (NCHC) and was an original software product developed by Steven Shiau and his group under the auspice of National Knowledge Innovation Grid (KING) of Taiwan. It was developed initially as a centralized system management tool aiming at small and median size PC clusters. It is nowadays recognized internationally as one of the most advanced mass backup solutions. Here, DRBL is used as an alternative scavenger for compute cycles of spare clusters. When needed, it converts systems of PC clusters into an aggregated and homogenous Linux system, simultaneously with a mass backup of the original systems, and recovery backup of the original systems once the need is satisfied. The most popular use is to convert a PC classroom into a compute Linux cluster. In such a case, compute cycles of the clusters can be fully exploited. In a grid environment, this is a perfect case to resource scale-up when in contingent need and once the situation-relieved resources will be released correspondingly. Such a dynamic feature can be beneficial for the financial services.

Fig. 8 The schematic of DRBL system

The schematic of DRBL system can be shown in Fig. 8, where DRBL duplicates image files of an operational system, e.g., Linux kernel, via network to the clients. The clients' original operational systems are not used. The clients are therefore temporarily turned into dedicated compute resources, which also provide additional security to financial data.

The test case here involves Monte Carlo simulations on Asian option pricing, on rainbow option pricing, and on a bootstrap VaR calculation, respectively (see section “[Distributed and Parallel Financial Simulation](#)”). The market parameters are given as risk-free interest rate $r = 0.1$, underlying asset spot price $S = 100$, strike price $X = 100$, duration to maturity $T = 125$, and volatility $\sigma = 0.3$. For the rainbow options, a linear weighted combination of four underlying assets is assumed with underlying prices of $S_i = 100, 110, 120, 130$ and the corresponding weightings of volatility $\sigma_i = 0.3, 0.4, 0.5, 0.6$. The correlation matrix is taken to be

$$\rho_{ij} = \begin{pmatrix} 0.5 & 0.4 & 0.5 \\ 0.4 & 0.3 & 0.4 \\ 0.5 & 0.4 & 0.6 \end{pmatrix}.$$

Table 1 Comparison of performance between DRBL-based PC platform with 32 nodes, FORMOSA II of NCHC with a batch job of 32 nodes and IBM cluster 1350 with a batch job of 32 nodes. The PCs are 20 XEON 2.6 GHz and 4GB RAM

	DRBL cluster	FORMOSA II	IBM cluster 1350
Asian option pricing (AOP)	81	49	24
Rainbow option pricing (ROP)	329	197	98
VaR calculation (based on ROP w/ bootstrap)	322	194	97

Unit: microsecs per Monte Carlo path. Averaged from 1000,000 Monte Carlo paths

Table 2 Comparison of speedup ratios based on the calculations in Table 1

	DRBL cluster	FORMOSA II	IBM cluster 13 50
Asian option pricing (AOP)	28.68	29.46	30.16
Rainbow option pricing (ROP)	27.31	28.59	29.34
VaR calculation (based on ROP w/ bootstrap)	27.20	28.10	29.10

Unit: Speedup ratio: CPU (nonparallel single node)/CPU (parallel single node)

The calculation of the VaR uses the same four-dimensional rainbow options with additional expectation of return 0.07, 0.08, 0.09, and 0.10 respectively. They are calculated in DRBL cluster as well as benchmarked with two cluster-based supercomputers in NCHC. The results are shown in Tables 1 and 2.

In Table 1, instead of giving a total wall clock time of the calculation with some given numbers of Monte Carlo simulations or paths, a more useful averaged single Monte Carlo simulation based on 1,000,000 simulations is used to demonstrate the performance when different system architectures are used. The results show that the traditional big irons, i.e., supercomputers, still outperform the cluster. Yet, considering there are no extra costs invested in the computing resources and still compute cycle in a sizable manner is obtained, the approach is appealing to be further developed in to a fully operational production system.

80.4.2.3 Pacific Rim Applications and Grid Middleware Assembly (PRAGMA) Grid

The Pacific Rim Applications and Grid Middleware Assembly (PRAGMA), founded in 2002, is an open international organization that focuses on a variety of practical issues of building international scientific collaborations in a number of application areas. PRAGMA grid is established by the resources and data-computing working group as a global grid testbed for benchmarking the interoperability of grid middleware and the usability and productivity of grids. The PRAGMA grid consists of physical resources as well as system administration supports from 29 institutions across 5 continents and 14 countries. It is an instantiation of a useful, interoperable, and consistently available grid system that is neither dictated by the needs of a single science domain, nor funded by a single national agency. It does not have uniform

Fig. 9 Software stack developed in the PRAGMA grid

infrastructure management yet is robust and supports a wide range of scientific applications. The software stack of the system is shown in Fig. 9.

The PRAGMA grid successfully tackles the issues of distance and time zone differences among sites, lack of infrastructure tools for heterogeneous global grid, nonuniform system and network environments, and diverse application requirements. For more technical details both in theory and practice, we refer to Abramson et al. (2006).

The similar test case in Sect. 80.4 was followed, but the platform was extended with a collection of clusters across institute boundaries. The common job submission is executed via a homogeneous middleware Globus Toolkit. We demonstrate the usefulness of the platform by grouping compute resources across national boundaries and still achieve good performance. The results are shown in Tables 3 and 4.

80.4.2.4 At-Home Style PC Grid

With the continued penetration of personal computers and the remarkable improvement of CPU processing speed, 80–90% of most PCs’ processing power is untapped, according to a study. This does not mean that many PCs remain turned off, but that the capacity of the CPU, the brain of the PC, is not fully utilized. In case the CPU is more extensively used when a task requiring an enormous number of operations, such as three-dimensional graphical processing, is assigned, it sits idle most of the time during word processing and Internet browsing because CPU processing speeds are much faster than the speeds of input from the keyboard or the communication line.

This fact led to the idea of virtually gathering the power of idle CPUs to use as a computer resource. In other words, this means networking numerous computers to make them work like a single high-performance computer, and assigning complex processing tasks to it. The assigned task will be divided into a myriad of small tasks and allocated to individual computers on the grid-like network. Even when

Table 3 Comparison of performance between group A, which consists of 13 nodes from NCHC and 15 from UCSD, and group B, which consists of 122 nodes collectively from UCSD, AIST, NCHC, and Osaka University. The details of resources are referred to (<http://pragma-goc.rocksclusters.org/pragma-doc/resources.html>)

	Group A	Group B
Asian option pricing (AOP)	68	56

VaR calculation (ROP w/bootstrap)	25.63	110.09

Unit: secs/per Monte Carlo path. CPU (nonparallel single node)/CPU (parallel single node)

increasingly faster CPUs, the power of PCs is not comparable to those of supercomputers, but in a networked environment where individual PCs simply process complex task in parallel, PCs can deliver surprisingly high performance. This is the core concept of CP grid computing (Fig. 10), and it came into a reality several years ago (Table 5).

The commoditization and the increased processing speed of PCs leads the growth of idle CPU power. This will facilitate the construction of PC grid computing system along with the improvement of the communication environment by broadband connectivity (Chen et al. 2006). In practice, a PC grid platform Korea@Home (or K@H) is used in our study. Its architecture is shown in Fig. 10. It is based on MS Windows. Asian option pricing is used to demonstrate the performance of the system, in which the number of iterations is taken to be 1,000,000. The duration to maturity is further divided by 10,000 periods, which push the system to run on the mass parallel system of K@H. To tackle this scale, or even larger scale for all kinds of possible scenarios in real trading practice, an off-line-distributed and parallel approach is adopted. The total number of Monte Carlo simulation is $1,000,000 \times 10,000$. It was divided into 10,000 jobs, and each job consists of 1,000,000 Monte Carlo simulations. The market parameters are given as above.

The results demonstrated here are not as good as expected (see Table 1). It shows that the speedup ratio is only 3.79. In this test, K@H further divides the jobs into ten groups. Each group was sent and run in a sequential fashion, which causes the low speedup ratio. However, if one looks into the executed CPU time for each job, our assumption is still valid. We simulated the result in a small cluster with the same scenario and Monte Carlo paths. The result shows 90% speedup can be easily achieved.

Fig. 10 The architecture of Korea@Home, a specific @Home style PC grid used in our case study (Jun-Weon Yoon 2008)

Table 5 Summary of the case for the PC grid calculations

Asian option pricing	Statistics
Number of Monte Carlo path	1,000,000 x 10,000
The running period (1) (Wall clock time)	28 h 51 m (104,911 s)
Number of jobs	10,000
CPU time per job	28 ~ 30s
Total running time (2) (Wall clock time)	4 days 14 h 31 m (397,919 s)
Speedup ratio $\frac{(2)}{(1)}$	3.79

80.4.2.5 RBNB Data Grid

RBNB DataTurbine in market data streaming is implemented here (see Fig. 11 for real-data plot in collaboration with Ebbe et al. 2007), in which the real data from iShares MSCI Taiwan index (ETF) and TSEC-weighted index from May 31, 2005, to May 31, 2008, and 30 days tick-by-tick trading data from Taiwan Futures Exchange Center (TAIFEX) are used and open in different file-based online channels from the RBNB DataTurbine. The purpose is to dynamically manage the high-frequency market data and connect the data with analysis applications on the fly. The system implemented up to date is for large-scale dynamic and static data management.

Fig. 11 RBNB DataTurbine streaming open for data channels of iShares MSCI Taiwan index (ETF) and TSEC-weighted index from May 31, 2005, to May 31, 2008, and 30 days tick-by-tick trading data from Taiwan Futures Exchange center (TAIFEX)

80.5 Conclusion

Securities trading is one of the few business activities where a few seconds processing delay can cost a company big fortune. The growing competition in the market exacerbates the situation and pushes further toward instantaneous trading even in a split second. The key lies on the performance of the underlying information system. Following the computing evolution in financial services, it was a centralized process to begin with and gradually decentralized into a distribution of actual application logic across service networks. Financial services have the tradition of doing most of its heavy lifting financial analysis in overnight batch cycles. However, in securities trading, it cannot satisfy the need due to its ad hoc nature and requirement of immediate response. A new computing paradigm, grid computing, aiming at virtualizing scale-up distributed computing resources, is well suited to the challenge posed by the capital market practices.

In this chapter, we revisit the theoretical background of how performance will affect the market competition. The core concept lies on information asymmetry. Due to the advance of IT, even in a split second it will be a matter of winning or losing in real market practice. After establishing the motivation, we reviewed recent grid development specifically used for finance service. Monte Carlo simulations are chosen not only because of their popularity in real world, but also because of their nature of so-called “fine grain” or mass parallelism approach. The success of Monte Carlo simulations lies on better random number generators. The well-recognized Sobol sequences as a quasi-random number generator are carefully studied to ensure the quality of Monte Carlo simulations when employed for mass parallelism. Then some popular basic option-pricing models, collectively Asian option pricing, rainbow option pricing, and VaR calculation with constant market parameters, are introduced as drivers to introduce more details of grids for better finance service. Finally, we test various grid platforms, based on the methodology of mass

parallelism and mass distribution, with the drivers. The real market data are also used, but at this stage they are only used to demonstrate the dynamic data management, in which grids can offer better.

Our future work will migrate grid platforms to cloud platform with HPC capability and extend them to broader use of big data and machine learning applications for more general financial services. Along the current track of this development, we will also develop models based on machine learning for option pricing and risk management with tick-by-tick daily market information.

Abstract

The board of directors must now prepare risk management policies for regimes of low-interest rates and increased loss rates to fulfill its fiduciary responsibility to ensure the safety and soundness of the financial institution. Negative rates and higher unexpected loss rate regimes can no longer be ignored, and bankers should seek answers to the following crucial questions: How should the balance sheet be managed if negative rates and higher losses prevail? Are the current risk management models appropriate for managing the balance sheet?

This chapter explains how the local volatility model can provide what-if financial simulations, essential to balance sheet risk management, to address these questions. In particular, the chapter proposes financial simulation assumptions for the base case and stress scenarios. It also formulates balance sheet strategies for community banks to manage capital, liquidity, credit, and interest rate risks consistent with the bank's risk culture while maintaining profitability. Furthermore, it demonstrates the validity of the local volatility model to navigate the impacts of COVID 19, allowing bankers to model balance sheet elements affected by the capital market's negative rate regimes. Finally, it highlights the limitation of interest rate models widely used today in dealing with the applications described above.

The authors would like to thank Lindsay Elizondo, Gnanesh Coomaraswamy, and Blessing Mudavanhu for their comments and suggestions.

81.1 Introduction: Modeling Interest Rate Movements in a Low-Rate Regime

A negative rate regime in the USA has become probable because of COVID 19. On March 24, 2020, the 3-month treasury rates fell to 1 basis point, with the potential to fall further. Additionally, some secured overnight financing rates (SOFR) were negative between June 29 and July 15, 2020. Furthermore, most developed economies have negative government rates.¹ The US positive rate regime is, in fact, an exception.

COVID19 has also resulted in higher expected and unexpected credit losses. The unemployment rate was rising to 15%, falling to 12% by June 2020, even before the impact of resurgence. Such an economic downturn can lead to a deep recession and deflation, leading to negative projected asset returns.

Community bankers should simulate what-if pro forma financial statements in light of COVID 19 and reevaluate the validity of the interest rate models to perform such simulations. Financial Institution Board members have the fiduciary responsibility to raise questions such as:

- What are the balance sheet strategies to manage negative rate and higher loss rate scenarios?
- Is the current risk management model appropriate for managing the balance sheet?

This chapter addresses these questions in two parts:

Part 1 describes the impact of COVID 19 on community bank performance. First, I propose the specifications of financial simulations, including what-if analyses to identify risk exposures. Second, based on the simulations, I suggest balance sheet strategies using the latest research. Finally, I show that the efficacies of these pro forma financial analyses depend on the appropriateness of the interest rate model used.

Part 2 describes the interest rate model that remains robust in the COVID 19 environment. I also identify the importance of the interest rate model to implement the proposed what-if scenarios and strategies to manage credit, interest rate, liquidity, and capital risk in a holistic modeling framework.

¹As of July 15, 2020, the 2-year government interest rates (basis points) of the following countries are France-59, Germany-66, Italy-6, Japan-0, 14, Spain -40, and the UK-10 (Sources: WSJ).

81.2 Part 1: Model Assumptions for Financial Simulations and Balance Sheet Strategies

81.2.1 COIVD 19: Challenges and Strategic Planning

The capital market does not expect the near-zero interest rate policy in the USA, nor the global negative interest rate policy (NIRP) will soon end. These policies' negative rates will "flow through to the markets."² However, the Federal Reserve Bank (San Francisco) chapter experts banks to "intermediate the transmission of the Fed policy" on the COIVD 19 shock, and the impact will evolve.

COIVD 19 will affect community banks with less diversified funding and products differently than wholesale banks. Therefore, it is more pertinent for community banks to "create and analyze bespoke shat-if scenarios" for the COIVD 19 regime, as PWC recommends (2020). In particular, competition to lower the funding rate to maintain the margin on the liability side as the lending rates are compressed.

81.2.2 Model Assumptions

THC's research suggests that the assumptions for the base case scenario should keep the current interest rates unchanged for two years, with increased projected loss rates. The level of increase will depend on the loan portfolio's credit exposure and borrower's risk profiles. The nonmaturity deposit account rates maintain a reasonable level to compete with wholesale banks and fintech companies.

Community banks should also simulate stress scenarios. Since the local volatility model estimates the probability of the 1-year rate becoming negative in five years is over 35%, the model suggests that a 100 basis point downward rate shock is reasonable as a stress test. Even if the bank resists offering negative deposit rates, the capital market rates will affect the pricing of products such as ARMs, where indices are often market based, such as the LIBOR or its replacement. However, to manage profitability, bank rates may not fall in step with the market rates, so margins may not be affected as significantly. Other developed economies have confirmed such relationships between capital market rates and loan rates. The stress scenario will also increase credit losses. The board and senior management should revise the performance dashboard based on both the base case scenario and the stressed scenario.

81.2.3 Balance Sheet Strategies

While these scenarios will adversely impact community banks' performance, other economies have shown that the results can be manageable, when senior management

²PIMCO (2019).

takes appropriate actions. McKinsey (2020) recommends banks should be “taking a more holistic approach to using (balance sheet management) tools.” Their survey suggests that banks should increase the balance sheet by originating profitable products. The emphasis is on identifying the most profitable products. When capital constrains the growth of the balance sheet, the fee-based business should increase.

Loan profitability should be holistically determined. The revenue is net of not only the funding cost, but also the borrowers’ option cost, credit risk charges, and noninterest expenses to support the products. The activity-based cost analysis can estimate the cost assigned to each product. Increasing capital via retained earnings is essential in this environment, as risk managers should note that the full impact of COIVD 19 is evolving and will not be felt immediately (Arseneau 2017).

In essence, based on a survey (see Alberts 2020), these bank strategies are acting as “transmission channels” for the Federal Reserve Bank Interest Rate Policy that seeks to increase the availability of credits to the real economy, by increasing lending and lowering the credit risk premium. The proposed strategies are consistent with the mechanics of banking, acting as the “transmission channel.”

81.2.4 The Validity of Interest Rate Models

The validity of financial simulations in the COIVD 19 environment, of course, will depend on the robustness of the interest rate model in the low-interest rate regime, and therefore, I must first address the validity of the interest rate model.

Interest rate models are central to valuing the embedded fixed-income options, which are prevalent in balance sheets, and are essential to enterprise risk management and market making. They are also the bedrock to building credit and liquidity models, as well as income/profitability simulations.³ Financial economists cannot overstate the importance of interest rate models to our economic system. However, many asset-liability models were developed in the 1990s and are not appropriate for today’s environment.

The current low-interest-rate regime challenges the robustness of many interest rate models.⁴ These models allow interest rates to fall to a prespecified level or to rise unreasonably high. In sum, these models fail to provide reasonable interest rate distributions, which are determined by capital market prices.

By way of contrast, the chapter describes the local volatility model, which allows the capital market prices to determine the interest rate distribution. That is, the local volatility model is “arbitrage-free,” analogous to level II fair value accounting principle in relative pricing. Hence, the local volatility model responds to changing market conditions and perceptions of interest rate uncertainties. To illustrate, the chart below depicts a rate probability distribution of the local volatility model. The

³See Ho and Coomaraswamy (2019).

⁴See Ho and Mudavanhu (2019).

Fig. 1 Probability distribution of 1 month rates at a 5 year horizon (March 6, 2020)

results show that the probability of the rate falling between -0.5% and -1% is 35% the probability for negative rates, in general, is 55% (Fig. 1).

The probability distributions estimated by the local volatility model enables senior management to measure the impact of COIVD 19 on balance sheet risk and the efficacy of balance sheet strategies.

81.3 Part 2: Interest Rate Model and Efficacy of Financial Simulations

In this section, we summarize the chapter that presented the local volatility model and its applications in 2019. We will provide an intuitive explanation of the model and the implied probability distributions of interest rates based on a sample of months from March 2019 to February 2020. From the empirical results, we will discuss several balance sheet strategies. we will further extend the discussion to financial-economic issues. Finally, we will introduce new approaches to balance sheet total return, lending, and funding strategies.

81.3.1 Local Volatility Model

Interest rate models should accept negative interest rates implied by swaption prices and asymmetric distribution of the frequency distribution of interest rates. The local volatility models such as Ulate (2019), Cox et al. (1981), and Ho and Lee (1986) follow the Ho-Lee formulation (see Appendix A) by not assuming a specific interest rate probability distribution, such as the normal or lognormal distributions. Instead, the local volatility model assumes the volatility is local, depending on the time horizon and the projected rate levels, local in the projected time, and rate level.

The model calibration uses both at-the-money and out-of-the-money swaptions to calibrate the interest rate movements and hence the rate distributions. The local volatility model uses the 80 at-the-money swaptions with terms 1, 2, 3, 4, 5, 7, and 10 years and tenor 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 15, 20, 30, and 91 out-of-the-money

swaptions with rates -100 , -50 , 50 , and 100 bp, for the same term and tenor. The local volatility model can then present the underlying rate distributions. In this sense, the local volatility model can then present the underlying rate distributions. In this sense, the local volatility model is arbitrage-free, as it is consistent with the capital market pricing of the yield curve and observed swaption prices.

Figure 2 below depicts the 1-month treasury rate distribution over a 5-year horizon as of March 6, 2020, and March 13, 2020, when the coronavirus pandemic greatly affected the treasury and swaption markets.

The results show that there is a significant implied probability of negative interest rates prevailing in 5 years. Indeed, the results indicate there is a 35% and 20% chance the 1-month rate will reach less than -0.5% and fall between -0.5% and 0% , respectively.

Three risk drivers are affecting the rate probability distribution: (1) the forward rate (2) market-perceived interest rate uncertainty, called the volatility curve, and (3) the out-of-the-money swaptions. These risk drivers determine the median, variance, and skewness of the distribution.

The following section describes the historical trends of the rate distributions as affected by these three risk drivers.

Fig. 2 Probability distribution of 1 month rate at a 5-year horizon. (a) March, 6 2020, (b) March, 13 2020

81.3.2 Rate Distribution Trend Analysis

81.3.2.1 Market Conditions

The shape of the yield curve determines the forward rates. The historical trends of the key rates, shown below, can partly explain the median rate of the historical rate distributions.

The 12-month daily treasury key rates depict the dynamic nature of the rate level and the shape of the yield curve. Via the swaption market, the perceived uncertainty and skewness of the rate distribution can provide useful information on a forward-looking basis.

81.3.2.2 Volatility Curve

The local volatility model uses swaptions to determine the uncertainty of rates along the yield curve. Figure 4 shows the market's perceived rate uncertainty. As expected, the market volatility was high during the post-2008 financial crisis, and again when the Brexit event occurred in 2011. The volatility again rose in the period of the trade war and more currently during the coronavirus pandemic.

81.3.2.3 Negative Rates

Given the fall in interest rates, increased volatility, and the change in the skewness of the distribution, the implied probabilities of negative interest rates change over the sample period. Below is the monthly estimate of the rate distributions over 12 months starting at the end of March 2019. The results show that August 2019 and March 2020 have significant implied negative rates.

The most substantial one-day losses of 2019 occurred in August after we saw significant market uncertainty as China suggested using their currency to strategize the trade war. Still, the risk subsided after the trade discussion resumed in the following months.

By December, the coronavirus outbreak in China became widespread, resulting in a rise in global market performance uncertainty. The risk heightened when the spread of the virus became a pandemic in March. Comparing the vol curve and rate trends, the significant rise in the probability of a negative rate is mainly due to the drop in the rate level, not as much as the increase in the normal rate risk.

81.3.3 Model Robustness: Historical Rate Distributions for Sample Dates Between March 2019 and March 2020

On March 29, 2019, the treasury curve was relatively flat, suggesting the projected forward rates were not high, and the curve level was high relative to subsequent months. The implied volatility was also low before the increase in volatility that resulted from the trade war uncertainty.

81.3.3.1 Empirical Evidence

The results reported in Figs. 3, 4, 5, and 6 show that the implied distribution is consistent with these observations. The distribution model is around 1%, with the rates not falling below zero. As a result, the probability distribution is positively skewed, with a median of 2%.

The following Figs. 6, 7, 8, and 9 further support these observations based on additional sample data.

As explained above, because of the escalation of the trade war, August 2019 experienced significant market uncertainty. Figure 3 shows that interest rates rose

Fig. 3 The historical trends of treasury key rates

Fig. 4 Historical volatility curves on interest rate risks. The results show that the short-term uncertainty is more pronounced in this coronavirus pandemic period, as reflected in the rise of the short-term rate volatilities. Note that while recent volatilities are lower than those in 2010, the reason is that the interest rates have fallen substantially since 2010. If the interest rate risk is measured by percentage change (lognormal model), then the current volatility is over 1500%.

Fig. 5 Historical implied probabilities of negative interest rates. While most periods do not exhibit a positive probability of negative interest rates, the swaption markets with both at-the-money and out-of-the-money swaptions identify the likelihood of negative rates in stress periods

Fig. 6 Probability distribution of 1 month rate at a 5-year horizon. (March, 29 2019)

Fig. 7 Probability distribution of 1 month rate at a 5-year horizon. (September 30, 2019)

Fig. 8 Probability distribution of 1 month rate at a 5-year horizon. (October 31, 2019)

Fig. 9 Probability distribution of 1 month rate at a 5-year horizon. (November 29, 2019)

significantly, and Fig. 4 shows that the implied volatility increase in the same period. Figure 6 shows that the median of the distribution shifted higher, and the rates fell below zero.

In late October, the yield curve is no longer inverted, and volatility fell. Figure 9 shows that the rate of distribution has a lower probability of negative rates, and the skewness is more pronounced than in the previous month.

By late November, the volatility fell further, and the yield curve remained flat around 1.75%. Figure 8 shows that the rate distribution does not have negative rates, and the skewness remained positive.

The results show that:

- The dynamic nature of the distribution indicates that the median, variance, and skewness of the distributions continually adjust to the market conditions as the yield curve, implied volatilities of the at-the-money swaptions, and the skewness affected by the out-of-the-money swaption pricing change over time.

- A lognormal distribution cannot model the distribution because lognormal distributions do not accept negative interest rates. When the interest rate is only 0.2%, the rate distribution is constrained to a narrow band on variations. Therefore, the projected simulations cannot be consistent with the swaption prices.
- The normal distribution cannot be consistent with the current low-interest-rate scenario as a result of the market “Risk Arbitrage” practice. If rates become significantly negative, investors have alternative investments without paying a significant price premium that results in high negative interest rates. For these reasons, the historical estimated distributions tend to be positively skewed, and there is a limit to the level of negative rates.

In summary, the results show that the rate distribution is dynamic, continually adjusting to the market perception of interest rate uncertainties and the skewness of the distribution. Many operating interest rate models estimate the skewness and floor rate separated from the model calibration estimation process.⁵ Additionally, some interest rate models are calibrated to at-the-money options only, excluding out-of-the-money options. The next section will discuss the limitations in fixed-income pricing when the extent of projected negative rates and rate distribution skewness is not dynamically estimated.

81.4 Implications of Skewness: Mean and Median of Rate Distribution

The previous sections show the importance of evaluating the rate distributions and the dynamic nature of the rate distribution, neither confined to a normal or lognormal distribution. The distributions should be defined by the mean, variance, and skewness.

81.4.1 Forward Rates and Expected Rates

Rate distribution skewness concludes that the forward rates, as determined by the yield curve, are not the market’s expected rates. The forward rates and expected rates are different, contrary to the expectation hypothesis. The rate distribution can explain the poor performance of the forward rates as a rate forecasting tool and offer an alternative to measuring the market expectation of future rates.

A market scenario can best explain the importance of using rate distribution. On March 20, 2020, the yield curve was upward sloping. The 1-month and 10-year rates were 0.04% and 0.92%, respectively. However, the capital market did not have to believe the 1-month rate would rise from 0.04% to 0.51%, or the 10-year rate from 0.92% to 1.06%, in one year. Instead, the capital market traded the caps to reflect the

⁵Calibration is explained in the White Paper 2019 “Embedded Option Pricing.”

Fig. 10 The difference between the par curve and the forward curve

market rate expectation, creating a negative skewness in the rate distribution. At the same time, the Federal Reserve Bank affected a steep yield curve for a broader economic purpose.

Figure 10 presents the difference between the par curve and the forward curve and the relevance of the market interest rate forecast (MIRF).

The average rate distribution, as depicted in Fig. 2, represents the market expectation, which is not the same as the forward rates, which intuitively is the median of the distribution.

81.4.2 The Skewness in Loan Pricing

The depiction of the rate distribution has many applications in the capital market. The model provides an estimation of the value of caps and floors of adjustable rate instruments as the rate distribution reports the probabilities of becoming in the money for the caps and floors. Consider the following example:

A 30-year adjustable-rate mortgage (ARM) may have an interest rate structure of 2/2/5, indexed to a 1-year treasury rate with a margin of 2.2%. If the loan has an initial rate of 3.25%, then the cap at the reset would be useful when the 1-year treasury rises to 5.25 ($3.25\% + 2\%$), or the 1-year treasury rate increases from today's rate of 0.8% to 3.25% in 5 years. The rate distribution provides the probability of the interest to reach the cap at 5.25%. If that scenario is not likely to prevail, the lending officer could lower the initial rate so that the ARM is competitive to the rate of the 30-year fixed-rate mortgage.

81.4.3 Stress Test the Balance Sheet and Limitations of Current Interest Rate Models

The distributions also provide valuable information for stress testing the balance sheet or a portfolio of balance sheet instruments. The results provide some measure of the likelihood of a stress scenario that may occur. The “likelihood” is estimated from capital market prices and is, therefore, objective and transparent. The local volatility model can simulate the balance sheet under the downshift of the yield curve for stress testing purposes.

Researchers developed many interest rate models in the 1980s when interest rates were much higher than those of today.

- The lognormal model cannot accept negative interest rates, and therefore, will fail for the stress test.
- The normal model accepts negative interest rates, but the projected model interest rates could be significantly negative. However, rates cannot be significantly negative when employing the risk arbitrage activities of “putting money under the carpet.” Any assumption of flooring the rate at a particular level would violate the arbitrage-free model assumption. That is, such a model cannot be consistent with the basic discount cash flow model when the embedded option value is negligible and hence would misprice the balance sheet items.
- Another commonly used model, the displaced diffusion model, specifies the minimum interest rate base on a lognormal model. Empirical evidence has shown that the minimum rate is dynamic, and the floor rate has to be estimated by the calibration.

81.4.4 Balance Sheet Enhance Return Strategies

The local volatility model has introduced the concept of a rate probability distribution. From the rate probability distribution, interest rate strategists can manage with mean, variance, and skewness of the probability distributions. To date, controlling the rate level risk and interest rate volatility is widely used in practice. In the low-interest-rate regime, balance sheet strategies should also focus on skewness.

Specifically, the pricing of caps and floors, and the use of out-of-the-money options are essential for hedging, buying, or selling options. There are many out-of-the-money options sold to customers on the balance sheet. The value of skewness of the interest rate probability distribution can be perceived differently from those priced in the capital market. The variance in the price offers profit opportunities.

81.5 Conclusions

Financial economists have categorically rejected the possibility of negative interest rates for over 35 years, resulting in much unwarranted research and the development of interest rate models. Today, the low-interest-rate regime has “broke(n) the Black

Scholes model, Pillar of Modern Finance.” Economists should critically evaluate the current operational interest rate models.

This chapter explains the local volatility model and provides empirical evidence of the validity and applications of the model to manage the impact of COIVD 19 on community banks. In particular:

- **Distribution skewness:** The interest rate model should use both capital market pricing of at-the-money and out-of-the-money options to define the rate distribution, the projected interest rate minimum, and the distribution skewness. The skewness affects the pricing of caps and floors of an adjustable-rate instrument. Furthermore, interest rate models without the calibration of the interest rate distribution do not provide a valuation model consistent with capital market derivative markets.
- **The expectation hypothesis:** The interest rate model’s rate distribution determines the market expected interest rate level, which is a more appropriate rate forecast than that suggested by the forward curve, as the expectation hypothesis suggests.
- **The Fisher equation.** The concept of the nominal interest rate is the sum of the economy’s real rate of return, plus the inflation rate (the Fisher equation) is a positive theory. By way of contrast, the arbitrage-free model is a normative theory. The arbitrage-free model can lead to timely actionable decisions and not relying on the concept of general market equilibrium.

This chapter explains the local volatility model and provides essential balance sheet applications in the COIVD 19 environment. In particular, the chapter

- Proposes financial simulation assumptions for the base case and stress scenarios.
 - Projected interest rates over 2 years.
 - Increasing loss rates over the simulation horizon
- Formulates balance sheet strategies for community banks to manage capital, liquidity, credit, and interest rate risks consistent with the bank’s risk culture while maintaining profitability.
- Demonstrates the validity of the volatility model to navigate the impacts of COIVD 19, allowing bankers to model balance sheet elements affected by the capital market’s negative interest rate regimes.

Highlights the limitation of interest rate models widely used today in dealing with the applications described above.

Appendix A: Interest Rate Model: A Review

Ho-Lee Model

Ho and Lee 1986 introduced the arbitrage-free interest rate model in 1984. “Arbitrage-free” means that the evolution of the yield curve movements must be consistent with the valuation of capital market benchmark derivatives and the market discount curve.

Swaptions and the swap curves are examples of derivatives and market discount curves, respectively. I called the process of implying the underlying yield curve movements from the derivative prices “Calibration.” (Ho (2019a)) Since the derivative prices determine the yield curve movements by calibration, by definition, there is no arbitrage opportunity in the capital market to exploit the pricing of derivatives. The Ho-Lee result shows that the calibrated probability distributions of interest rates can take on many forms depending on the time horizon and the selected rate to be considered.

Normal Model Versus Lognormal Model

When interest rates were high, around 6%, in the 1980s, interest rates tended to rise and fall by the same amount. The normal model (Ho and Lee (1986)) hypothesizes that rates are equally likely to rise and fall, which is approximately consistent with the swaptions’ prices. That is the normal model measures the rate change by the basis point change, a basis point shift. However, the normal model allows for negative interest rates, an assumption that financial economists categorically rejected. In response, the financial modelers replaced the normal model with the lognormal model.

The lognormal model (Black et al. 1990) assumes interest rates take random walks, analogous to that of the stocks, which always remain positive. The model measures change by the percentage change. When rates are low, the percentage of change can be high. The lognormal model projects rates rising rapidly, creating a positive skewness of the rate distribution, an undesirable attribute.

Nearly 35 years of research sought to resolve these inconsistencies with observed market prices. The figures below illustrate the complexity of interest rate simulations by comparing the outputs of a lognormal model and a normal model. The charts depict the monthly 1-month swap rates simulated over 30 years. The BGM model,⁶ an operational interest rate model, generates 257 interest rate paths under a lognormal (on the left) and normal model (on the right). These interest rate paths are consistent with market pricing of the swaps and a portfolio of swaptions, satisfying the arbitrage-free model assumption.

The simulation shows that the lognormal model does not allow negative interest rates, resulting in a positively skewed rate distribution. By way of contrast, the normal model allows for significantly negative interest rates while maintaining the rate distribution to be symmetric (Figs. 11 and 12).

Appendix B: Local Volatility Model Description

Financial economists have made tremendous progress in interest rate modeling in the past 35 years. Models such as Ho and Lee (1986), Black et al. (1990), Cox et al. (1981), Hull and White (1990), Black and Karasinski (1991), Brace et al. (1997), and

⁶Reference: Technical Notes explains the BGM model.

Figure 11 Underscores the limitation of these interest rate models. Today, interest rate frequency distribution is neither lognormal nor normal. The former does not accept negative rates. The latter cannot take out-of-the-money option prices to determine the asymmetric cap and floor premiums and often leads to significant negative interest rates.

Figure 12 Presents interest rate paths over 30 years. The results depict the limitations of the lognormal and normal interest rate models. The lognormal model is positively skewed with the mean 1-month rate that exceeds the median rate at a time horizon. The normal model has no skewness with the average rate and the median rate the same.

Longstaff et al. (2002) continually enhance interest rate modeling. These models have also introduced many new concepts such as martingale, lattice, recombining, delta hedge, risk-neutral measure q , physical measure p , kernel, vol surface, lognormal and normal models, OAS and Greeks, string theory, stratified sampling, rational option exercise rules, and CEV skew model. The study of interest rate modeling has even become a core course in the mathematics department.

For the following equations, we use the notations:

r = a short – term rate

$\emptyset$ = term structure of volatilities.

$\sigma(t)$ = term structure of volatilities

dz = wiener process; normal distribution over a short time

The basic models from which extend many other models for credit risks yield curve movements, computational efficiencies:

$$dr = \emptyset(t)dt + \sigma(t)dz$$

The term structure of volatilities is independent of the rate level in the normal model. The Heath et al. (1992) models determine the term structure of volatilities using the forward rates.

$$dr = \emptyset(t)rdt + \sigma(t)rdz$$

The term structure of volatilities is proportional to rates in the lognormal model. Black et al. (1990) avoids negative rates.

$$dr = \emptyset(t)(1-r)dt + \sigma(t)r^{0.5}dz$$

The Cox et al. (1981) model shows where the rates mean revert to some long-term rate and rate change depends on the term structure of volatilities and positively related to the rate level

$$dr = \emptyset(t, r)dt + \sigma(t)r^{\alpha}dz$$

The elasticity (α) of the constant elasticity variance model is between 1 and 0.1. BGM (LIBOR market model) is a CEV model with an efficient algorithm that fits precisely to market pricing of swaptions. These models do not accept negative rates. To allow for negative rates, BGM and Hull-White models allow for a modeler to set the floor rate, which can be negative.

$$dr = \emptyset(t)dt + \sigma(t)\eta(r)dz$$

The local volatility model allows for the out-of-the-money options to specify the rate distribution enabling the rate distribution $\eta(r)$ to fit the out-of-the-money option prices (Ho and Mudavanhu 2019).

The established interest rate models do not allow for the swaption prices to specify the rate distribution. Instead, these models impose the swaptions be priced based on a form of lognormal models or a normal model with a constraint of the minimum rate. The local volatility model seeks to overcome these problems in a low-interest-rate regime by explicitly determine the rate distribution $\eta(r)$ from the OTM option prices.

Applications of Logistic Regression and Hazard Method in Accounting and Finance Research

82

Feng Gao

Abstract

This chapter introduces commonly used models to study whether or when an event occurs in accounting and finance research. I begin with parametric models based on the different survival time assumptions and then move on to a semi-parametric regression model, i.e., the Cox proportional hazards model. Finally, I introduce the use of logistic regression in discrete survival time. After reviewing prior literature using these methods, I use an empirical setting to illustrate the applications of these methods in SAS and compare the inferences.

82.1 Introduction

Hazard models are widely used statistical methods that are used to analyze data in clinical trials. Researchers are interested in the time until the occurrence of an event, such as being cured of diseases or death – these events are one-time events. These

F. Gao (✉)

Department of Accounting and Information Systems, Rutgers University, New Brunswick, NJ, USA

e-mail: fgao@business.rutgers.edu

models are also used to estimate events that happen multiple times, like the relapse of diseases. These models have been applied to research areas other than medical research, such as economics, finance, and accounting.

In accounting and finance research, there is often a need to estimate the risk of certain notable events, including the failure of firms (i.e., Shumway 2001; Iwasaki 2014; Bhattacharjee et al. 2009; Gerakos et al. 2013; Fjesme et al. 2021), small business owners (e.g., Agarwal et al. 2005), hedge funds (e.g., Lee and Kim 2014), or banks (e.g., Audrino, Kostrov, and Ortega 2019). Researchers are also interested in the factors leading to personnel turnover (e.g., Jenter and Kanaan 2015; Maturana and Nickerson 2020).

Researchers also predict the likelihood of bond default (e.g., Moeller and Molina 2003), the beginning of foreclosures (e.g., Agarwal et al. 2018), the termination of an initial public offering (e.g., Chen, Guo, and Lin 2010), the early payoff or default of personal loans or credit card accounts (e.g., Banasik et al. 1999; Bellotti and Crook 2009), or the likelihood of regulatory actions (e.g., Leverty and Grace 2018). These studies share one common feature – the variable of interest is whether events would occur and when they occur. The statistical methods used include various hazard regression models and logistic regression. In this section, I briefly introduce the theory and application of commonly used models. In later sections, I first review the empirical literature in more detail and then use the data on class action lawsuits and whistleblowing to illustrate the application of different hazard models.

82.1.1 Hazard Models

82.1.1.1 Hazard Models: Some Basic Concepts

A key concept in hazard models is the survival time until an event occurs (T). When the time to event T is a continuous random variable, its cumulative distribution function is¹

$$F(t) = \Pr(T \leq t) = \int_0^t f(u) du.$$

The probability density function (pdf) of T is

$$f(t) = \frac{dF(t)}{dt} = -\frac{dS(t)}{dt}.$$

The survivor function is

$$S(t) = \Pr(T > t) = 1 - F(t).$$

¹I use the notation from Gao and He (2020) throughout the paper.

By definition, $S(0) = 1$, $S(\infty) = 0$. This function measures the probability of survival at time t if a subject is alive at the origin of time ($t = 0$), and it is decreasing in time.

The hazard function, i.e., an instantaneous risk that an event will happen at time t , is defined as

$$\lambda(t) = \lim_{\Delta t \rightarrow 0} \frac{\Pr(t \leq T < t + \Delta t | T \geq t)}{\Delta t} = \frac{f(t)}{S(t)}.$$

The hazard function is not a probability; instead, it is an instantaneous risk that an event will happen at time t . The hazard function is often interpreted as the expected number of events in a one-unit interval of time, so it is also called the hazard rate. The reciprocal of the hazard rate is sometimes called the Mills ratio (Mills 1926), which gives the expected length of time until an event happens. The relationship between these functions can be expressed in multiple formats.

$$\lambda(t) = \frac{f(t)}{S(t)}$$

or

$$\lambda(t) = -\frac{d}{dt} \log S(t),$$

or

$$S(t) = \exp \left[-\int_0^t \lambda(u) du \right].$$

The cumulative hazard function is

$$\Lambda(t) = \int_0^t \lambda(u) du.$$

The relationship between the survivor function and the cumulative hazard function can be rewritten as

$$S(t) = \exp [-\Lambda(t)],$$

and the relationship between the probability density function, hazard function, and the cumulative hazard function is

$$f(t) = \lambda(t) \exp [-\Lambda(t)].$$

The most commonly used methods to estimate the survivor function are Kaplan-Meier estimator and life-table estimator. The Kaplan-Meier estimator is also known as the product-limit estimator. It is a nonparametric statistic that was independently

developed by Kaplan and Meier (1958). It can be used to measure the fraction of patients that survive for a certain amount of time after taking medication or receiving treatment, or the length of unemployment after people lose their jobs. I briefly introduce the Kaplan-Meier estimator below.

Assume that a total number of k events are observed for a sample of n individuals, where $k \leq n$. Assume these k events occur at distinct times, and $0 < t_1 < t_2 < \dots < t_k$. So, t_i is a time when at least one event happened. Let d_i be the number of events that happened at time t_i and n_i the number of subjects that have not yet had an event or have not been censored at time t_i , where $1 \leq i \leq k$. The Kaplan-Meier estimator for the survivor function is defined as

$$\hat{S}(t) = \prod_{i: t_i \leq t} \left(\frac{n_i - d_i}{n_i} \right).$$

For $t < t_1$, $\hat{S}(t)$ is defined as 1. For $t > t_k$, $\hat{S}(t) = 0$ if there are no censored times greater than t_k . $\hat{S}(t)$ will be undefined if the censored times are greater than t_k . The Kaplan-Meier estimator changes value only at the observed survival time.

The standard error of the Kaplan-Meier estimator is most commonly estimated by Greenwood's formula:

$$\text{var}[\hat{S}(t)] = [\hat{S}(t)]^2 \sum_{i: t_i \leq t} \frac{d_i}{n_i(n_i - d_i)}.$$

The variance formula helps to construct the limits of the $(1 - \alpha)100\%$ confidence intervals at the specific time t of $\hat{S}(t)$, i.e.,

$$\hat{S}(t) \pm z_{\alpha/2} \cdot \sqrt{\text{var}[\hat{S}(t)]}.$$

This confidence interval is time dependent and does not apply to the entire sample. The limitation of the Kaplan-Meier estimator is that we cannot use it to estimate survival after controlling for covariates.

The life-table estimator uses an algorithm that is similar to the Kaplan-Meier estimator. It also counts the actual number of events from the longitudinal data. It is also known as the actuarial-table estimator. It could handle a large sample of survival data in which survival times are grouped into intervals.

Assume the survival times are grouped into $k + 1$ intervals $(0, t_1)$, (t_1, t_2) , $\dots$, (t_{k-1}, t_k) , (t_k, ∞) . Let d_i be the number of events, c_i be the number of censored cases, and n_i be the number of subjects at risk at the beginning of the time interval (t_i, t_{i+1}) , where $0 \leq i \leq k$, $t_0 = 0$, and $t_{k+1} = \infty$. For any $j = 1, \dots, k$, the life-table estimator for the survivor function is defined as

$$\hat{S}(t_j) = \prod_{i=0}^j \left(\frac{n_i - \frac{c_i}{2} - d_i}{n_i - \frac{c_i}{2}} \right).$$

The estimation of the variance of life-table estimator is similar to the application of Greenwood's formula for Kaplan-Meier estimator,

$$\text{var}[\widehat{S}(t_j)] = [\widehat{S}(t_j)]^2 \sum_{i=0}^j \frac{d_i}{(n_i - \frac{c_i}{2} - d_i)(n_i - \frac{c_i}{2})}.$$

82.1.1.2 Parametric Hazard Models

The nonparametric methods do not allow researchers to control for explanatory variables, but parametric hazard models do. Assume a vector $\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{ip})^T$ for the explanatory variables of an individual i . Both continuous variables and indicator variables for qualitative classifications can be explanatory variables in parametric hazard models. The vector $\boldsymbol{\beta} = (\beta_1, \beta_2, \dots, \beta_p)^T$ represents the coefficients to be estimated. We assume that a linear predictor $\boldsymbol{\beta}^T \mathbf{x}_i = \sum_{j=1}^p \beta_j x_{ij}$ affects the survival rate through some function $\psi(\boldsymbol{\beta}^T \mathbf{x})$. The most common parametric models are the accelerated failure time (AFT) models.

Let S_0 and λ_0 be the baseline survival function and the baseline hazard function. AFT models assume $S_i(t) = S_0(\psi t)$ and $\lambda_i(t) = \psi \lambda_0(\psi t)$ for all t . The logarithm of survival time is

$$\log T_i = \sum_{j=1}^p \beta_j x_{ij} + \sigma \epsilon_i = \boldsymbol{\beta}^T \mathbf{x}_i + \sigma \epsilon_i,$$

where $\boldsymbol{\beta} = (\beta_1, \beta_2, \dots, \beta_p)^T$ represents the vector of unknown regression parameters, $\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{ip})^T$ is the vector for a total of p explanatory variables of an individual i , and σ is an unknown scale parameter. Different AFT models are named after the distribution of *survival time* T rather than the distribution of ϵ . These models are estimated using the maximum likelihood method regardless of the distribution of T .

I first briefly describe the exponential model, one of the commonly used AFT models. If T is assumed to follow the exponential distribution, its pdf function is

$$f(t) = \lambda \exp(-\lambda t).$$

The survival function is

$$S(t) = \exp(-\lambda t),$$

where $\lambda = \exp(-\boldsymbol{\beta}^T \mathbf{x})$, and the hazard function is assumed to be independent of survival time t , i.e.,

$$\lambda(t) = \lambda > 0.$$

An extension of the exponential model is the Weibull model. If T is assumed to follow a Weibull distribution, its pdf function is

$$f(t) = \lambda \gamma t^{\gamma-1} \exp[-\lambda t^\gamma].$$

The survival function is

$$S(t) = \exp[-\lambda t^\gamma],$$

where $\gamma = \frac{1}{\sigma} > 0$, and $\lambda = \exp(-\beta^T \mathbf{x}/\sigma) > 0$. When the Weibull shape parameter σ equals one, the Weibull model is equivalent to the exponential model.

The log-normal model is when T is assumed to follow a log-normal distribution (i.e., $\log T$ follows a normal distribution). The corresponding pdf function is

$$f(t) = \frac{1}{\sqrt{2\pi}\sigma t} \exp\left\{-\frac{1}{2}\left(\frac{\log t - \mu}{\sigma}\right)^2\right\},$$

The corresponding survivor function is

$$S(t) = 1 - \Phi\left(\frac{\log t - \mu}{\sigma}\right),$$

where $\beta^T \mathbf{x} > 0$, $\sigma > 0$, and Φ is the cumulative distribution function for the normal distribution.

The generalized gamma model is when T is assumed to follow a three-parameter generalized gamma distribution. Its pdf is

$$f(t) = \frac{\gamma \tau^\theta}{\Gamma(\theta/\gamma)} t^{\theta-1} \exp[-(\tau t)^\gamma], \theta > 0, \tau > 0, \gamma > 0$$

where Γ is a complete gamma function. Both the Weibull model and log-normal model are nested within the generalized gamma model. For example, the generalized gamma distribution is also the Weibull distribution (when $\theta = \gamma$ and $\lambda = \tau^\gamma$).

When T follows a log-logistic distribution (i.e., $\log T$ follows a logistic distribution), we have the log-logistic model. The pdf function is

$$f(t) = \frac{\lambda \gamma t^{\gamma-1}}{(1 + \lambda t^\gamma)^2},$$

and the survival function is

$$S(t) = \frac{1}{1 + \lambda t^\gamma},$$

where $\gamma = 1/\sigma$ and $\lambda = \exp(-\beta^T \mathbf{x}/\sigma)$. The log-logistic model has no nesting relationship with any of the previously introduced models.

82.1.1.3 Semiparametric Hazard Models

Unlike the parametric methods, semiparametric models do not assume the distribution of the survival time T . The Cox proportional hazard model is a widely used semiparametric model. The model assumes $S_i(t) = [S_0(t)]^\psi$ and the hazard function is $\lambda_i(t) = \psi\lambda_0(t) = \lambda_0(t) \exp(\boldsymbol{\beta}^T \mathbf{x}_i)$, where S_0 and λ_0 denote the baseline survival function and baseline hazard function. $\boldsymbol{\beta}$ is the vector of unknown regression parameters, $\mathbf{x}$ is the vector of explanatory variables, and λ_0 is an unspecified baseline hazard function. Because $\boldsymbol{\beta}^T \mathbf{x}_i$ is still used for estimating the regression parameters, the Cox proportional hazard model is semiparametric method.

The hazard ratio is a relationship between the instantaneous hazards of two groups. For example, the hazard ratio for individuals i and j is

$$\frac{\lambda_i(t)}{\lambda_j(t)} = \frac{\lambda_0(t) \exp(\boldsymbol{\beta}^T \mathbf{x}_i)}{\lambda_0(t) \exp(\boldsymbol{\beta}^T \mathbf{x}_j)} = \exp[\boldsymbol{\beta}^T (\mathbf{x}_i - \mathbf{x}_j)].$$

In the Cox proportional hazard model, the hazard ratio was often used to measure the effect of an intervention on the occurrence of events (i.e., the treatment vs. the placebo). This ratio does not require the knowledge of the baseline hazard function λ_0 due to cancelation – a major advantage of the Cox proportional hazard model.

Another advantage of the Cox proportional hazard model is the ability of the model to incorporate time-dependent covariates. The hazard ratio does not reflect a time unit of the study. Because the hazard rate is an instantaneous risk that an event happens at time t , the hazard ratio can be simply interpreted as the relationship between the instantaneous hazards in two groups over the whole study time period.

82.1.1.4 Logistic Regression

Although the survival time is often assumed to be continuous, it can be discrete. If the survival time can only be observed in certain intervals (such as in the number of years), the data are commonly referred to as discrete-time data. Let the probability of an individual i experiencing an event at time t be P_{it} ($P_{i0} = 1$).

The odds that an event occurs at time t for an individual i if it has not happened is

$$O_{it} = \frac{P_{it}}{1 - P_{it}}.$$

The proportional odds model assumes $O_i(t) = \psi O_0(t)$ for all t , where O_0 denotes the baseline odds function.

By incorporating the explanatory variables, the model then becomes

$$O_i(t) = O_0(t) \exp(\boldsymbol{\beta}^T \mathbf{x}_i).$$

O_0 is an unspecified baseline odds function, $\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{ip})^T$ is the vector for a total of p explanatory variables of an individual i , and $\boldsymbol{\beta} = (\beta_1, \beta_2, \dots, \beta_p)^T$ is the vector of unknown regression parameters. It follows that $\boldsymbol{\beta}^T \mathbf{x}_i = \sum_{j=1}^p \beta_j x_{ij}$.

The dependent variable is the logarithm of the odds of the outcome, so the coefficients measure the change in the odds ratios. The proportional odds model can be estimated by a standard maximum likelihood method through the traditional logistical regression model. The outcome variable follows a binomial distribution. The advantage of logistic regression is that it is a widely used parametric method and easy to understand.

For any two individuals, i and j , the ratio of their odds can drop out of the baseline hazard function because they are cancelled out.

$$\frac{O_i(t)}{O_j(t)} = \frac{O_0(t) \exp(\boldsymbol{\beta}^T \mathbf{x}_i)}{O_0(t) \exp(\boldsymbol{\beta}^T \mathbf{x}_j)} = \exp[\boldsymbol{\beta}^T (\mathbf{x}_i - \mathbf{x}_j)]$$

Similar to the Cox proportional hazard model, the ratio of the odds does not depend on time t . Sometimes, the proportional odds model is also called the Cox proportional hazard model for discrete-time data.

The Cox model is estimated using the partial likelihood function. Assume that there are n independent individuals, and for each individual i , the data consist of three parts: the observed time Y_i , the event indicator δ_i , and explanatory variables vector $\mathbf{x}_i$. The partial likelihood function can be written as

$$PL(\boldsymbol{\beta}) = \prod_{i=1}^n \left[\frac{\exp(\boldsymbol{\beta}^T \mathbf{x}_i)}{\sum_{t_j \geq t_i} \exp(\boldsymbol{\beta}^T \mathbf{x}_j)} \right]^{\delta_i},$$

where $\sum_{t_j \geq t_i} \exp(\boldsymbol{\beta}^T \mathbf{x}_j)$ includes all individuals who are still at risk at the survival time t_i . Accordingly, the log-partial likelihood is

$$pl(\boldsymbol{\beta}) = \sum_{i=1}^n \delta_i [\boldsymbol{\beta}^T \mathbf{x}_i - \log \sum_{t_j \geq t_i} \exp(\boldsymbol{\beta}^T \mathbf{x}_j)]$$

The score function and the Fisher information matrix function of the log-partial likelihood are

$$\begin{aligned} U(\boldsymbol{\beta}) &= \frac{\partial pl(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}} = \sum_{i=1}^n \left[\delta_i \mathbf{x}_i - \frac{\sum_{t_j \geq t_i} \mathbf{x}_j \exp(\boldsymbol{\beta}^T \mathbf{x}_j)}{\sum_{t_j \geq t_i} \exp(\boldsymbol{\beta}^T \mathbf{x}_j)} \right], \text{ and } \\ I(\boldsymbol{\beta}) &= -\frac{\partial^2 pl(\boldsymbol{\beta})}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}^T} \\ &= \sum_{i=1}^n \left[\frac{\sum_{t_j \geq t_i} \mathbf{x}_j \mathbf{x}_j^T \exp(\boldsymbol{\beta}^T \mathbf{x}_j)}{\sum_{t_j \geq t_i} \exp(\boldsymbol{\beta}^T \mathbf{x}_j)} - \frac{\sum_{t_j \geq t_i} \mathbf{x}_j \exp(\boldsymbol{\beta}^T \mathbf{x}_j) \sum_{t_j \geq t_i} \mathbf{x}_j^T \exp(\boldsymbol{\beta}^T \mathbf{x}_j)}{\left(\sum_{t_j \geq t_i} \exp(\boldsymbol{\beta}^T \mathbf{x}_j) \right)^2} \right]. \end{aligned}$$

Table 1 Comparing different models

	Parametric hazard model	Cox proportional hazard model	Logistic regression model
Model type	Parametric	Semiparametric	Parametric
Estimation method	Maximum likelihood method	Partial likelihood method	Maximum likelihood method
Dependent variable	The logarithm of the duration	The logarithm of the hazard	The logarithm of the odds of the outcome
Distribution of the dependent variable	It depends on the assumption of the survival time T	Not specified	The outcome follows the binomial distribution
Interpretation of the coefficient	Change in the duration	Change in the hazard ratios	Change in the odds ratios
Advantage	Provides efficient estimates if the shape of the distribution of T is known	No need for the baseline hazard or the distribution of T . Robust estimates	It can fit discrete-time data
Disadvantage	Need to specify the distribution of T correctly. Unable to incorporate time-dependent covariates	Usually appropriate for continuous-time data only	Not used for continuous-time data

Similar to parametric regression models, the Wald statistics, the score statistics, and the likelihood ratio statistics are common test statistics for semiparametric models.

If two or more events occur at the same time, the partial likelihood estimation might be invalid. Such events are quite common for data with annual or even monthly frequencies. The usual remedies to handle tied survival time are Breslow's approximation and Efron's approximation. These methods usually take some computational time because they are based on the exact method. An alternative solution is to consider the survival time as discrete and estimate it using logistic regression.

Another advantage of the Cox proportional model is that it can fit time-dependent covariates. Sometimes, all covariates may be time independent, which means they are covariates measured at the baseline ($t = 0$). It is also possible that covariates immediately prior to negative events are of more interest to researchers. Further, some covariates can vary by year, which means they can also be time dependent. The Cox proportional hazard model can be used to accommodate time-dependent covariates.

In Table 1, I present a table briefly summarizing and comparing these models. Parametric hazard models and logistic regression models are both parametric methods, whereas Cox proportional hazard model is a semiparametric method.

The parametric models are estimated using the maximum likelihood method, and Cox proportional hazard model is estimated using the partial likelihood method.

The dependent variables differ across these models. Regardless of the assumption of the distribution of the survival time T , the dependent variables are the logarithm of the duration until an event occurs. The dependent variable for the Cox proportional hazard model is the logarithm of the hazard. If the sign of a coefficient in a parametric regression model is positive, it would be negative in the Cox proportional hazards model. This is intuitive – if an explanatory variable increases the duration until an event occurs, it lowers the hazard or risk of the event. The dependent variable in the logistic regression model is the logarithm of the odds of the event. The expected sign of the coefficients in the logistic regression model is the same as those in Cox proportional hazards model.

The distribution of the dependent variable for parametric hazard models depends on the assumption of the survival time T . Such an assumption is not necessary for Cox proportional method. The distribution of the outcome variable is the binomial distribution in the logistic regression model. The coefficient estimates from parametric hazard models measure the change in the duration for changes in the explanatory variables; in Cox proportional hazard models, they measure the change in the hazard ratios; in logistic regression models, they measure the change in the odds ratios.

If the assumption the distribution of survival time T is known, parametric hazard models provide efficient estimates of the coefficients. However, it requires researchers to correctly specify the distribution of T , and it cannot be used to incorporate time-dependent covariates. In contrast, Cox proportional hazard model does not require researchers to specify either the baseline hazard or the distribution of T . In addition, it provides more robust estimates than parametric hazard models. This model can be used to estimate continuous-time data, and it can fit time-dependent covariates. The logistic regression model is suitable for fitting discrete-time data. It is easy to understand, and the coefficients are easy to interpret.

82.2 Literature Review

The literature has used various models to predict the likelihood of certain events, such as corporate failure. For example, Ohlson (1980) predicts the likelihood of corporate bankruptcy within 1 year using variables including total liabilities, working capital, net income (all deflated by total assets), firm size, and the ratio of funds from operations divided by total liabilities. He also predicts bankruptcy within 2 years if a company did not fail within 1 year or the most recent 2 years.

Also forecasting bankruptcy, Shumway (2001) develops a formal hazard model that can be viewed as a discrete accelerate failure time model or a logit model using all firm-year observations. Using data over 31 years, he finds that some accounting ratios, such as working capital, retained earnings, and sales (all deflated by total assets), are poor predictors of bankruptcy. He also introduces several market-driven

variables that are good predictors in forecasting corporate failures, including market size, past stock returns, and standard deviation of stock returns.

Recent literature has begun using the Cox proportional hazard model in forecasting various events, including personal and corporate bankruptcy, personnel turnover, hedge fund disappearance, acquisitions, IPOs, mergers and acquisitions, loan default, loan prepayment, and regulatory action against failing financial institutions. Agarwal, Chomsisengphet, Liu, and Mielnicki (2005) use the Cox proportional model to assess the impact of state bankruptcy exemption levels on small business owners' decision to file for bankruptcy. They find that higher levels of bankruptcy exemptions levels increase the likelihood of bankruptcy. Bhattacharjee, Higson, Holly, and Kattuman (2009) also use the model to evaluate the impact of macroeconomic instability on two forms of firm that exits in the UK, i.e., bankruptcies or acquisitions. They find an opposing effect of macroeconomic instability – it increases the hazard of bankruptcy but decreases the hazard of acquisition. Using survey data of Russian industrial firms, Iwasaki (2014) applies the Cox proportional hazards model to examine the survival of Russian industrial firms and finds the following important factors, i.e., corporate governance, human resource, and the influence of the board on management.

Brown, Goetzmann, and Park (2002) use the Cox proportional hazard model to examine factors contributing to the failure of hedge funds. They find that the success of hedge funds depends on both absolute and relative performance, excess volatility, and on fund age. Brown, Cookson, and Heimer (2019) use a setup like the Cox proportional hazard model and find that better financial market development on Native American reservations leads to a higher likelihood of entering credit markets.

Jenter and Kanaan (2015) use the Cox proportional hazard model to predict the forced turnover of CEOs and find that the effect of poor industry performance is stronger than the effect of market performance. Khanna, Kim, and Lu (2015) use the Cox method to examine whether CEO connectedness affects how soon fraud is detected. They find that it takes longer to uncover fraud when a CEO has better connections with top executives and directors through past employment, education, or social organization. Maturana and Nickerson (2020) examine the impact of a teacher filing for personal bankruptcy on the likelihood of keeping her job as a public school teacher in the state of Texas in the following year. Leverty and Grace (2018) find causal evidence that regulators delay interventions against failing financial institutions before elections. Fjesme, Galpin, and Moore (2021) use the model to investigate the likelihood of rejected applicants of the London Stock Exchange between 1891 and 1911 and find them more likely to file for liquidation than successful applicants.

Gerakos, Lang, and Maffett (2013) have also used the accelerated failure time model to predict the time until the suspension of trading on a stock exchange together with a negative cumulative return over the 60 days prior to delisting, assuming that the failure rates follow log-normal distribution. They find that firms listed on London's Alternative Investment Market (a privately regulated exchanges) have lower postlisting returns and failure rates than newly listed firms listed on traditionally regulated exchanges. These firms are comparable to those listed on US

Pink Sheets. Doidge et al. (2009) use the Cox proportional hazard model to predict the decision of a foreign firm to cross-list in the USA. Their findings suggest that controlling shareholders are less likely to cross-list when private benefits of controlling shareholders are high. Johnson (2005) also use the Cox model to predict the closure of investment accounts at mutual funds. They find observable shareholder characteristics that can be used to predict whether an account will be short term or long term on the day an account is opened. Becker, Ivkovic, and Weisbenner (2011) use the Cox proportional hazard model to predict when a stock is going to be sold after purchase, conditional on no prior sale. They find that a local senior investors is less likely to sell a share of stock than a nonlocal nonsenior investor.

Hazard models are often used in predicting the default of debt. For example, Banasik, Crook, and Thomas (1999) use it to estimate the length of time until default happens and thus examine when borrowers default rather than if they will default. This question is important because the lender could set the interest rate to compensate for the default risk. They use personal loan data from a UK financial institution. The data on some loans are censored due to the lack of default or prepayment as of the end of the sample period. They use a competing risk approach to model two likely events in the lifetime of a loan, i.e., prepayment of the loan or default. In other words, the survivor function models the distribution of both the length of time until the loan defaults and the time until the loan is repaid early.

In addition to predicting the default likelihood of individual borrowers, survival models are also used to study corporate bonds. For example, Moeller and Molina (2003) use the Cox proportional model to examine how the default probability of high-yield corporate bonds (i.e., junk bonds) changes over time. They use corporate bonds that appeared in the “Recent Corporate Bond Offerings” published by Moody’s with a rating of Ba1 or lower for approximately 6 years in the 1980s and find a constantly increasing risk of default over time, especially after the debt has been outstanding for 4 years.

Several researchers use different methods on the same data for comparison. Stepanova and Thomas (2002) use different extensions of the Cox proportional hazards model to analyze personal loan data in a major UK financial institution. Rather than using continuous characteristics such as age, they assign the values into 15–20 equal bands, thus developing a coarse classifying approach. They show that survival analysis models are competitive with (and sometimes superior to) the standard logistic model. Further, Bellotti and Crook (2009) show that the Cox proportional hazards model is competitive compared to logistic regression for predicting default on credit card accounts. They incorporate time-varying macro-economic variables such as bank interest rates, unemployment, and housing prices and show that these variables increase the model’s predictive ability. Lee and Kim (2014) find that the mixed Cox proportional hazards model predicts hedge fund failure more accurately than other models, such as fixed covariate proportional models and discrete logit models. Agarwal, Amromin, Ben-David, and Dinc (2018) use both parametric models (Exponential hazard, Weibull hazard, and linear probability model) and semiparametric models (Cox proportional hazard model) to predict the start of foreclosure in 2009–2010. They find that foreclosure is delayed

on delinquent mortgages in the districts of committee members by 0.5 months. The estimated costs to lenders is substantial. It is greater than the campaign contributions made by the political action committees of the largest mortgage servicing banks to the committee members.

82.3 Empirical Application

To illustrate the application of these methods, I obtain a sample of firms with class action lawsuits and examine the influence of employee whistleblowing on the probability of case dismissal. I identify 236 class action shareholder lawsuits filed in Federal courts from 2004–2014 from the Securities Class Action Services (SCAS) database using the Institutional Shareholder Services. Out of these lawsuits, 121 cases are dismissed during the sample. The rest are active lawsuits as of the end of the sample period. Firms with employee whistleblowing discrimination cases filed are based on data from the Occupational Safety and Health Administration (OSHA). Firm characteristics, such as the level and volatility of stock returns, total assets, and sales growth, come from COMPUSTAT and CRSP. Table 2 tabulates the details of the variable definition.

I start with parametric models. First, I use the logistic model to examine whether lawsuits against firms with employee whistleblowing are more or less likely to be dismissed, i.e.,

$$Prob(Dismissed_{t+k} = 1) = \beta_1 + \beta_2 * Whistleblowing_t + \beta_3 * Assets_t + \beta_4 * Sales_growth_t + \beta_5 * Return_t + \beta_6 * Volatility_t + \varepsilon \quad (1)$$

The SAS program is the following:

```
* 1. Parametric Estimation: Logistic;
```

Table 2 Variable definition

Variables	Definition
<i>Duration</i>	The number of years between the class action lawsuits and the date of dismissal for cases that are dismissed, or the end of the sample period, i.e., October 31, 2015
<i>Dismissed</i>	An indicator variable equal to 1 if a class action lawsuit is dismissed
<i>Whistleblowing</i>	An indicator variable equal to 1 if the firm has experienced a whistleblowing allegation and 0 otherwise
<i>Assets</i>	The natural logarithm of total assets
<i>Sales_growth</i>	The growth rate of annual sales in the past 3 years
<i>Return</i>	The firm's market-adjusted 12-month stock return prior to the lawsuit announcement
<i>Volatility</i>	The natural logarithm of the standard deviation of firm-specific returns in down weeks/the standard deviation of firm-specific returns in up weeks

Table 3 Estimating model (1) using logistic regression

Panel A Coefficient estimates

```

proc logistic data=firms descending;
model dismissed = Whistleblowing Assets Sales_growth Return
Volatility;
quit;

```

I summarize the results of estimating model (1) using the logistic regression in Table 3. Panel A tabulates the coefficient estimates, standard error, and p-values of the Wald Chi-square statistic. The variables that are significantly different from zero include *Whistleblowing*, *Assets*, and *Sales_growth*. For example, lawsuits associated with employee whistleblowing are less likely to be dismissed (coef. = -1.6162 ; $p\text{-value} = 0.0242$), while cases against firms with more assets and faster sales growth are more likely to be dismissed (coef. = 0.2102 , $p\text{-value} = 0.0145$; coef. = 0.9166 , $p\text{-value} = 0.0979$, respectively).

Panel B tabulates the odds ratio of the coefficients to evaluate the economic significance of these variables. The odds ratios are the exponentiated coefficients. For example, Panel A shows that the coefficient estimate of *Whistleblowing* is -1.6162 , its exponential is $\exp(-1.6162) = 0.199$ after rounding. Compared with lawsuits that are not associated with employee whistleblowing, the odds of a lawsuit being dismissed versus not dismissed are reduced by a factor of 0.199. This effect appears to be economically significant.

We next use parametric models with different assumptions of the distribution of T to estimate the duration (i.e., survival time) until an event (i.e., a case being dismissed) occurs. In this case, the longer the survival time, the less likely a lawsuit is dismissed. Depending on the assumption of the distribution of the survival time (i.e., exponential, Weibull, log normal, or log logistic), we choose one of the following SAS commands.

```

* 2. Parametric Estimation: Exponential;
proc lifereg data=firms;
  model duration*dismissed(0)=
Whistleblowing Assets Sales_growth Return Volatility /
D=exponential;
run;

* 3. Parametric Estimation: Weibull;
proc lifereg data=firms;
  model duration*dismissed(0)=
Whistleblowing Assets Sales_growth Return Volatility/ D=weibull;
run;

* 4. Parametric Estimation: Log normal;
proc lifereg data=firms;
  model duration*dismissed(0)=
Whistleblowing Assets Sales_growth Return Volatility/ D=lnormal;
run;

* 5. Parametric Estimation: Loglogistic;
proc lifereg data=firms;

```

Table 4 Coefficient estimates from parametric duration analysis

Panel A Exponential model		
Variables	Coef. estimate	P-value
<i>Whistleblowing</i>	1.6532	0.0056

model duration*dismissed(0)=  
Whistleblowing Assets Sales_growth Return Volatility/ D=Llogistic;  
run;
```

After estimating the four parametric duration models, we report the coefficient estimates for each of the four models in Table 4. Despite different assumptions of the distribution, the coefficient estimates have the same signs, suggesting the same inferences across these models. For example, the coefficient on *Whistleblowing* is positive and significantly different from zero in all models, mostly at the 1% level. This indicates that lawsuits against firms with employee whistleblowing have a longer expected duration and are less likely to be dismissed. Note that even though the coefficients have the opposite signs from the logistic model, the inference remains the same.

We need to transform the parameter estimates to obtain the economic significance. Take the coefficient on *Whistleblowing* from Panel A of Table 4 for an example – $\exp(1.6532) = 5.223$. Therefore, cases against firms with employee

Table 5 Coefficient estimates from semiparametric survival analysis

Parameter	Parameter estimate	Standard error	Chi-square	Pr > ChiSq	Hazard ratio
<i>Whistleblowing</i>	-1.2002	0.5959	4.0575	0.0440	0.301
<i>Assets</i>	0.1336	0.0565	5.5917	0.0180	1.143
<i>Sales_growth</i>	0.5805	0.3459	2.8147	0.0934	1.787
<i>Return</i>	-0.1500	0.1898	0.6244	0.4294	0.861
<i>Volatility</i>	-0.1071	0.1490	0.5168	0.4722	0.898

whistleblowing have an expected duration of 5.223 times that for cases without employee whistleblowing. The effect of whistleblowing on the likelihood of class action lawsuits appears economically significant, as the empirical findings based on logistic regression. Similarly, the inferences on *Assets* are also consistent for both logistic regression and parametric duration analysis. However, none of the coefficients on *Sales_growth* is significantly different from zero, which differs from the variable being marginally significant using logistic regression.

Next, we use a semiparametric method, i.e., the Cox proportional hazards model, to estimate the hazard function. The SAS program below illustrates how we implement the estimation, dealing with ties using Efron's approximation. We tabulate the coefficient estimates in Table 5. The statistical significance of the variables is similar to that using logistic regression.

However, the signs of the coefficients are exactly the opposite of those from the parametric duration analysis. Still, the inferences are the same – the Cox proportional hazard model estimates the hazard ratio, which indicates the occurrence of dismissal. In contrast, the parametric duration models estimate the survival time until dismissal. The economic significance of the coefficients can also be obtained by taking the exponential of the coefficient. For example, $\exp(-1.2002) = 0.301$. This means that the hazard of a lawsuit being dismissed decreases by 69.9% if the lawsuit is associated with employee whistleblowing.

  model duration*Dismissed(0)=
  Whistleblowing Assets Sales_growth Return Volatility / ties=efron;
run;
```

82.4 Conclusion

This chapter briefly discusses a few commonly used hazard models in accounting and finance research. Researchers in these fields are often interested in predicting the time until bankruptcy, the decision to cancel intimal public offering, being delisted from an exchange, default of corporate debt and personal loans, and a dramatic

change in stock price. Hazard models can also be used to predict time until events such as executive turnover.

I first introduce parametric models based on the different assumptions of the distribution of the survival time. Next, I describe a semiparametric regression model, i.e., the Cox proportional hazards model. I also introduce the use of logistic regression when dealing with discrete-time data. Using data on class action lawsuits and employee whistleblowing data, I illustrate how to apply these methods in SAS and compare the inferences.

Cube Root Utility Theory

83

Jack Clark Francis

Abstract

The von Neumann-Morgenstern (vNM) utility function suggested here has loss aversion and consistently increasing utility of wealth between $-\infty$ and ∞ . It is also concave over favorable outcomes and convex over unfavorable outcomes. The function contains a consistent preference for positively skewed outcomes. The weighted probabilities in Kahneman and Tversky's (KT's) cumulative prospect theory do not align with the vNM requirement that the probabilities sum to one; nevertheless, important advantages are gained from the vNM assumption.

Keywords

Utility function · Kahneman-Tversky prospect theory · Cube root function · von Neumann-Morgenstern (vNM) utility theory · Radical function · Risk aversion · Loss aversion · Absolute risk aversion · Relative risk aversion

83.1 Introduction

A cube root is a number x that satisfies the relationship $y = \sqrt[3]{x} = x^{1/3}$. Figure 1 illustrates two cube root utility functions that are mirror images of each other. Equation (1) represents an S-shaped solid curve in Fig. 1 that slopes continually upward. Economic theory assumes people always prefer more money to less money; the solid curve in Fig. 1 reflects that assumption. The dotted line in Fig. 1 that decreases monotonically does not

Fig. 1 Two symmetric cube root gain-loss functions

Note: The two cube root utility functions in Fig. 1 are mirror images of each other, but the dotted curve is implausible and is not be discussed further

represent plausible economics because it illustrates the preferences of someone who always prefers less money over more money. Therefore, this entry proposes and analyzes the solid cube root utility function in Fig. 1 that is defined in Eq. (1).

$$U(x) = \sqrt[3]{x} = x^{1/3} \quad dU/dx > 0 \quad (1)$$

Figure 2 is a modified version of the solid curve in Fig. 1. The solid curves in Figs. 1 and 2 both illustrate cube root utility functions that manifest the preferences suggested by Daniel Kahneman and Amos Tversky's (1979, 1992) prospect theory.¹

83.1.1 Initial Analysis

This chapter suggests a von Neumann-Morgenstern (vNM) cube root utility function, $U(x)$, which generates all the behaviors in Kahneman and Tversky's prospect theory (1979, 1992) except the weighted probabilities. This vNM theory is defined on dollar gains and losses measured from the origin and these gains and losses are represented by x in the radical Eq. (1).

Although the economics in Eq. (1) mimics the economics in the KT's prospect theory, the mathematics in the cube root utility function are more useful because

¹See Kahneman and Tversky (1979). Also see Tversky and Kahneman (1992). These articles and related articles are reproduced in a book of readings edited by Kahneman and Tversky (2000).

Fig. 2 A cube root utility function that aligns with Kahneman and Tversky
Notes: The cube root utility function is a reconfigured version of the solid S-shaped curve in Fig. 1. It is defined by the two following cube root equations: $y = 2\sqrt[3]{10} x^{1/3}, x < 0$, and $y = \sqrt[3]{10} x^{1/3}, x > 0$

vNM utility theory requires that the probabilities sum to one. As a result, some impressive behavioral research supporting KT’s cumulative prospect theory model with weighted probabilities is not included here.² What is more essential here is the mathematical expectation, standard deviation, variance-covariance matrix, and other important classical probability theories that can be used only if the probabilities sum to one, as assumed in vNM utility theory. Except for the fact that weighted probabilities are not used in the vNM model proposed here, all the rest of KT’s prospect

²Kahneman and Tversky (KT) introduced prospect theory with weighted probabilities in 1979 and 1992. This branch of behavioral economics is important and research in that direction should continue in the future. A paper by J.C. Francis that is similar to this chapter is published in the Review of Quantitative Finance and Accounting, 2021.

Fig. 3 Three S-Shaped Functions and One Linear Function, $U(x)$

Notes: The straight black line through the origin in Fig. 3 is a reference line representing a linear utility function with a slope of $dU(x)/dx = 1$. The Kahneman-Tversky value function is the dashed curve denoted KT in the legend. The solid gray curve that is symmetric about the origin represents Eq. (1); this is the simplest cube root utility function. The dotted curve represents the cube root utility function with each negative util multiplied by 3.25 and each positive util multiplied by 2; these two simple modifications show how easy it is to bring the cube root function closer to KT's dashed curve (see footnote 5)

theory emerges unscathed. Reformulating KT's prospect theory in a vNM format creates a new model that is more compatible with many existing economic, finance, decision theory, and psychological models. In addition, it will be shown below that cube root utility theory also provides important advantages over other popular vNM utility functions such as the log function and the square root function. Instead of competing with or detracting from KT's prospect theory, the vNM model introduced here suggests new and useful ways to employ prospect theory.

The linear utility function (black line), which has a slope of $dU/dx = 1$ in Fig. 3, is a reference line. Figure 3 compares Eq. (1) (the gray curve, denoted CR1 in the legend) with the Kahneman-Tversky value function (dashed curve, denoted KT in legend). KT have referred to graphs like these two curves as "S-shaped functions" (Kahneman and Tversky 1979, page 179).³ Generally over losses KT's S-shaped

³We follow KT's use of the phrase "S-shaped function" (KT, 1979, page 179). Their exponent of 0.88 is so close to 1.0 that KT's value curve is nearly linear. In fact, several researchers prefer to use piecewise linear approximations to our S-shaped function; for instance, see Nicholas Barberis and Wei Xiong, 2012. Unfortunately, piecewise linear functions are not able to span the space between positive infinity and negative infinity with a single equation. See Harel, Francis and Harpaz (2018) about functional forms.

function has a steeper slope than Eq. (1). This is because KT uses an exponent of +0.88 instead of an exponent of +1/3 for all x , and KT multiply the losses by a coefficient of 2.25 to compute the disutility from losses.⁴ The dotted curve (CR2 in legend) shows how simple it is to manipulate the cube root function to make it align more closely with KT's curve; this is accomplished by making the losses in Eq. (1) slope downward more steeply and by making the gains slope upward more steeply.⁵ Eq. (1) and KT's value function (that is, CR1 and KT in Fig. 3) are both S-shaped functions with a point of inflection at the origin. They can easily be modified to resemble each other more closely than illustrated in Fig. 3.

Equation (1) is represented by a single continuous line between positive infinity and negative infinity. It has both absolute risk aversion (ARA) and relative risk aversion (RRA), generates a consistent preference for positively skewed outcomes, and never conflicts with (Kahneman and Tversky 1979) or (Tversky and Kahneman 1992).⁶ The positively sloped cube root function in Eq. (1) is the simplest form of an infinite number of different S-shaped radical utility functions. Many, but not all, of these radical utility functions have desirable characteristics. In the conclusion, it will be shown below that the square root, logarithmic, exponential, and other frequently used utility functions do not possess as many desirable characteristics as the cube root utility function. Furthermore, each involves significant deficiencies.

Section 83.1.2 contains a review of the literature. Every research item discussed supports KT's prospect theory, the vNM cube root utility function, and the other vNM qualified radical utility functions because they are all economically similar. Section 83.2 dichotomizes various utility functions into two groups: functions that are qualified to analyze utility theory and functions that are unqualified. Section 83.3 explains why the cube root utility function is a useful utility function. Section 83.4 contains an initial analysis of the cube root utility function. Section 83.5 focuses on the gains in the concave segment (the positive line segment) of the cube root utility function. Section 83.6 analyzes the losses in the convex segment (the negative line segment) of the cube root utility function. Section 83.7 uses the Taylor Expansion to analyze the decision-maker's skewness

⁴KT's cumulative prospect theory paper (1992, Eq. (5)) analyzes the following S-shaped function:

$$U(x) = \begin{cases} x^{0.88}, & x \geq 0 \\ -2.25(-x)^{0.88}, & x < 0 \end{cases}$$

This is the equation underlying the dashed curve denoted KT in Fig. 3.

⁵The dotted curve in Fig. 3 represent: $U(x) = \begin{cases} 2x^{1/3}, & x \geq 0 \\ -3.25(-x)^{1/3}, & x < 0 \end{cases}$

⁶See Kahneman and Tversky (1979) and Tversky and Kahneman (1992).

preferences. Section 83.8 contains summary and concluding remarks. Appendix A generalizes the cube root results discussed in this chapter to other vNM radical utility functions.

83.1.2 Review of the Literature

Framing a Utility Function Harry Markowitz (1952) was the first to analyze the utility from gains and the disutility from losses relative to a *reference point* at the origin⁷, as KT have acknowledged (KT 1979, page 276). Markowitz proposed a utility function that contained both concave and convex segments. However, Markowitz left it for KT to link the concave region of the utility function with gains and the convex region with losses.

The Disposition Effect In 1985 Hersh Shefrin and Meir Statman analyzed the tendency of investors to prematurely sell stocks while they were still appreciating (Shefrin and Statman 1985). They also reported that investors tend to hold depreciating stocks for too long. These two unprofitable investor tendencies are referred to as the “disposition effect.” In 1998, Terrance Odean reported that brokerage accounts of 10,000 investors he analyzed provided further evidence supporting the disposition effect (Odean 1998b). Andrea Frazzini (2006) analyzed quarterly market data covering 29,000 mutual funds and found additional support for the disposition effect (Frazzini 2006). Other researchers have also published findings that support the disposition effect; some of these are discussed below.

Prospect theory provides theoretical explanations for the empirically observed aspects of the disposition effect. Shefrin and Statman, Odean, and Frazzini studied investors’ decisions to sell appreciating stocks before they reached their peak prices. Some of these appreciating stock prices will rise up into the concave section of KT’s utility function and this will cause the investor to become risk-averse. This increasing risk-aversion motivates investors to liquidate the appreciating assets. Second, Shefrin, Statman, Odean, and Frazzini studied investors’ reluctance to sell stocks when their prices were declining. Declining stock prices move down into the convex section of KT’s utility function where risk-taking becomes attractive. The resulting increased willingness to assume risk makes the investor increasingly likely to hold a depreciating stock in hopes that its falling price will rebound. Third, these scholars studied empirical evidence that investors fear losses more than they enjoy equal-sized gains. When the declining price of an asset falls through the inflection point at the origin, KT’s value function changes from concave to steeply convex. This increase in prospect theory’s loss aversion function explains why investors fear losses more than they enjoy gains of equal size.

⁷Markowitz (1952). KT acknowledge Markowitz’s contributions near their Fig. 3 in their 1979 paper. Kahneman and Tversky (1979).

Frazzini (2006) also discusses how security prices can underreact to news. He argues that if many investors display the disposition effect, stock prices may “underreact” to news, returns may be more predictable, and post-announcement prices may drift.

Mental Accounting In 1985 Richard Thaler noted that many people categorize life’s events in economic terms. Some of these people create mental accounts that are retained and used in decision-making, self-control, budgeting expenditures, planning, and saving for specific purposes (such as saving for college, planning a trip, or medical care). Furthermore, many investors categorize profitable investments as good outcomes and unprofitable investments as bad outcomes (Thaler 1985).⁸ The way a person chooses to assign resources to such categories can unintentionally create biases and departures from rational decision-making. Once adopted, these departures from rationality can become repetitive and might even be lifelong. Understanding the shortcomings of mental accounting can improve decision-making and open new research opportunities.

Grinblatt and Han (2005) use mental accounting and prospect theory to create a profitable momentum trading strategy (Grinblatt and Han 2005). (Frydman et al. 2018a, b) extended Thaler’s mental accounting to include what they call rolling mental accounting (Frydman et al. 2018a, b). Their laboratory experiments show that reinvestment decisions can cause reductions in the disposition effect that increase the profitability of trading.

The Mehra-Prescott Equity Risk Premium Puzzle In 1985 Rajnish Mehra and Edward Prescott reported a surprisingly large risk premium between the rates of return from common stock and Treasury bills during the century before 1985 (Mehra and Prescott 1985). They said it is difficult to explain this large empirical risk premium because the amount of risk aversion needed to justify it is theoretically implausible. Many empirical studies tried and failed to rationalize the oversized Mehra-Prescott equity risk premium. Then, in 1995 Shlomo Benartzi and Richard Thaler offered a two-part theoretical explanation for the over-sized Mehra-Prescott equity risk premium (Benartzi and Thaler 1995). First, Benartzi and Thaler suggested that investors are very loss averse. In other words, most investors are much more afraid of losses than they are pleased by an equal-size gain. These asymmetric risk preferences were previously explained by KT’s prospect theory (1979). Second, Benartzi and Thaler report that investors act as if they evaluate their portfolios annually, even if the portfolio’s planning horizon spans decades. That is, investors make their portfolio decisions as if they were operating with a one-year planning horizon. This myopic behavior is called “narrow framing.”

⁸ Also, see Barberis and Huang 2006.

Narrow Framing Barberis et al. (2006) provided further support for Benartzi and Thaler's 1995 finding that investors make decisions as if they were operating with a 1-year planning horizon (Barberis et al. 2006). The decision-making process called "narrow framing" gained popularity. Since 1995, much important research that is discussed below uses narrow framing to enrich the research. Recently, for example, Nicholas Barberis, Lawrence Jin, and Baolian Wang (October 2019) used narrow framing to investigate 22 prominent stock market anomalies.⁹

Realization utility As mentioned above, Richard Thaler's research into mental accounting revealed that many investors categorize profitable investments as good outcomes and unprofitable investments as bad outcomes. This focus on realized gains and realized losses motivated Nicholas Barberis and Wei Xiong to develop a utility realization theory based on an individual's investment transactions (Barberis and Xiong 2012). Realization utility is a narrowly framed analysis of decision-making that focuses on transactions involving a single stock, house, or mutual fund. The Barberis-Xiong realization utility theory model can rationalize the disposition effect and other behaviors that are part of prospect theory.¹⁰

Investigating narrow framing In 2001 Barberis and Huang created an asset pricing model based on mental accounting, loss aversion, the "house money effect," and several other realistic market assumptions (Barberis and Huang 2001a, b). The model simulates investor 1-year forecasts and decisions involving 500 stocks over 1–10,000 time periods (years). These experimental results are used to explore narrow framing and other implications of the model. Barberis and Huang's computer simulations support prospective theory and narrow framing. The next paragraph combines the Barberis and Huang conclusions with other important empirical evidence.

Empirical Investigation of Behavioral Finance Theory In 2016 Barberis, Mukherjee, and Wang assessed prospect theory, mental accounting, loss aversion, and narrow framing empirically using *historical* returns from individual stocks.¹¹ Their discussion of (their Fig. 1) explains how historical relative frequencies are transformed into weighted probabilities. Both the Barberis, Mukherjee, and Wang 2016 historical study and the 2001 Barberis and Huang forecasting model that was mentioned above develop results that are supportive of prospect theory. In their conclusions about these two studies, Barberis, Mukherjee, and Wang hypothesize

⁹Nicholas Barberis, Lawrence Jin, and Baolian Wang. "Prospect Theory and Stock Market Anomalies," NBER Working Paper 27155, May 2020, DOI 10.3386/w27155.

¹⁰The Barberis-Xiong realization utility theory differs from the vNM utility model analyzed here. Furthermore, Barberis and Xiong focus on utility functions that are linear or piecewise linear, which differs from this entry's curvilinear utility theory.

¹¹Barberis, Nicholas and Mukherjee, Abhiroop and Wang, Baolian, 2016. Prospect Theory and Stock Returns: An Empirical Test. February Issue. *Review of Financial Studies*, see Section "4 Conclusions."

that “sophisticated investors may exert effort to try to forecast a stock’s future return distribution; less sophisticated investors, on the other hand, may content themselves with thinking about a stock in terms of its past returns” (2016, Section 4 Conclusions).

Analyzing KT’s S-shaped value function Li and Yang built an equilibrium model to analyze prospect theory’s S-shaped value function (Li and Yang 2013). Under numerical parameters, which align with prospect theory, they show four findings:

- (i) The concavity/convexity of the value function can drive the disposition effect.
- (ii) The disposition effect can lead to momentum in stock returns that generates annual price momentum of roughly 1%.
- (iii) The disposition effect can explain why there is more trading in rising markets than in falling markets.
- (iv) The concavity/convexity of the value function alone, in the absence of loss aversion, raises equity premiums. These findings support other prospect theory studies by different researchers.

Empirical Price Illusion Birru and Wang provide empirical evidence that investors suffer from a nominal price illusion that causes them to overestimate the room for price growth in low-priced stocks relative to the room for price growth in high-priced stocks (Birru and Wang 2016). They report widespread evidence that investors systematically overestimate the skewness available from investments in low-priced stocks.

Empirical Study of Jackpot Payoffs Conrad, Kapadia, and Xing show that firms with a high potential for default also tend to have a relatively high probability of achieving large jackpot payoffs (Conrad et al. 2014a, b). This result is consistent with the well-known investor preference for skewed, lottery-like payoffs.

Empirical Analysis of Loss Realizations In 2016 Alex Imas demonstrated that following a realized loss, individuals tend to avoid risk. In contrast, he also showed that if the loss remains unrealized, most people tend to take on greater risk (Imas 2016).

Weighted Probabilities Weighted probabilities are an important part of prospect theory. Weighted probabilities should continue to be developed, but not with the vNM model suggested here. Consider a simple risky choice to clarify these issues. Many people would be willing to pay \$10 for an honest gamble with a one-in-ten chance to win \$100. According to vNM utility theory, this preference is irrational because the expected utility from winning, $E[U(0.1 \times \$100)]$, exactly equals the absolute value of the utility from the entry fee, $|U(-\$10)|$. It is simply not logical to pay \$10 to enter a gamble that does not increase the gambler’s expected utility. But most people overlook this rational vNM explanation and make their decision by overweighting the small probability of the large gain, as follows: $E[U(0.11 \times \$100)]$

$> |U(-\$10)|$. The 11% weighted probability in this decision is determined psychologically; it is not an objective probability. This decision violates the axioms of vNM utility theory and the foundations of classical probability theory. However, KT and other behavioral economists have conducted numerous experiments with weighted probabilities and have published impressive laboratory evidence that this is the way many people actually think.¹²

Separating Two Behavioral Economics Models KT's Eq. (6) in their cumulative prospect theory paper (1992), which is illustrated in KT's Figs. 1 and 2, create a transfer function between KT's weighted probabilities and the vNM objective probabilities. In their 2016 study, Barberis, Mukherjee, and Wang provide details about these computations in their Fig. 1 and its accompanying discussion.¹³ These complicated computations can be avoided by using the popular vNM model suggested here. Using vNM probabilities that sum to one is suggested for three reasons. First, using vNM probabilities permits using the mathematical expectation, standard deviation, variance-covariance matrix, and other powerful aspects of classical probability theory that cannot be used with KT's weighted probabilities that do not sum to one. Second, using the vNM model is more likely to generate cross-fertilizing research between economics, finance, decision theory, and psychology because these theories are mathematically compatible with the objective vNM probabilities. Third, Markowitz's Nobel Prize winning portfolio theory (Markowitz 1952), Sharpe's Nobel Prize winning Capital Asset Pricing Model (Sharpe 1964), Black-Scholes Nobel Prize winning option pricing theory (Black and Scholes 1973), and other important theories are based on objective vNM probabilities that are not compatible with KT's weighted probabilities. KT's weighted probabilities are incompatible with the Nobel Prize winning theories and that incompatibility hinders research efforts to compare and connect these important theories.

The preceding review of the literature provides strong support for KT's prospect theory and weighted probabilities.¹⁴ Research into behavioral economics with weighted probabilities is clearly important and should be continued. But we argue that the behavioral economics research with weighted probabilities should be continued separately from research involving the vNM model suggested here. Separating these two important behavioral economic models would not detract from either one, but it would make both more straightforward and easier to employ.

"Advances in Prospect Theory: Cumulative Representation of Uncertainty." *Journal of Risk and Uncertainty*. 5(4): 297–323.

¹³Barberis, Nicholas and Mukherjee, Abhiroop and Wang, Baolian. 2016. "Prospect Theory and Stock Returns: An Empirical Test." February Issue. *Review of Financial Studies*.

¹⁴For additional review of prospect theory research findings see Nicholas Barberis 2013, "Thirty Years of Prospect Theory in Economics: A Review and Assessment," *Journal of Economic Perspectives*, Vol. 27, No. 1: 173–196.

The prospect theory research reviewed above motivated the development of the vNM cube root utility theory suggested here. The cube root utility function rationalizes the same economic issues that KT's cumulative prospect theory rationalizes, but the vNM model is based on the more widely used theories about utility and classical probabilities.

Before delving into the capabilities of cube root utility theory let us pause to investigate some complications that severely cripple several well-known utility functions.

83.2 Qualified and Unqualified Utility Functions

Log Utility Since logarithms are not defined for negative numbers, the log function cannot analyze losses. Thus, the positive utility curve $U(x) = \ln(1 + x)$, $x \geq 0$, is often accompanied by a negative *workaround function*, for instance, $-\ln(1 - x)$, $x < 0$, to create what appears to be, but is actually not, a single S-shaped function, which spans the horizontal axis between $-\infty$ to $+\infty$. Thus, the solid black curve in Fig. 4 is really composed of a convex function and a significantly different concave function that are linked at the origin to form a complicated S-shaped curve.

The Square Root Function Like the log function, the square root is severely handicapped because it is not defined over negative numbers. The negative workaround function: $U(x) = -(-x)^{1/2}$, $x < 0$, is sometimes added to the positive curve, $U(x) = x^{1/2}$, $x \geq 0$, to create what, falsely, appears to be one continuous gray S-shaped curve in Fig. 4. Actually, Fig. 4 illustrates two different concave functions that are linked at the origin to form a contrived S-shaped curve.

In contrast to the log and square root functions, the cube root function in Fig. 4 is represented by the one single, simple dashed curve, $U(x) = x^{1/3}$, which is defined in Eq. (1). Both the first and second derivatives of Eq. (1) are undefined at the origin, but we can still use a single equation between $-\infty$ to $+\infty$.

Summarizing, the solid black curve and the solid gray curve in Fig. 4 are assembled from a total of four different curvilinear functions. The log and square root workaround functions in Fig. 4 span the negative portion of the real line in an artificial and contrived manner. These workaround functions differ from the associated log and square root curves that underlie the positive half of the S-shaped utility curves.¹⁵ The negative and positive segments have different derivatives. These differences disqualify the log, square root, and similarly constructed utility functions from being able to analyze problems that involve any losses.

¹⁵The complete solid black log function: $U(x) = \begin{cases} \ln(1 + x), & x \geq 0 \\ -\ln(1 - x), & x < 0 \end{cases}$.

The complete solid gray square root function: $U(x) = \begin{cases} x^{1/2}, & x \geq 0 \\ -(-x)^{1/2}, & x < 0 \end{cases}$.

Fig. 4 Two unqualified and one qualified utility function

Unqualified Radical Functions The infinite number of functions of the form $y = x^{1/n}$ are called *radical equations*. The value of n is very important in radical functions. Numerous qualified radical equations with n an odd, positive integer, can span the real set with a single line. These radical functions are qualified to analyze losses, $x < 0$. For example, the cube root function and many similar radical utility functions with exponents like $\frac{1}{5}$, $\frac{1}{7}$, $\frac{1}{9}$, $\frac{1}{11}$, ad infinitum, are qualified to analyze losses.

The cube root function in Eq. (1) and Figs. 1, 2 and 3 is one of the qualified radical utility functions. In addition, other cube root utility functions can be constructed, for example, $U(x) = ax + bx^{1/3} + cx^{1/5}$. Various versions of the cube root utility functions can be formulated to be qualified utility functions.

In contrast, all radical utility functions with even integer values of n in $y = x^{1/n}$ are *unqualified* for further utility analysis because they are undefined for negative values of x . The square root function is a popular example of a radical utility function that is unqualified to analyze losses because $n = 2$ and 2 is not an odd integer.

83.3 Selecting the Most Desirable Radical Utility Function

Figure 5 illustrates three qualified radical utility functions that all generate similar economic behaviors.¹⁶ These three are a tiny fraction of the countably infinite number of similar qualified radical utility functions that could be illustrated in

¹⁶Appendix A analyzes these findings in more detail and suggests more general conclusions.

Fig. 5 Three qualified S-shaped utility functions

Fig. 5. Nevertheless, Fig. 5 suggests clearly that the cube root utility function generates a wider range of utility outcomes than other radical utility functions. A wider range of utility outcomes is more desirable than a smaller range of outcomes because it illustrates the results more clearly and dramatically. For this reason, the cube root utility function was selected as the most desirable radical utility function. As a result, the cube root utility function is the focus of this analysis. If circumstance arise in which a narrower range of responses is useful, a different radical utility function can be selected for that analysis.

Notes: If many qualified radical vNM utility functions were graphed together, they would asymptotically approach the horizontal axis as their exponents approached zero.¹⁷ The cube root radical utility function generates a wider range of utility outcomes than any other qualified radical utility function, which makes it more informative in many applications than the other qualified radical utility functions that are closer to the horizontal axis

83.4 Analysis of the Cube Root Utility Function

To reproduce Eq. (1) in different formats you can set $\alpha_1 = \alpha_2 = 1$ and $\gamma_1 = \gamma_2 = 1/3$ to derive Eqs.(3) and (4), for example.

$$U(x) = \sqrt[3]{x} = x^{\frac{1}{3}} \quad (2)$$

¹⁷To be more specific, the utility approaches +1 when x is positive, and -1 when x is negative.

$$= \begin{cases} \alpha_1 x^{\gamma_1}, x \geq 0, \alpha_1 = 1, \gamma_1 = 1/3 \\ \alpha_2 x^{\gamma_2}, x < 0, \alpha_2 = 1, \gamma_2 = 1/3 \end{cases} \quad (3)$$

$$= \begin{cases} x^{1/3} \\ -(-x)^{1/3} \end{cases} \quad (4)$$

The solid gray S-shaped curve denoted CR1 in Fig. 1 illustrates the cube root utility function that occurs when $\gamma_1 = \gamma_2 = 1/3$ and $\alpha_1 = \alpha_2 = 1$. The dotted S-shaped utility curve in Fig. 3 is an asymmetric cube root utility function with $\gamma_1 = \gamma_2 = 1/3$, $\alpha_1 = 2$ and $\alpha_2 = 3.25$. Following KT's (1992) numerical example, prospect theory is illustrated as the dashed curve in Fig. 3 with $\gamma_1 = \gamma_2 = 0.88$, $\alpha_1 = 1$ and $\alpha_2 = 2.25$.

Tversky and Kahneman (1981, 1992) and others have shown that people tend to avoid risk when a prospect is presented in a favorable environment, $x > 0$. That is, during a bull market most investors become risk-averse. However, many of these same investors might become risk-seekers when an equivalent outcome is introduced in a negative framework, $x < 0$. More specifically, during a bear market many people become risk-takers. This *cognitive bias* occurs as people react differently when asked to choose between positive and negative environments (two different frames) that have outcomes with the same absolute value. *Framing* helps reveal this cognitive bias.

Following Markowitz (1952), KT incorporated framing into utility theory by bifurcating the utility (value) function at the origin in their 1979 and 1992 papers. Figure 3 shows different qualified cube root utility functions that are bifurcated at the origin to form a concave (risk-averse, upper, happy frame) segment and a convex (risk-taking, lower, unhappy frame) segment. The concave and convex segments can be linked at the origin to form a single function. Eq. (3) can also represent asymmetric line segments when $\alpha_1 \neq \alpha_2$.

Barberis and Huang show that it is the kink at the origin in a utility function that creates *loss aversion* (Barberis and Huang 2001a,b). Qualified radical vNM utility functions like the cube root utility function in Eq. (1), was selected to be the focus of this chapter because it provides a single continuous line between positive infinity and negative infinity that can be kinked at the origin. The asymmetric dotted cube root utility function in Fig. 3 illustrates the case in which $\alpha_1 = 2$ and $\alpha_2 = 3.25$. In this case, the dotted utility function in the negative segment of Fig. 1 represents stronger loss aversion than the solid gray curve that has $\alpha_1 = \alpha_2 = 1$.

83.5 Analysis of the Utility Function with Favorable Outcomes, $x > 0$

The positive half of the solid gray S-shaped curve in Fig. 3 represents Eq. (3). This positive line segment is analyzed in this section, and the negative line segment is analyzed in Sect. 83.6. The γ_1 exponent in Eq. (3) is set equal to 1/3 to create Eq. (5).¹⁸

¹⁸Results like those reported in Sects. 83.5 and 83.5 can also be obtained with exponents of $\frac{1}{5}, \frac{1}{7}, \frac{1}{9}, \frac{1}{11}$, ad infinitum, as illustrated in Fig. 3 and shown more explicitly in Appendix A.

$$U(x) = \alpha_1 x^{1/3}, x \geq 0, \alpha_1 > 0 \quad (5)$$

83.5.1 Marginal Utility Is Positive When $x > 0$

Equation (6), the first derivative of Eq. (3), measures a person's marginal utility under favorable circumstances. This derivative is not defined for $x=0$.

$$U'(x) = \frac{d}{dx} [\alpha_1 x^{1/3}] = \frac{\alpha_1}{3x^{2/3}} > 0, \alpha_1 > 0, x > 0 \quad (6)$$

The sign of this first derivative with respect to x is positive, which means that between zero and positive infinity the decision-maker prefers large gains over small gains.

Equation (7) is the second derivative of Eq. (3).

$$U''(x) = \frac{d^2}{dx^2} [\alpha_1 x^{1/3}] = -\frac{2\alpha_1}{9x^{5/3}} < 0, \alpha_1 > 0, x > 0 \quad (7)$$

The negative sign on the second derivative indicates that the cube root utility function has diminishing marginal utility over the range of favorable outcomes. This implies that the cube root utility function in Eq. (3) is concave in the positive quadrant. These equations with these signs represent wealth maximizing risk-averse behavior over the concave line segment.

Equation (8) is the third derivative of Eq. (3), and it is positive.¹⁹

$$U'''(x) = \frac{d^3}{dx^3} [\alpha_1 x^{1/3}] = \frac{10\alpha_1}{27x^{8/3}} > 0, \alpha_1 > 0, x > 0 \quad (8)$$

The derivatives above are used to analyze Absolute Risk-Aversion (ARA) in the next section.

83.5.2 Analyzing Absolute Risk-Aversion (ARA) for Favorable Outcomes, $x > 0$

The Arrow–Pratt Measure of Absolute Risk-Aversion (ARA), named after Kenneth Arrow (1965) and John W. Pratt (1964), measures how an investor's preference for risk changes in response to changes in the investor's wealth. If an investor wants to put more money in risky assets as his/her wealth increases, he/she is said to be

¹⁹The first derivative is positive in Eq. (4), the second derivative is negative in Eq. (5), and the third derivative is positive in Eq. (6), this suggests the investor prefers positive skewness. Later, a Taylor series expansion is employed to make a stronger statement about the decision-maker's preference for positive skewness.

exhibiting decreasing *ARA* (*DARA*). This is normal *DARA* behavior that is more rational and realistic than constant *ARA* (*CARA*) or increasing *ARA* (*IARA*). Eq. (9) defines $ARA(x)$ for the cube root utility function.

$$ARA(x) = -\frac{U''}{U'} = \frac{2}{3x} > 0, \alpha_1 > 0, x > 0 \quad (9)$$

Because Eq. (10) has a negative sign and x is always positive in this range, the cube root utility function always has *DARA* over the range of positive outcomes.

$$ARA'(x) = \frac{d}{dx}[ARA(x)] = \frac{d}{dx}\left[\frac{2}{3x}\right] = -\frac{2}{3x^2} < 0, \alpha_1 > 0, x > 0 \quad (10)$$

83.5.3 Analyzing Relative Risk-Aversion (RRA) When $x > 0$

Arrow-Pratt's concept of Relative Risk-Aversion (*RRA*) also measures how an investor's preference for risk adjusts in response to changes in the investor's wealth. *RRA* differs from *ARA* as suggested by the following relation : $RRA(x) = xARA(x)$. *RRA* for the cube root utility function is indicated in Eq. (11).

$$RRA(x) = xARA(x) = \frac{2}{3} > 0 \quad (11)$$

If an investor wants to invest a greater *proportion* of his/her wealth in risky assets as his/her wealth increases, he/she is said to be exhibiting decreasing *RRA* (*DRRA*). Constant *RRA* (*CRRA*) is more rational and realistic than *DRRA* or increasing *RRA* (*IRRA*) (I. Friend and M. Blume, 1975). Equation (12) shows that over the range of positive outcomes the cube root utility function exhibits *CRRA*. *CRRA* is one of the qualities the cube root utility functions possess and some alternative utility functions lack.

$$RRA'(x) = \frac{d}{dx}[RRA(x)] = \frac{d}{dx}\left[\frac{2}{3}\right] = 0 \quad (12)$$

83.6 Analysis of the Utility Function with Unfavorable Outcomes, $x < 0$

This section focuses on the lower (losses) segment of Eqs.(1) and (3), which is rewritten as Eq. (13).

$$U(x) = \alpha_2 x^{1/3}, x < 0, \alpha_2 > 0 \quad (13)$$

Figure 3 illustrates a symmetric solid gray curve when $\alpha_2 = 1$. And Fig. 3 illustrates the asymmetric dotted curve when $\alpha_2=3.25$.

83.6.1 Analyzing Marginal Utility When $x < 0$

Equation (14) is the first derivative of Eq. (13); it equals the marginal utility of losses in an unfavorable environment. For any value of x , $x^{2/3}$ is always positive; thus, the first derivative is positive.

$$U'(x) = \frac{d}{dx} [\alpha_2 x^{1/3}] = \frac{\alpha_2}{3x^{2/3}} > 0, x < 0, \alpha_2 > 0 \quad (14)$$

This positive marginal utility indicates that if a typical person had to lose money they would always rather have small losses than large losses. This behavior represents rational economic behavior.

Equation (15) is the second derivative of Eq. (13). The positive sign of the second derivative implies that over the range from negative infinity to zero, the decision-maker experiences increasing marginal utility as x increases.

$$U''(x) = \frac{d^2}{dx^2} [\alpha_2 x^{1/3}] = -\frac{2\alpha_2}{9x^{5/3}} > 0, x < 0, \alpha_2 > 0 \quad (15)$$

The range of x values is strictly negative throughout section. For negative values of x , the value of $x^{5/3}$ will also always be negative. This negates the negative sign of the derivative and makes the derivative positive. When Eq. (15) is positive, the left-hand side of the utility curve in Fig. 2 is convex. The convex line segment of the cube root utility function suggests that risk-taking behavior tends to prevail when losses occur.

Equation (16) is the third derivative of Eq. (13)

$$U'''(x) = \frac{d^3}{dx^3} [\alpha_2 x^{1/3}] = \frac{10\alpha_2}{27x^{8/3}} > 0, x < 0, \alpha_2 > 0 \quad (16)$$

For any value of x , the value of $x^{8/3}$ is always positive; so, the third derivative is positive.

83.6.2 Analyzing Absolute Risk-Aversion (ARA) for $x < 0$

As mentioned above, the Arrow–Pratt Measure of Absolute Risk-Aversion (*ARA*) measures how an individual's preference for risk responds to changes in the person's wealth. Equation (17) defines *ARA* for the cube root utility function under unfavorable outcomes.

$$ARA(x) = -\frac{U''}{U'} = \frac{2}{3x} < 0, x < 0, \alpha_2 > 0 \quad (17)$$

The negative sign on Eq. (18) indicates that the individual, while experiencing losses, $x < 0$, will experience diminishing *ARA* (*DARA*).

$$ARA'(x) = \frac{d}{dx}[ARA(x)] = \frac{d}{dx} \left[\frac{2}{3x} \right] = -\frac{2}{3x^2} < 0 \quad (18)$$

Most economists believe *DARA* is logical behavior because investing a larger proportion of one's money in risky assets seems appropriate as a person's wealth increases.

83.6.3 Analyzing Relative Risk-Aversion (RRA) When $x < 0$

As mentioned above, the Arrow-Pratt measure of Relative Risk-Aversion (*RRA*) differs from *ARA* as follows : $RRA = xARA(x)$. Equation (19) defines *RRA* for the cube root utility function over the range of unfavorable outcomes.

$$RRA(x) = xARA(x) = \frac{2}{3} \quad (19)$$

The first derivative of Eq. (19) equals zero, indicating the cube root utility function has constant *RRA* (*CRRA*) over the range of unfavorable outcomes.

$$RRA'(x) = \frac{d}{dx}[RRA(x)] = \frac{d}{dx} \left[\frac{2}{3} \right] = 0 \quad (20)$$

Equation (20) indicates that an investor who is risk-averse under favorable states will become a risk-taker in unfavorable circumstances. The findings above combine to suggest that the cube root utility function is designed to generate wealth maximizing behavior.

83.7 A Taylor Series Expansion of $\alpha_1 x^{1/3}$

The Taylor series expansion in Eq. (19) is used to analyze fluctuations in utility from gains and losses. The Taylor series expansion is used to show that qualified radical utility functions have a consistent preference for positively skewed outcomes.

$$f(x) = f(x_0) + f'(x_0)(x - x_0) + f''(x_0) \frac{(x - x_0)^2}{2!} + f'''(x_0) \frac{(x - x_0)^3}{3!} + R \quad (21)$$

where *R* is a remainder that is omitted in the approximations that follow.

This analysis focuses on the first three moments. Empirical financial research suggests it is not worthwhile to consider more than an investment's first three statistical moments²⁰ (Arditti 1967) (Kraus and Litzenberger 1976). Empirically,

²⁰The subject of Taylor series approximations of utility functions and its application to expected utility in finance has a long history. For a discussion of these applications, see Garlappi and Skoulakis 2011.

the fourth and higher-order moments often have statistically insignificant explanatory power, have signs that alternate from one sample to the next, or have both problems. So, the fourth and higher-order moments are omitted here. Following the suggestion of Levy and Markowitz (1979), which was derived in a slightly different context, we set the expected value of x to be $x_0 = E(x)$ in Eq. (22).

$$f(x) \cong \alpha_1 E(x)^{\frac{1}{3}} + \frac{1}{3} \alpha_1 E(x)^{-\frac{2}{3}} \cdot (x - E(x)) + \frac{1}{3} \left(\frac{-2}{3} \right) \alpha_1 E(x)^{-\frac{5}{3}} \cdot \frac{(x - E(x))^2}{2!} + \frac{1}{3} \left(\frac{-2}{3} \right) \left(\frac{-5}{3} \right) \alpha_1 E(x)^{-\frac{8}{3}} \cdot (x - E(x))^3 / 3! \quad (22)$$

The expected value of Eq. (22) shows that the prospect's expected utility is positive. It is comforting to find that the expected value is positive because it would be irrational economic behavior to invest in a prospect that did not have a positive expected payoff. For the cube root utility function, Equation (22) is reformulated in terms of $\alpha_1 E(x)^{\frac{1}{3}}$ below.

$$E \left[\alpha_1 (x)^{\frac{1}{3}} \right] \cong \alpha_1 E(x)^{\frac{1}{3}} + \alpha_1 \frac{1}{3} \left(\frac{-2}{3} \right) E(x)^{-\frac{5}{3}} \cdot E \left((x - E(x))^2 \right) / 2! + \frac{1}{3} \left(\frac{-2}{3} \right) \times \left(\frac{-5}{3} \right) \alpha_1 E(x)^{-\frac{8}{3}} \cdot E \left((x - E(x))^3 \right) / 3!$$

The following un-numbered equation is a simplified version of the preceding un-numbered equation.

$$\alpha_1 E \left(x^{\frac{1}{3}} \right) \cong \alpha_1 E(x)^{\frac{1}{3}} - \alpha_1 \frac{2}{9} E(x)^{-\frac{5}{3}} \cdot \sigma^2 / 2! + \frac{10}{27} \alpha_1 E(x)^{-\frac{8}{3}} E \left((x - E(x))^3 \right) / 3!$$

The equation above shows that for the cube root utility function, the first and third moments have a positive impact on expected utility, while the variance has a negative impact on expected utility. This last equation shows that outcomes with positive skewness are always preferred over similar outcomes that are not positively skewed.

83.8 Summary and Conclusions

The mathematics in Eqs.(1) through (20) suggest the qualified radical utility functions and, in particular, the cube root utility function, are good economic theories.

The cube root utility function rationalizes the same economic issues that KT's cumulative prospect theory rationalizes, but the vNM model is based on more widely used theories about utility and classical probability theory. These are the utility theories and probability theories used in several other Nobel Prize winning economic theories and in other social sciences as well.

83.8.1 Summary Points About Cube Root Utility Theory

The infinite number of qualified radical utility functions discussed in this chapter contains the following desirable characteristics.

- (i) The cube root function and the similar radical functions are framed to include both a concave line segment and a convex line segment in a single equation.
- (ii) A countably infinite number (all equations with odd exponents) of other qualified radical utility functions have the same desirable characteristics as the cube root function that was analyzed in Eqs.(1)–(20). A few of the most plausible qualified radical utility functions are analyzed further in Appendix A.
- (iii) The cube root utility function can span a wider range of utility outcomes than the other qualified radical utility functions, as shown in Fig. 5. For this reason, the cube root utility function is considered more desirable than the other qualified radical utility functions.
- (iv) Using vNM utility with probabilities that sum to one enables us to use the mathematical expectation operator, standard deviation, variance-covariance matrix, and other important classical statistical tools that cannot be used in KT's 1979 and 1992 prospect theories.
- (v) The general formula Eq. (3) can be reformulated to assume varying shapes to model an infinite number of different of economic behaviors.

83.8.2 The Economics

The large family of qualified radical utility functions each generate the following kinds of desirable economic behavior:

- (i) Positive marginal utility of wealth and returns over the real set.
- (ii) Consistent risk-aversion over the concave (positive) segment of the real set.
- (iii) Consistent risk seeking over the convex (negative) segment of the real set.
- (iv) Consistent preference for positively skewed outcomes.
- (v) Rationalization of loss aversion when it is formulated to be appropriately asymmetric.
- (vi) All other complicated economic behaviors from Kahneman and Tversky's cumulative prospect theory (Tversky and Kahneman 1992), with the exception of the weighted probabilities.

83.8.3 Comparing Utility Functions

Table 1 summarizes the good and bad characteristics of some popular utility functions, which compete with the cube root function.

All of the criterion listed in column one of Table 1 have the most favorable results for the cube root function, which suggests it is more useful for utility analysis than the alternative utility functions.

Showing that the qualified radical utility functions analyzed above generate behaviors that align with a wide range of desirable outcomes suggests that the vNM theory is more likely to find useful applications in economics, finance, decision theory, and psychology than the competing utility functions. The qualified radical utility functions are also more amenable to various adaptations and linkages than KT's cumulative prospect theory because the objective vNM probabilities sum to one. This chapter concludes that it would be advantageous for behavioral economics research with weighted probabilities to be carried out separately from research involving vNM models. Separating these two important behavioral economic models would not detract from either one, but it could make each one more useful.

Table 1 Summary of advantages and deficiencies of popular utility functions

Criteria for a useful utility function	Five competing utility functions				
	Cube root utility function	Quadratic utility function	Square root utility function	Log utility function	Exponential utility function
<i>Does x span the real line between $-\infty$ to $+\infty$?</i>	Yes, with a single equation	Yes, if it faces down	No, it is undefined for losses	No, it is undefined for losses	No, it is undefined for losses
<i>A positive monotone function, $\frac{dU(x)}{dx} > 0$?</i>	Yes, more wealth is always preferable	Yes, but in only one quadrant	No, it is undefined for losses	No, it is undefined for losses	No, it is undefined for losses
<i>A consistent preference for positive skewness?</i>	Yes	Not consistently	No skewness preference	No skewness preference	No skewness preference
<i>Can losses, $x < 0$, be analyzed?</i>	Yes	Yes	Not able to analyze losses	Not able to analyze losses	Not able to analyze losses
<i>Absolute risk aversion (ARA)</i>	DARA is desired	IARA is not desirable	DARA is desired	DARA is desired	CARA is not desirable
<i>Relative risk aversion (RRA)</i>	CRRA is desired	CRRA is desired	CRRA is desired	CRRA is desired	IRRA is not desirable
<i>Always represents rational economic behavior?</i>	Yes, it is never irrational	Not all segments behave rationally	No, undefined for losses	No, undefined for losses	No, CARA always exists
<i>Can this vNM function explain the complicated behaviors of KT's prospect theory?</i>	Yes, except the weighted probabilities	No, it has many shortcomings	No, it has many shortcomings	No, it has many shortcomings	No, it has many shortcomings
<i>Total desirable yes answers</i>	8 yes answers	3 yes answers	2 yes answers	2 yes answers	Zero yes answers

Appendix A – Further analysis of radical functions

Table A shows the first three derivatives of the first three radical utility functions. These derivatives provide necessary and sufficient conditions to align with similar findings from KT’s cumulative prospect theory.

The numerous qualified radical utility functions with an inflection point at the origin that are discussed above can replicate the complicated economic behaviors generated by KT’s cumulative prospect theory. These qualified radical utility functions differ from KT’s cumulative prospect theory only because they are all based on the vNM probability assumptions instead of including KT’s weighted probabilities.

Appendix Table A – Derivatives of qualified radical utility functions

	$U(x) = \sqrt[3]{x} = x^{1/3}$	$U(x) = \sqrt[5]{x} = x^{1/5}$	$U(x) = \sqrt[7]{x} = x^{1/7}$
1) dU/dx	$\frac{1}{3x^{2/3}}$	$\frac{1}{5x^{4/5}}$	$\frac{1}{7x^{6/7}}$
2) d^2U/dx^2	$-\frac{2}{9x^{5/3}}$	$-\frac{4}{25x^{9/5}}$	$-\frac{6}{49x^{13/7}}$
3) d^3U/dx^3	$\frac{10}{27x^{8/3}}$	$\frac{36}{125x^{14/5}}$	$\frac{78}{343x^{20/7}}$

Notes: The first two derivatives of radical utility functions with an odd (but not even) number in the denominator of the exponent have diminishing positive marginal utility. In addition, the third derivatives combined with the Taylor series reveals that the decision-maker always prefers positively skewed outcomes. Table A is not extended to include an infinite number of additional columns, but it is possible to get similar results for exponents of 1/9, 1/11, 1/13, 1/15, ... ad infinitum.

A Global Comparative Study of Impact Investments Research in Academic Institutions

84

Rachel Calipha and Itzhak Venezia

Abstract

This chapter analyzes the comparative contributions of academia to the development of social impact investment in recent years. This subject is quite fashionable and relatively new, so it is important to explore the ways and directions in which it is being promoted by the academy. To this end, we investigated the following issues: how many papers were written about social impact investment in each of the last several years (as a metric of academic evolution), the relative involvement of public versus private sector universities (presumably the former should be more concerned about social issues), which academic disciplines are active in this area (as an indication of the backgrounds and perspectives of the researchers in the field), the distribution of the methods of analysis (mainly to explore to what extent the knowledge is grounded in theory and empirical results), and the extent to which the academic papers were funded by external sources (as a crude measure of the authors' independence). We also documented the papers published in this area and catalogued them according to their various disciplines. A list of sponsors who contributed to these papers is provided as a database for researchers who are seeking financial aid. Finally, the academic influence of these papers is examined.

84.1 Introduction

The field of impact investing has grown significantly in recent years. The annual impact investor survey conducted by the Global Impact Investment Network (GIIN) shows that the value of the assets managed by impact investing organizations has grown from \$77.4 billion in 2015 (GIIN 2016) to \$404 billion at the end of 2019 (GIIN 2020). In addition, the Global Steering Group (GSG), a group that catalyzes impact investment, went from representing 15 countries and the EU in 2015 (EVPA 2017) to representing 33 countries and the EU in 2020 (GSG 2021). In the same vein, the 2020 World Investment Report (UNCTAD 2020, p. 187) stated that the value of “sustainability-dedicated investments” (which include impact investments) is estimated in the range of \$1.2 to \$1.3 trillion at the end of 2020.

The speed at which this area is evolving calls for a frequent review of the ways and directions in which it is advancing. Therefore, in this chapter we examine the pace and direction of the dissemination of new academic knowledge in impact investing in the hope that this knowledge will contribute to the assessment of its future growth and trajectory. A previous comprehensive review of the scope of research in this field was conducted by Daggers and Nicholls (2016), who examined the period between 2010 and September 2015.¹ The current study adds to the literature in the following ways. First, in light of the rapid pace at which the field is expanding (according to the GIIN 2020 data above, impact investments have grown at least five-fold since the previous study), a frequent review of it is recommended. Second, we sharpen the previous knowledge by studying more detailed data. Doing so enables us to explore several issues not hitherto examined, e.g., the relative involvement of public versus private sector universities in this field; the academic disciplines active in this area; the distribution of the methods of analysis; and the extent to which the academic papers were funded by external

¹Daggers and Nicholls's (2016) paper followed other review studies (see, e.g., Nicholls and Pharoah 2008; Lyons and Kickul 2013; Höchstädter and Scheck 2015; Clarkin and Cangioni 2016; Rizzello et al. 2016; and Friedrich-Silber and Rosenhek 2000). Broccardo and Mazzuca 2019, provided a review but studied only social impact bonds and Kubátová and Kročil 2020 did not use the umbrella term SII.

sources. Third, we provide a list of the papers we found in this area arranged by their various disciplines. Fourth, a list of sponsors who contributed to these papers is provided as a database that will serve researchers who seek financial aid. Finally, we examine the academic impact of the research in this area.

The chapter is constructed as follows. In Sect. 84.2, we present the terminology of impact investments and related activities. In Sect. 84.3, we present our methodology and data sources. In Sect. 84.4, the results are presented, and in Sect. 84.5 we present our conclusions

84.2 The Terminology of Impact Investments and Related Activities

A representative recent definition of impact investments was provided by the GIIN (2020): “Impact investments are investments made with the intention to generate positive, measurable social and environmental impact alongside a financial return.” This term follows other similar terms that represent analogous concepts, such as sustainability, socially responsible investment (SRI), corporate social responsibility (CSR), social investment (SI), environmental, social and governance (ESG), social impact bonds (SIB) and social impact investment (SII). All of these terms refer to activities aimed at incorporating externalities into the decisions of individuals and firms to optimize the welfare of society and not only that of the individual. The terms may differ in their aims, means, scopes, and measures but are quite closely related, so it is difficult to separate one from the other. Moreover, new, related terms are continuously being proposed. For example, the term “integral investing” (Kubátová and Kročil 2020), which adds aims and metrics to impact investing, recently emerged.²

This study focuses on Social impact investment (SII). SII (see, e.g., Daggers and Nicholls [2016]) is an umbrella term that encompasses the terms *impact investing* and *social investment*. It is important to distinguish between these two terms. The first was proposed by the Rockefeller Foundation in 2007 in a strategic attempt to create a momentum of positive investment with social and environmental impact in the USA. The second, in contrast, was developed earlier in a less strategic environment, mainly in Europe. Another distinction between the terms is their focus (Daggers and Nicholls 2016, p. 6). Impact investing involves the use of capital to create specific social or environmental impact, whether through direct allocation of capital, investment in funds, or contractual agreements such as SIBs. Its focus is therefore mainly on investor behavior and motivations. Social investment involves providing social sector organizations (SSO) access to repayable

²This term adds positive cultural and behavioral aspects and human development to the basic aims of impact investment (which are only profit and positive societal and/or environmental impact). Integral investing also suggests adding team culture, ethics, morals, and personal values of team members to the basic metrics of profits and ESG criteria required by impact investing.

capital whose providers are motivated to create social or environmental impact. As a result, there is more of focus on the investee.

84.3 Data and Methodology

The study was conducted by means of two main databases that list papers published in various areas: SCOPUS and Google Scholar. Papers that address social impact investment were chosen. The period reviewed was from 2015 to December 2020. A search for the keywords *impact investing* (II), *social investment* (SI), *social impact bonds* (SIB), and *social impact investment* (SII) in abstracts or titles was conducted. The final sample consists of 119 papers published in journals or working papers, but excludes books. Classification into the various categories (discipline, method of analysis, academic affiliations of the authors, and whether the research received external funding) was conducted subjectively by the authors based on the titles, abstracts, and acknowledgments sections of the chosen papers. When these sections did not provide sufficient information, the entire paper was read. The classification of universities in the USA into private or public was inferred from the website UnivSearch: US College and University Directory (<http://www.univsearch.com/state.php>) and the classification of European universities was taken from Wikipedia (https://en.wikipedia.org/wiki/Category:Private_universities_and_colleges_in_Europe). Finally, to examine the academic influence of research on social impact investment research we measured the h-index. This index expresses the number of articles (h) in a journal that have received at least h citations. It quantifies both journals' scientific productivity and their scientific impact and is also applicable to scientists, countries, and so on. The index was taken from Scimago Journal & Country Rank (<https://www.scimagojr.com/>).

84.4 Results and Discussion

In what follows, we present the findings of our study in six subsections, each of which corresponds to one of the different topics we investigated.

84.4.1 Evolution of the Field Over Time

Table 1, below, shows the yearly number of papers published during our study period. We cannot detect a statistically significant trend from this table, possibly due to the small number of years studied, although a visual inspection reveals a slightly positive trend. This modest increase in publications stands in contrast to the rapid growth in impact investments mentioned above and to the more detailed data published by the GIIN (2020) shown in Table 1.

Table 1 Number of papers and volume of Assets under Management by year

Year	Number of papers	Assets under Management (AUM) ^b
2020 ^a	30	N/A
2019	32	404
2018	23	239
2017	10	228.1
2016	8	114
2015	16	77.4

^aPartial year, until November 2020

^bIn billions of dollars. Source: GIIN (2020). AUM refers to the total market value of the investments or assets managed by fund managers, DFIs (government-backed entities), bank/diversified financial institutions, foundations, family offices, pension funds, insurance companies, and others.

84.4.2 Distribution of the Research Institutions (Public University, Private University, or Nonacademic Institution)

The country where the research was conducted can give us some indication of which countries are most concerned with the subject of social impact investment. Scientifically and economically developed countries would be expected to produce more research on impact investment than less developed ones. In this regard, the only surprising finding is that the USA, the country that leads the world in research publications in most areas, lags behind the UK in terms of research on social impact investment. The finding that research of the subject is concentrated in only two countries that together conduct more research than all the others combined is also striking. Our findings are consistent with those of Daggers and Nicholls (2016), with the exception of the growth of publications in Italy in recent years.

In addition, most of the publications were written by authors from public universities, except for those published in the USA and Germany. Whereas in the USA the number of private universities (for-profit and nonprofit) greatly exceeds that of public ones (2672 vs. 1626 in 2019, or 62% vs. 38%), they are almost evenly matched in terms of research on impact investments. But because public universities are usually much larger than private ones (enrollment in public universities in the USA was 14.9 million students in 2019 vs. only 5.2 in private universities, [Statista 2020]), we cannot conclude which type of institution is more concerned with impact investments (Table 2).

84.4.3 Relative Weight of the Academic Disciplines Involved in Impact Investment Research

In Table 3, we present the distribution of papers among the various academic disciplines involved in the study of social impact investment. By definition, impact investments are concerned with investing and hence with finance, economics, business, and management. Since impact investments also concern externalities

Table 2 Number of universities by country and type (private vs. public) and nonacademic institutions

Country	Number of universities ^a	Private	Public	Nonacademic institutions
England	40	0	40	1
USA	21	11	10	1
Italy	14	2	12	0
Canada	5	0	5	0
Germany	5	3	2	0
Australia	4	0	4	0
France	4	1	3	0
Switzerland	4	0	4	0
Austria	3	0	3	0
South Africa	3	0	3	1
Korea	2	0	2	0

Hong Kong	1	0	1	0
Kazakhstan	1	0	1	0
Luxembourg	1	0	1	0
Malaysia	1	0	1	0
Norway	1	0	1	0
Spain	1	1	0	1
Turkey	0	0	0	1
Total	114	18	96	5

^aThe university is determined by the main author’s affiliation.

Table 3 Distribution of social impact investment papers among the various disciplines

	Finance and Economics	Business and Management	Public Policy	Social Policy
Number of articles	23	52	14	24
Percentage	20.4%	46.0%	12.4%	21.2%

and society, they are related to public finance and policy. It thus comes as no surprise that most papers are published in journals associated with these disciplines. The list of papers categorized by discipline is presented in [Appendix 2](#). This list could be useful to researchers who seek to focus on a particular discipline. It could also serve as a benchmark for future studies that examine the direction that impact investment has taken.

84.4.3.1 Types of Analysis Used in Social Impact Investment Research

In [Table 4](#), we present the distribution of papers according to the types of analysis they employ: theoretical, scoping, qualitative, and empirical. An interesting insight

Table 4 Allocation of social impact investment papers by method of analysis

	Theoretical	Scoping	Qualitative	Empirical
Number of articles	19	31	56	13
Percentage	16.0%	26.1%	47.1%	10.9%

Table 5 Number of funders by funding origin

Funding origin	Number of funders
UK	10
European Union	6
Canada	6
USA	4
Italy	4
Korea	3
South Africa	2
Abu Dhabi	1
Czech Republic	1
Spain	1
Belgium	1
Total	39 ^a

^aThe number of funders is greater than the number of papers since four of the papers were sponsored by more than one funder

that emerges from this table is the paucity of empirical research (11%) relative to scoping (26%) and qualitative analysis (47%). One reason for this imbalance is that the field is still in its infancy and there remains a need to delineate its objectives and the possible means of reaching them, to clarify which organizations should be examined, to identify the parties that may gain or lose from impact investments, and so on. Since, theoretically, impact investment has unquantifiable pros and cons, its net effects on welfare are only a matter of empirical findings (i.e., real data pertaining to the theories and assertions regarding impact investing; see, e.g., Spiess-Knafl and Aschari-Lincoln 2015; Karpenko and Voronzhak 2018; Mersland et al. 2020). It therefore may seem that additional empirical research is needed. Notably, however, since the period of the previous survey by Daggers and Nicholls (2016), several data bases have been constructed and are available for research, thus increasing the likelihood that the relative intensity of empirical research will grow in the future.

84.4.4 Funding

Table 5, below, which lists the number of funded papers in all countries, shows that only 29% (35/119) of the papers were funded, and the sources of funding were mainly from the UK, Canada, and the European Union (other than the UK). Most of the funds came from governments (see Appendix 1 for details), a fact that indicates their higher relative concern with social impact investments.

Table 6 Number of papers by journal and h-index

Journal ^a	h-Index	Number of papers
<i>Public Money & Management</i>	46	9

<i>International Journal of Voluntary and Nonprofit Organizations</i>	0	2

^aJournals with fewer than two publications are not presented.

84.4.5 Academic Influence of Social Impact Investment Research

The findings presented in Table 6 show that articles that address social impact investments have been published in a variety of journals and there is no one main journal associated with the field. Another notable observation is that papers on social impact investments are published in journals with low h-indices (only three papers were published in journals with an h-index higher than 100). This may be due to fact that the field is in its early stages of development and/or to the fact that it comprises a very specific research niche area.

84.5 Conclusions

From our findings, we observe that the growth of impact investments over the last few years has been much more rapid than the academic developments in this area. Moreover, empirical studies on the subject comprise a paltry 11% of total research. Nonetheless, this type of research is crucial if one is to convince others of the benefits or disadvantages of impact investing. Thus, the influence of academia on social impact investment seems to hinge to a great extent on its ability to produce meaningful empirical research in this area. This, in turn, requires the existence of extensive databases, the lack of which could be partly to blame for the current paucity of empirical studies (see, e.g., Reisman et al. 2018; Jamieson et al. 2020).

Furthermore, the dearth of empirical research could be part of the reason for the weak academic influence exhibited by the relatively low h-indices of the journals where papers in the area are published. Most leading journals in economics and finance insist that authors publishing in their journals support their claims with sound empirical analysis. It would be difficult for the area to become mainstream without the respectability gained by publishing papers in leading journals, and in order for this to happen, databases are needed to facilitate the kind of analysis that these journals demand.

In addition, our findings indicate that the UK and the USA are dominant in this area in all respects: the number of papers published, the number of universities involved with these publications, and the sponsorship (especially the UK). This is hardly surprising since these are developed countries with mature SII markets and well-established SII public policies (OECD 2019). What is somewhat surprising is the relatively meager participation of other developed countries in publications and the absence of developing countries, who have the most to gain from SII.

Universities and governments both play important roles in economic development. Universities' roles include teaching, conducting research, and serving as innovative engines for economic development (Geiger 1986, 1993; Leslie and Caldwell 1990; Leslie 1993; Florida et al. 2006). The role of governments is to set policies and, where necessary, provide funds to help to achieve its goals (Stiglitz 1997; Adelman 2000). An important conundrum is whether research (universities) or policy (government) comes first and what the optimal division of tasks between them is.

In the social sciences (as opposed to the natural sciences and medicine), practice usually precedes research, so that it is common to engage in studying and conceptualizing a new social phenomenon after it has been taking place in the real world, accompanied by policy (Calipha and Gidron 2020). The evolution of the third sector usually follows a different path, with research and conceptualization preceding practice and policy. This is true for many countries, but in the case of the Israeli third sector, as we show below, this pattern is particularly striking. One wonders how the fact that impact investments are business/nonprofit hybrids (i.e., their agendas include social goals in addition to profits) will influence the patterns of their evolution. Observing the development of the third sector in Israel may provide insights regarding this question.

In Israel, research activity on the third sector began in the 1970s and 1980s, when foreign and local researchers began to study related subjects.³ Then, in the 1990s, came international conferences that led to joint international projects that provided tools for defining the field and facilitated international comparisons.⁴ The projects' outcomes accelerated further academic research, and so on.⁵ It is worth noting that during this period, NGOs contributed significantly to society and their number

³See, e.g., Kramer 1970, 1976, 1981, 1984; Katan 1988; Eran 1992; Jaffe 1979, 1982, 1983, 1985, 1987; Yishai 1987; Gidron 1984; Gidron and Bargal 1986; Gidron and Chesler 1994.

⁴Salamon et al. (1999).

⁵See, e.g., Bar-Mor 1999; Gidron 1999; Gidron and Katz 1998; Gidron et al. 2003; Shay et al. 1999; Silber and Rosenhek, 2000; Telias et al. 2000.

significantly increased over the years. The influence of academia became more significant only later in the process, after academic researchers managed to develop local databases and enhanced government involvement through joint meetings that eventually paved the way for the field to enter the mainstream.⁶ Today, the third sector in Israel has an impressive presence in society (Calipha and Gidron 2020).

Only time will tell whether social impact investments will develop in a similar manner, but in any case, it seems that the strong involvement of academia in this area is crucial for its advancement. We hope this chapter will assist future researchers to propose ways in which academia can work to increase its effect on social impact investments.

Financial Crisis, Capital Requirement, and Stress Tests: Evidence from the Extreme Value and Stable Paretian Estimates

85

Tony Sio-Chong U and Jacky Yuk-Chow So

Abstract

Stress tests are exercises to determine the losses that might occur under “unlikely but plausible” circumstances. The objective of this chapter is to demonstrate that the “fat tail” of the stable Paretian distribution can capture the extraordinary risk during financial crisis, as well as normal market conditions. Rather than assuming a normal distribution and then add the “stress tests,” a stable Paretian VaR will capture both and is more parsimonious statistically. The Central Limit Theorem and probability theory are applicable to the “stress tests.” (Diebold et al., *J Risk Finance* 1(2):30–35, 2000) believe that extreme value statistics are preferable. This argument is valid if regulators and corporations are interested in managing “extreme risk” only. The soundness and the safety of the financial markets and the banking system and the “externality” issues, however, reveal that good risk management must consider “normal market” conditions as well as “crisis” that will be captured by the density of the whole distribution, not just the tails. In this chapter, a relatively new technique will be used to choose the appropriate number of “extremes.” The difficulty in estimating the density of the stable Paretian distribution will be overcome by using a simple and reliable Fourier series method.

85.1 Introduction

From 2008 to 2012, the financial crisis in the USA and Europe highlighted the limitation of the Value-at-Risk (VaR) method as an effective risk management tool for financial managers and regulators. Because VaR uses a backward-looking approach and assumes a normal market and a normal distribution, “extra-ordinary” risk created by financial crises and “non-normal” fat-tailed distribution cannot be captured accurately. In other words, portfolio risk, and thus capital for banks and firms, will be insufficient to cover the extremely large losses that are underestimated by a normal distribution. Akhigbe et al. (2012) and Garel and Petit-Romec (2017) showed that bank capital is necessary but may not be sufficient to prevent crisis. In addition, the FDIC insured the deposits as the failure of their insured banks.¹ The regulation seems safe and sound for both banks and households. The reality is a billion dollars are injected into the banking system. Most financial institutions request government’s bailout. Buser et al. (1981) have showed that the FDIC might have intentionally underpriced the insurance premium to attract more banks to be FDIC members. Besides, the banks have underestimated the risk; the fragility of financial system is completely exposed.

Stress tests have been recommended by the regulators, such as IMF, Bank of International Settlements (BIS), US Federal Reserve Banks, and the European Banking Authority (EBA), etc., to “complement” the results from the VaR analyzes since the Asian financial crisis and the bankruptcy of the Long Term Capital Management (LTCM) Ltd. The usefulness and the effectiveness of stress tests, however, are not subject to serious testing until the recent global financial crisis triggered by the subprime mortgage loan crisis in the USA.

The principle of stress tests is to determine the losses that might occur due to the bad state of economy. After conducting the stress tests, US bank regulators announced that ten big US banks must raise \$75 billion. Money center banks such as the Bank of America, Citigroup, Wells Fargo, etc., were required to increase their Supervisory Capital Assessment Program (SCAP) buffer by \$33.9 billion, \$5.5 billion, and \$13.7 billion, respectively. Financial company, such as GMAC, was also required to increase capital by \$11.5 billion.

In 2011, the European Banking Authority conducted similar stress test for 90 banks in 21 countries and found that eight European banks are not strong enough to withstand a prolonged recession and need to raise €2.5 billion in capital. German bank Helaba failed the test but withdrew from the test, contesting the methodology used and releasing its own results on its website (see BBC News, Business, July 15, 2011). Nordbank and Norddeutsche Landesbank both challenged the stress test results saying they didn’t reflect how strong they were, with Nordbank saying that “this result in no way reflects the economic reality of our banks” (“8 Banks Flunks European Stress Test; 16 More Barely Pass,” USA Today, July 15, 2011). The Greek

¹The standard insurance amount is \$250,000 per depositor, per insured bank, for each account ownership category.

finance minister, Evangelos Venizelos, said that “the criteria were particularly harsh, they were extreme.”

Obviously, regulators believe that stress tests are important for the soundness of financial markets and institutions. However, some corporate executives have reservation about the stress test results. The reservation may be due to the “externality” created by the stress test results and the statistical deficiency of the stress tests.

1. Externality and Signal: Mr. William Dudley, President and CEO of the Federal Reserve Bank of New York believes that banks do not want to proactively raise capital during the financial crisis because capital raises might signal that they were in fact weak and stock price may be depressed.² Bank’s decision not to raise capital increases the likelihood of the “bad state of the world” – an important externality. Additional capital doesn’t just make the bank stronger, it also makes the entire banking system more stable. This is the collective action problem that the SCAP was designed to remedy.
2. Deficiency of stress tests: many researchers have pointed out that the stress tests are ad hoc and not probabilistic. Without an idea of the related probability estimates, the top management does not know whether to treat the results seriously or not. Raising a large amount of stress capital will increase the cost of capital significantly.

The objective of this study is to conduct empirical tests to demonstrate that, similar to the VaR plus stress test, the “fat tail” of the stable Paretian distribution can capture extraordinary risk during financial crisis. Since the normal distribution is a special case of the stable Paretian distribution, “normal market” condition is implicitly captured. In addition, because the stable distribution belongs to the stable family, central limit theorem (CLT) holds and probability can be assigned to “stress tests.” With the more accurate estimates for the worst-case scenario derived from the stable family, risk-based capital can be estimated for different banks or companies that have different risk. This risk-based capital system will reduce the externality problem.

Because the density of the stable Paretian, based on characteristic function, is quite challenging, this chapter proposes a Fourier series-based method to calculate Value-at-Risk (VaR). This method can be used to evaluate the VaR of portfolio with different characteristic exponents (α) of assets; the key idea is to expand the distribution with Fourier series and the coefficients of the expansion are close relatively to the characteristic functions of returns of different assets. Note that Samuelson (1967) and Merton (1969) have studied portfolio risk for symmetric stable Paretian distribution. In order to capture financial crisis, we will use the “rare-event” equilibrium model recommended by Liu et al. (2005).

Our preliminary empirical results show that the VaR plus stress test can be more accurately estimated by using the stable Paretian VaR. For normal distribution, the risk of assets is determined by one factor, volatility (σ) and the upside and downside

²www.newyorkfed.org/newsevents/speeches/2011/dudl

movements of returns are symmetric. Therefore, it cannot predict the catastrophic market risk precisely. For stable Paretian distribution, the risk of assets is determined by three factors; characteristic exponent (α), skewness (β), and scale (c). The catastrophic market risk or extraordinary risk is captured by characteristic exponent (α), skewness (β) values the asymmetric movements of returns, and the ordinary risk is predicted by scale (c). Moreover, normal distribution is the special case of stable Paretian distribution with $\alpha = 2$ and $\beta = 0$. The tail index (characteristic exponent) is critical; DuMouchel (1983) let the tails tell the story also assumes that the appropriate number of extremes can be determined. McCulloch (1997) has pointed out the importance of large sample size for testing the “stability” of the stable family. The comparison between normal distribution, stable Paretian distribution with Coronel-Brizio and Hernandez-Montoya (2005)’s extreme value method shows that the VaR estimations based on different α of assets yielded more accurate than other models, the detail is given in So and U (2012).

This chapter also makes two more contributions to the literature. First, we document that some companies met the required capital by increasing the weight of risk-free assets instead of raising capital. This asset allocation strategy is consistent with the fact that most banks prefer not to increase capital during the recession but using a low risk-low return investment strategy. This safety-first rule may be appropriate during financial crisis and is not because of the concern of weakness signaled nor its negative possible impact on stock prices. It will not create externality either because if the risk of the asset portfolio is low enough, no new capital will be necessary.³ Our results show that Bank of America, Wells Fargo, and Citigroup had inadequate capital in 2008 that is consistent with the announcement of US bank regulators. After that, we found that most banks increased their weight of risk-free assets to meet the required capital ratio instead of raising capital recommended by US bank regulators.

85.2 Literature Review

After the subprime mortgage crisis in 2008, many literatures have found that liquidity and credit risks are very critical for maintaining an orderly market as well as the confidence of investors. (see Castiglionesi et al. (2014), Cornett et al. (2011), Freixas et al. (2011), Ivashina and Scharfstein (2010), and Keister and McAndrews (2009) for more details on liquidity risk. See Correa et al. (2014), Galai and Wiener (2012), and Yang and Zhou (2013) for more details on credit risk.) These studies found that market liquidity substantially decreased in 2008. Banks then reacted by holding excess reserves, which resulted in higher borrowing costs and many corporations and households were not able to obtain financing from financial institutions. Consequently, the subprime mortgage crisis spread from the financial sector to the real economy. The

³Some European banks in fact held lot of government bonds after 2008 because they are classified as the safest assets and required no risk-based capital. That laid down the European Debt crises when the sovereign risks of some countries were very high.

latter was a key factor that escalated the propagation of the subprime mortgage crisis. The credit default swap spreads increased to 1500 basis points (Ivashina and Scharfstein 2010), and the credit ratings of most banks in the United States were downgraded. Their stock prices plunged more than 30%. These significant losses exacerbated the liquidity freeze in the real economy. Allen and Gale (2001) developed a model to explain how bubbles were created by risky assets and concluded that the economic crisis was the consequence of a bubble burst. However, the classic definition of the bubble should rely on the fundamental value of risky assets, it cannot be easily verified because the pricing methods of different assets (e.g., real estates, stocks, and bonds) are quite different from each other. In Allen and Gale (2001), the fundamental value of risky assets is the discounted value of the net returns.

Yet how could banking systems be so vulnerable to failure even though they are carefully monitored by regulators? Flannery (2014) estimates the probability of default for 25 of the largest banks in USA based on their market equity. The results show that the probability of their default far exceeded the 0.1% standardized risk weight stipulated by the Basel standard. He concludes that the supervisory metrics from book capital measures are seriously flawed. In other words, the tail risk measured by market value is much higher than that in the book value measures. Consequently, capital requirements facilitated by using an accounting-based ratio do not actually reveal the real risks of financial institutions. Hovakimian and Kane (2000) point out that bank accountants are prone to overstating the amount of capital and understating the risks, even so regulators seem reluctant to enforce market value-based measures instead of book value-based measures.

On the other hand, defining and measuring crises are challenging tasks. Allen and Gale (2001) document different crises over the past three decades. However, they find that it is difficult to define the length and depth of market downturns before they could be viewed as a “crisis.” Acharya et al. (2012) and Brownlees and Engle (2011) indicate that a proxy for financial crises would be a decline of over 40% over the next 6 months in the aggregate stock market. Therefore, a market value-based measure to evaluate the capital losses during the crisis is crucial and necessary. Here, a parametric method is recommended because it is more efficient. Instead of using simulations, the Fourier-cosine expansion is employed to produce more accurate estimates, especially for the stable Paretian distribution. VaR with fat-tailed distribution under an efficient numerical approach, thereby can provide a comprehensive risk measure for the practical use of banks internally and supervisory purposes.

85.3 Methodology

In this chapter, the integrated VaR and stress test method will be proposed. VaR is a financial measure that evaluates the return with a specific probability. The stress test is a risk management tool for measuring the impact on firm of specific events and/or movements in a set of financial variables. Accordingly, the stress test is viewed as a complement to the VaR model. In our model, we simply consider the values of total

assets⁴ (TA_{t+1}) are greater than or equal to the debts ($D_{t,t+1}$) at time t and the maturity at $t+1$ with the interest rate of debt (r_d), that is,

$$\begin{aligned} TA_{t+1} &\geq D_{t,t+1}(1+r_d) \\ TA_t(1+r_{t+1}) &\geq D_{t,t+1}(1+r_d) \\ \frac{1+r_{t+1}}{1+r_d} &\geq \frac{D_{t,t+1}}{TA_t}, \end{aligned} \quad (1)$$

where r_{t+1} are the returns of total assets at time $t+1$. Denote the debt per assets ratio (d) as $d = \frac{D_{t,t+1}}{TA_t}$, and capital ratio (cr),⁵ $cr = 1 - d$, then Eq. (1) becomes,

$$cr \geq \frac{r_d - r_{t+1}}{1 + r_d} \quad (2)$$

Our estimations of r_{t+1} are continuous compound returns,⁶ Eq. (2) expressed as

$$cr \geq 1 - \exp(r_{t+1} - r_d). \quad (3)$$

The estimations of r_{t+1} in recession are the critical part of our model.⁷

The total assets of firms can be viewed as a portfolio. The $w_{0t}, w_{1t}, \dots, w_{nt}$ are the weights of assets at time t , $r_{0t+1}, r_{1t+1}, \dots, r_{nt+1}$ are the continuous compound returns of each asset at time $t+1$. We specified r_{0t+1} be the risk-free rate r_f . The returns of the total assets or the portfolio (r_{pt+1}) at time $t+1$ are given by,

$$r_{pt+1} = w_{0t}r_f + w_{1t}r_{1t+1} + \dots + w_{nt}r_{nt+1}, \quad (4)$$

thus, the returns with a given probability θ can be determined by the VaR model. Therefore, Eq. (3) becomes

$$cr \geq 1 - \exp(VaR(\theta, w_{0t}, \dots, w_{nt}) - r_d), \quad (5)$$

where $VaR(\theta, w_{0t}, \dots, w_{nt})$ is given as follows,

$$\Pr(w_{0t}r_f + \dots + w_{nt}r_{nt+1} \leq VaR(\theta, w_{0t}, \dots, w_{nt})) = \theta. \quad (6)$$

We denoted the required capital ratios (rcr) as follows

⁴It contains all risky assets and a risk-free asset.

⁵In this study, we simply assume the debt is equal to the liability. Therefore, we have $TA = L + C = D + C$ and $cr + d = 1$. If the total liability included long term liability (LL), then we may add the long-term liability ratio ($l = LL/TA$) to the left-hand side of Eq. (2).

⁶ $r_{it+1} = \ln\left(\frac{p_{it+1}}{p_{it}}\right)$ and p_{it} are the price levels at time t .

⁷Regime shift model can generate mixed distribution that has fatter tail than normal. However, the CLT may not be directly applied to obtain the distribution of aggregate returns.

$$rcr = 1 - \exp(VaR(\theta, w_{0t}, \dots, w_{nt}) - r_d). \quad (7)$$

The right-hand side of Eq. (5) is called the required capital ratio.⁸ If the capital ratio is high enough, we could invest much more in the risky assets. However, companies invest too much in risky assets without adequate capital, such that Eq. (5) is invalid, the company will have a probability of θ or higher to go bankrupt, we denote this as the probability of bankruptcy or bankruptcy risk. In this case, the companies had two ways to avoid bankruptcy. One way is to increase the capital ratio, the other way is to increase the weight of risk-free assets, thus the VaR decreased and Eq. (5) can be fulfilled.⁹

In practice, companies needed to maximize the returns and also reach the required capital ratio. Therefore, the following equation should be satisfied,

$$\begin{aligned} & \max_{w_{0t}, \dots, w_{nt}} E[w_{0t}r_f + \dots + w_{nt}r_{nt+1}], \\ & \text{subject to } cr \geq 1 - \exp(VaR(\theta, w_{0t}, \dots, w_{nt}) - r_d). \end{aligned} \quad (8)$$

Using Lagrange multiplier method, we can solve (8).

85.4 VaR Models

In the previous section, the critical part is to determine the loss of the total asset with a specific probability θ . In this section, VaR models will be proposed, and $VaR(-\theta, w_{0t}, \dots, w_{nt})$ are evaluated by a Fourier series-based method. We considered the one factor model, let the returns of different assets at $t + 1$ (r_{it+1}) be

$$r_{it+1} = a_i + b_i X_{t+1} + \varepsilon_{it+1}, \quad (9)$$

where $X_{t+1} \sim S(\alpha_X, \beta_X, c_X, \delta_X)$ is the α_X -stable Paretian distribution,¹⁰ it is independent of the residuals ε_{it+1} and $\varepsilon_{it+1} \sim S(\alpha_i, \beta_i, c_i, \delta_i)$. Moreover, ε_{it+1} and ε_{jt+1} are statistically independent for any $i \neq j$. ε_{it_1} and ε_{it_2} are also statistically independent for all $t_1 \neq t_2$. Nolan and Ojeda-Revah (2013)'s algorithm can be used to estimate the

⁸Buser et al. (1981) showed optimal capital structure of banks with and without FDIC insurance and with "underpriced FDIC insurance premium." In contrast with their optimal capital structure, our required capital ratio focuses on the optimal capital structure under a very low probability of default rather than the break even point of tax shield and the cost of bankruptcy in Buser et al. (1981). Our optimal structure may be suboptimal in Buser et al. (1981) but more reliable in the whole economy.

⁹Acharya et al. (2014) pointed out that the bank bailouts may transfer the financial sector credit risk to sovereign credit risk. Consequently, the sovereign bonds became more risky. If risk free assets are not really risk free, such as the European sovereign bonds, the risk could be very high: two way causality of the European debt crisis in 2002. In this situation, we may allow the r_f follows another stable distribution.

¹⁰We consider X_{t+1} as the benchmark return, it is similar to the market return of Capital Assets Pricing Model.

parameters when the residuals are stable distribution. We can extend this model to Fama-French model (Fama and French 1993) or ARMA model. Therefore, the returns of total assets at time $t + 1$ can be expressed by,

$$r_{pt+1} = w_{0t}r_f + \sum_{i=1}^n w_{it}r_{it+1} = A_t + B_tX_{t+1} + \phi_{t+1}, \quad (10)$$

where $A_t = w_{0t}r_f + \sum_{i=1}^n w_{it}a_i$, $B_t = \sum_{i=1}^n w_{it}b_i$ and $\phi_t = \sum_{i=1}^n w_{it}\varepsilon_{it+1}$. If ε_{it+1} are independent stable Paretian distributed with same characteristic exponent, α_ε , then ϕ_{t+1} is a stable Paretian distribution. The proof is given by property 1 in McCulloch and Lee (2008),

$$\phi_{t+1} = \sum_{i=1}^n w_{it}\varepsilon_{it+1}, \quad (11)$$

we have

$$\phi_{t+1} \sim S(\alpha_\varepsilon, \beta_{\varepsilon t}, c_{\varepsilon t}, \delta_{\varepsilon t}),$$

where

$$\begin{aligned} \beta_{\varepsilon t} &= \frac{\sum_{i=1}^n |w_{it}|^\alpha c_i^\alpha \text{sign}(w_{it}) \beta_i}{c_{\varepsilon t}^\alpha}, \\ c_{\varepsilon t} &= \left(\sum_{i=1}^n |w_{it}|^\alpha c_i^\alpha \right)^{\frac{1}{\alpha}}, \quad \text{and} \\ \delta_{\varepsilon t} &= \sum_{i=1}^n w_{it} \delta_i. \end{aligned} \quad (12)$$

We call this model as Stable (SA). Moreover, the distribution of r_{pt+1} can be estimated by Theorem 1 with $m = 2$. If ε_{it+1} are independent stable Paretian distributions with different characteristic exponents, say α_i , then we need to use Theorem 1 with $m = n + 1$ to estimate the distribution of r_{pt+1} , and we call this model as Stable (DA).

Theorem 1 If Y_j are independent random variables, with $Y_j \sim S(\alpha_j, \beta_j, c_j, \delta_j)$ for all $j \in \mathbb{N}$, and the cumulative distribution functions of each Y_j can be approximated in a closed interval $[u, v]$, then the cumulative distribution function of $Z = \sum_{j=1}^m \omega_j Y_j$ can be approximated by following,

$$\Pr(Z < s) \approx \frac{s - u}{v - u} + \sum_{k=1}^N \frac{(b - a)\tilde{A}_k}{k\pi} \sin\left(k\pi \frac{s - u}{v - u}\right),$$

where

$$\tilde{A}_k = \frac{2}{b - a} \operatorname{Re} \left\{ \exp\left(-i \frac{k\pi}{b - a}\right) \prod_{j=1}^m \varphi_j\left(\frac{k\omega_j\pi}{b - a}\right) \right\},$$

$i = \sqrt{-1}$ and φ_j is the characteristic function of Y_j . The proof of this Theorem is given in U et al. (2016).

According to Theorem 1, we can estimate $\Pr(r_{pt+1} < y)$ in Stable (SA) with $Y_1 = X_{t+1}$ and $\omega_1 = B_t$, $Y_2 = \phi_{t+1}$ and $\omega_2 = 1$ and $s = y - A_t$. For the Stable (DA), we can set $Y_1 = X_{t+1}$ and $\omega_1 = B_t$, $Y_2 = \varepsilon_{j-1t+1}$ and $\omega_j = w_{j-1t}$ for $j = 2, \dots, n+1$ and $s = y - A_t$.

85.5 Empirical Results

85.5.1 Investment Companies

In this section, we considered an investment company that invested in two stocks, American Express (AXP) & Cisco System (CSCO), and a risk-free asset (r_f). The returns of Dow Jones Index are used as benchmark index (X_{t+1}) in Eq. (10). We chose weekly data from 2/1992 to 12/2010, we first used weekly data¹¹ from 2/1992 to 8/2001 and Nolan and Ojeda-Revah (2013)'s algorithm¹² to estimate a_i and b_i in Eq. (9). The Nolan (2001) maximum likelihood technique is used to estimate parameters in different models:

- The residuals in (9) are stable, Paretian distribution with different α , we say stable (DA).
- The residuals (ϕ_{t+1}) in Eq. (10) are stable Paretian distribution that is given by Eq. (11), we say stable (SA).
- The traditional one-factor model with normal uncertainty disturbance, we say normal.

And parameters of above models are given in Table 1. We then determine the VaR in Eq. (6) from 9/2001 to 12/2010 weekly data¹³ with Theorem 1.

In Tables 2 and 3, we assumed the interest rate of debt (r_d) in Eq. (5) was equal to zero. Table 2 shows that the required capital ratio with the probability of bankruptcy is less than 0.1% under different weights of risk-free assets. We use different models to compare the impact of the changes in allocation of assets on the required capital ratio. (a) Stable (DA) model: the required capital ratio was reduced rapidly if the company invested less in CSCO, but the required capital ratio was reduced slowly if we only decrease the weight of AXP. (b) Stable (SA) model: we take average of α of two assets; therefore, the extraordinary risk of these two assets is assumed to be the same. The result shows that difference in required capital ratios among different methods of reducing the weight of two risky assets is not obvious. The largest

difference in capital ratio between rAXP and rCSCO is around 10%. It is much smaller than the largest difference in capital ratio (35%) in Stable (DA). In a normal model, the required capital ratio is very low, and its changes are not sensitive to the changes of the weight of risk-free assets. Figure 1 shows the graphic results of Table 2. If a company has inadequate capital, the company can raise the capital. However, the “externality” problem will increase the cost of capital. Otherwise, the company can increase the weight of risk-free assets then required capital ratio can be reduced, but the profitability will be limited by this change.

Table 3 shows the result of maximum expected return with the required capital ratio constraint. Given a probability of bankruptcy, increasing the weight of risk-free assets can reduce the required capital ratio. In contrast with Stable (DA) model and Stable (SA) model, the optimal portfolio is quite different in different models. First, the weight of CSCO is much less than the weight of AXP in the Stable (DA) model, but the results are opposite in Stable (SA) model. Second, the weight of risk-free assets in Stable (DA) model is much less than that of Stable (SA) model. This is consistent with Table 2 that reducing the weight of CSCO can rapidly reduce the required capital ratio. In the Stable (SA) model, the allocation of two risky assets is relatively close together, because the extra-ordinary risks of two assets are assumed to be equal in this model.

Table 3 The allocation of AXP and CSCO in Eq. (8) with different capital ratios (cr) and the probability of bankruptcy (θ) is 0.1%

	Model	$r_f = 0.01\%$	AXP	CSCO	Expected Returns	Empirical Results	Min. Returns	The % of bankruptcy
Cr = 30%	Stable (DA)	19.55	65.49	14.96	0.71	0.03	-23.16	0
	Stable (SA)	45.97	16.63	37.4	0.8	0.02	-12.62	0
	Normal	-135.22	118.26	116.96	1.27	0.07	-58.56	1.22
Cr = 20%	Stable (DA)	46.36	43.67	9.98	0.48	0.03	-15.44	0
	Stable (SA)	63.97	11.09	24.94	0.54	0.01	-8.41	0
	Normal	-56.84	78.85	77.99	0.85	0.05	-39.04	1.22
Cr = 10%	Stable (DA)	73.17	21.84	4.99	0.24	0.02	-7.72	0
	Stable (SA)	81.98	5.55	12.48	0.28	0.01	-4.2	0
	Normal	21.54	39.45	39.01	0.43	0.03	-19.53	1.22

Therefore, the company reduced the weight of both assets to decrease the extra-ordinary risk of the total assets in this model, so the weight of risk-free assets is higher in this model than that of the Stable (DA) model. In the Stable (DA) model, the company can keep less risk-free assets by holding less of CSCO, so higher returns are yielded. It is consistent with the empirical results that the returns in the Stable (DA) model are higher than that of the Stable (SA) model without any bankruptcy in both models. In the normal model, although the empirical returns are the highest, but the company gets bankruptcy. It is not preferred in this study (Fig. 2).

85.5.2 US Banks

In tradition, VaR model is used to determine the potential loss of the portfolio and the returns are assumed normally distributed, especially for banks. However, in the crisis period, they find that the potential loss is underestimated by using the VaR model. Therefore, bank regulators proposed the stress test to explain the potential loss in the crisis period. The idea is to assume different scenarios in economic downturns and how they affect the risk-based capital requirement of the banks. However, this method is nonparametric, without involving any probability theory. In our argument, the traditional VaR model cannot capture the extra-ordinary risk, so it underestimates the potential loss in a crisis period. Then, the stress analyzes how the extra-ordinary risk changes the capital requirement of the banks. In our paper, we seem to create a bridge to connect the traditional VaR model and the stress test. Our stable VaR model captures the extra-ordinary risk via the characteristic exponent (α), it gives more accurate estimates of VaR, as shown in previous section. We can also change the

Fig. 1 The description of Table 2

parameters to satisfy different scenarios, for example, we can reduce α to allow the higher extra-ordinary risk in the future, or we may require lower bankruptcy risk (θ). Therefore, the capital ratio will change accordingly. In this chapter, we focus on the required capital ratio with different bankruptcy risks.

The implementation to the Bank of America Corp., the Wells Fargo & Co., the Citigroup Inc., the Regions Financial Corp., and the SunTrust Banks Inc. will be contemplated in this section. For simplicity, the total asset will be classified into four categories, that is, risk-free assets (including cash and balances due from depository institutions, Federal funds sold and securities purchased under agreements to resell), security assets (including all derivatives and securities), loans and leases financing receives (including all loan assets), and other equities (including premises and equipment, goodwill, intangible assets, and other assets). These are obtained from the

Fig. 2 The description of Table 3

Federal Deposit Insurance Corporation (FDIC) database. The parameters of security assets are estimated by using market index with monthly data from January 1990 to December 2011. Three indices Nikkei 225, S&P 500, and Dax 100 are collected, and the average of these indices is the proxy of the market index in this study. The parameters of loans and leases allowance are proxied by the returns on weighted average of 30-year maturity bond in long position (the proxy of gain from loan) and 1-year maturity bond in short position (the proxy of deposit cost). These indices are collected from the database “CRPS,” then half-year parameters can be evaluated via Eq. (12). The results of monthly parameters are given in Table 4. Other equities are assumed as normal distributed with $c = 0.03$ and $\delta = 0.01$ from 2005 to 2011 (the average value of the assets containing in the other equities). Risk-free rate and interest rate of debt (the average value of deposit, short term, and long-term debts rates) are assumed 1% p.a. and 6% p.a., respectively. We used the consolidated financial statement from the FDIC to find ratios of securities per total asset (S/A), loans and leases per total asset (L/A) and other equities per total asset (O/A). We postulated these assets are statistically independent then we can compute half-year required capital ratios with Eqs. (5), (6) and Theorem 1. The results are given in Tables 7, 8, 9, 10, and 11. The raising capital (RC) is computed through the following equation

$$RC = \frac{rcr \times TA_t - c_t}{1 - rcr}, \quad (13)$$

Table 5 The details of Treasury's bank bailout between 2008 and 2011, the details can be found at <http://money.cnn.com/news/specials/storysupplement/bankbailout/>

Name of banks	Treasury's bank bailout
Bank of America	\$15 billion in October 28, 2008 ^a and addition \$10 billion in January 9, 2009.
Wells Fargo	\$25 billion in October 28, 2008.
Citigroup	\$25 billion in October 28, 2008.
Regions financial	\$3.5 billion in November 17, 2008.
SunTrust	\$3.5 billion in November 17, 2008, \$1.35 billion in December 31, 2008.

^aInitially allocated to Merrill Lynch, which Bank of America purchased on Jan. 1, 2009 Source: Treasury Dept.

where c_t is the capital at time t and rcr is the required capital ratio with probability of default θ in Eq. (7).

As shown in Tables 7, 8, 9, 10, and 11, all banks need to raise their capital before 2008. For example, the Bank of America needs more than 12% capital ratio in 2007 such that it can reduce the probability of default to 1.5%, it needs to increase more than \$50 billion in capital. This was a warning of the US banking system. After that, a financial crisis started in 2008 and the treasury department injected billions of dollars into the financial market. The amounts are similar to our estimations, that is, the Wells Fargo was injected with \$25 billion that is close to our estimation of \$23.06 billion in the fourth quarter of 2008 with 4% probability of default (see Table 8). For Citigroup, the amount was \$25 billion that is similar to our estimation of \$20.97 billion (see Table 9). For Regions Financial, the amount is \$3.5 billion that is close to our estimation of \$3.22 billion (see Table 10). On the other hand, three large banks (the Bank of America, the Wells Fargo, and the Citigroup) have lower capital ratios than others, and all of them are less than 10% before 2008. The probability of default was more than 4% before 2008. That is a dangerous signal for the banking system.

First, all banks in our study got the bailout from the US government (see Table 5) and the capital ratio increased after the Treasury's bank bailout. The government also wants to stimulate the economy. The amount of loans should be increased significantly. However, all banks reduced the L/A ratio and increased the weight of risk-free assets from the first quarter of 2009 to the end of 2009. On the other hand, if we postulated the worst economy in the future, banks may raise their capital until it

reaches to the required capital ratio with a lower probability of bankruptcy, such as 1%. It can be viewed as a stress test with different scenarios, that is, the Bank of America needed to raise its capital ratio to 11.62% with 1.5% probability of default or the bank may need to raise the capital ratio to 13.53% with 1% probability of default. The required capital becomes much more than that needed at 1.5%. However, it will cause the bank loans to decrease and the cost of capital to increase, and it may slow down the economic growth in USA. The government should recover the confidence of investors but minimize the impact of the weak economic environment. It can be concluded as reducing the bankruptcy risk with minimal rising of capital. In this chapter, we recommend holding a suitable weight of risk-free assets instead of raising capital. It can reduce the probability of bankruptcy and lighten the increase in cost of capital. As shown in Tables 7, 8, and 9, the Bank of America increased the weight of risk-free assets from 6.76% in 2008 to 16.01% in 2010; the Wells Fargo increased from 5.59% in 2008 to 7.61% in 2010; the Citigroup increased from 19.79% in 2008 to 22.82% in 2010. Figs. 3 and 4 show the changes in the weight of risk-free assets amongst different banks. In Fig. 3, the total amount of cash increased significantly in the first quarter of 2009, especially for the Bank of America and the Citigroup. In Fig. 4, the “Federal funds sold and securities purchased under agreements to resell” of the Bank of America are increased substantially after 2008, and the Citigroup is at a peak before 2008, because it suffered a lot in subprime mortgage crisis since it invested a huge amount in Collateralized Debt Obligations (CDO) before the crisis. If the Federal funds sold and securities purchased under agreements to resell are viewed as US government subsidy through the Quantitative Easing (QE).¹⁴ Fig. 5 depicts the amount of loan decreases after 2008. It shows that QE cannot increase the amount of loan after the US bank regulators’ announcement. They increase the weight of risk-free assets such that they can reach the capital requirement. It explains why banks do not increase the loan significantly. The small banks (the Regions Financial & the SunTrust) do not increase their weight of risk-free assets, since the raising capital is around \$2.5 billion, which is relatively smaller than the big banks (Fig. 6).

Second, we estimate the parameters of the different banks by using their end-of-day stock prices (the average of bid-ask prices) from 2003 to 2011. As shown in Table 6, the extraordinary risks of the banks are at the peak in the crisis period. The stock prices slumped more than 30%, thus capital ratios reduced before government bailout. After 2008, the banks got the bailout and reallocated their portfolios. One of the reasons is to achieve the capital requirement, and another reason is to stay away from the market. Two reasons are correlated, once the money is drawn from the market, the required capital ratio reduces, and the banks can reach the capital requirement without raising billions of dollars in their capital. After the crisis, the extra-ordinary risk of the market decreases, and the bankruptcy risks of the banks

¹⁴The QE1 is announced in November 2008.

“These banks are strong and have too much capital now,” said RBC Capital Market’s analyst Gerard Cassidy, who predicts all major banks that ask for dividends and buybacks in 2013 will be approved.

The banks have surplus capital, because the extraordinary risk of the market is reduced and the portfolio reallocated. They require dividend payout or share buybacks. In Miller and Rock (1985), they introduce information signal model and conclude that the dividend policy gives signals of future prospects of companies. Increasing the dividend payout signals good news and share prices increase. Braggion and Moore (2011) find the abnormal returns when dividend policy is changed. Therefore, the banks ask for the dividend payout to push up their stock prices, so that the capital ratio increased. The banks can reach the capital requirement.

Third, we observe the allowance of bankruptcy risks of different banks are different. In the Bank of America, it is required to raise \$33.9 billion. The close estimation is \$33.93 billion with 1.5% bankruptcy risk. In the Wells Fargo and the Citigroup, the closest values of raising capital are \$14.6 billion and \$4.39 billion, respectively, which are in the 4% probability of default. The Regions Financial is \$2.93 billion with 1.25% bankruptcy risk and the SunTrust is \$2.58 billion with 1.5% bankruptcy risk. Our explanations are (1) the assets of the Bank of America, the Citigroup, and the Wells Fargo are almost ten times the other two banks. The US government may allow a higher probability of bankruptcy for banks with huge amounts of assets because they can change their portfolio easier than small banks. (2) The structure of loans of different banks may not be the same, while we aggregate all of them (It may include mortgage loans and commercial loans, etc.) as one component. It may cause the difference. (3) The numerical error of our algorithm, we estimate required capital ratios, but the raising capital is very sensitive to the required capital ratio. Therefore, the error in the raising capital enlarges. The Bank of America requires the lowest probability of bankruptcy (1.5%) than other big banks (the Wells Fargo and the Citigroup). One main reason is the big loss suffered by acquiring the Merrill Lynch in December 2008. Merrill Lynch reported the loss of \$15.3 billion in the fourth quarter of 2008 and the Bank of America suffered the loss of \$ 1.75 billion, the stock price is down at \$7.18, dropped by 13.7%. Mr. Lewis (the chief executive of the Bank of America) said, “. . . He was surprised to learn in December, three months after the bank snapped up Merrill Lynch in a shotgun deal, that the magnitude of losses at the

brokerage was far greater than expected. He said he had considered walking away from the deal at that point, but was persuaded not to, partly by regulators who feared that a failure to seal the deal could set off a new round of panic in the markets. . .” (See “For Bank of America, the Pressure Mounts Over Merrill Deal” by LOUISE STORY in January 17, 2009, in *The New York Times*).

Fourth, the Wells Fargo and the Citigroup are trying to increase their capital into a more safe level. They kept increasing their capital ratios from 2009 to 2011, therefore the bankruptcy risk was reduced from 4% to 3%. However, the Sun Trust increased the weight of security assets from 13.93% in the first quarter of 2009 to 17.27% at the end of 2011 and reduced the weight of risk-free assets to 2.56%. Therefore, its bankruptcy risk increases from 1.5% to 2.5%. Regions Financial also increased the weight of security assets from 15.54% in the first quarter of 2009 to 20.05% at the end of 2011, but it also increased the weight of risk-free assets from 3.62% to 5.69%. Therefore, its bankruptcy risk remains at 1.25%. The bankruptcy risk of the Bank of America is around 2% in 2011. It may not be worse, since the subprime mortgage crisis is over, and the big loss from the Merrill Lynch has subsided. The government may allow a higher bankruptcy risk since the Bank of America is one of the Big Four banks in America. Big banks tend to reduce the bankruptcy risk through increasing the risk-free weight and the capital, but small banks tend to increase their profits through increasing the weight of security assets and decreasing loans and leases.

85.6 Conclusion

This study proposes a VaR and stress test-integrated method. We introduce a VaR-based method to evaluate the required capital ratio. After that, the comparison of VaR estimations in different models is proposed. In June 2009, J.P. Morgan Investment Analytics and Consulting Romain Berry describe “. . . a risk manager should not rely too much on VaR calculations since they may be underestimated quite often. . .” This chapter tackles this issue by using the stable Paretian distribution instead of the normal distribution and statistical evidence is given. The normal distribution captures all risks in one parameter. On the other hand, stable Paretian distribution separates the risks into extraordinary risk and ordinary risk with different parameters. It is more suitable for the risk managers to make decisions in normal period and also the crisis period. Some authors apply the extreme value theory to the VaR. However, it may not be suitable in the normal period and are not flexibly used to maximize expected returns, since the idea of extreme value theory only considers the tail of distributions. As shown in Fig. 7, the normal distribution tries to capture the extreme returns by increasing the standard derivation (σ). However, it will underestimate the probabilities around the mean. In stable Paretian distribution, the extra-ordinary risk and ordinary risk are captured by different parameters α and c . Therefore, it fits the empirical distribution much better. A Fourier series-based method gives us a new tool to calculate the stable Paretian distribution with different α . Therefore, by separating the extra-ordinary risk of assets, company may find a better asset structure such that higher profit can be obtained. The empirical results in Tables 2 and 3 support these arguments. Finally, we find out five banks that are required to raise the capital. As shown in Tables 7, 8, 9, 10, and 11, all

banks needed to raise their capital before 2008, it is the signal that the banking system will be in trouble in the crisis period. All banks decreased lending ratios in their portfolio significantly after the bank regulator's announcement, even though the purpose of government bailout is to prop up the capital and new loans. The "externality" issue of the banking system is a major reason such that the government-regulated banks should reach an adequate capital to prevent banks run. In this chapter, we show that the required capital ratios reduced significantly after increasing the weight of risk-free assets. This paper gives rational reasons that banks take these actions. In this chapter, total assets are simply classified into risk-free asset, loans, and securities. They are log-stable Paretian distributed with different characteristic exponents. However, this assumption neglects the correlation of assets. The diversification effect will be underestimated. Therefore, banks may hold excessive capital which is not necessary, especially for the normal period. The copula method will be one of the ways to tackle this issue in our future research (Tables 12, 13, 14, 15, 16, and 17).

The Economics of and Accounting for Lease Transactions

86

Cheng-Few Lee and Ryan McDonough

Abstract

This chapter explores a company's decision to enter into a lease contract to finance capital investments. We discuss the motivations behind the lease-versus-buy tradeoff in terms of both the economics of and accounting for lease financing arrangements. Throughout our discussion, we reference academic research related to the lease-versus-buy decision, the factors influencing the extent of leasing activity, the economic consequences of lease financing, and the role of lease-related accounting standards. We also provide a detailed review of the provisions in the current lease accounting standards that were recently issued by the Financial Accounting Standards Board and the International Accounting Standards Board.

86.1 Introduction

Capital expenditure decisions are among the most fundamental and important decisions made by corporate managers. When making investment decisions, corporate managers are confronted with the choice to either purchase an asset or, alternatively, enter into a lease contract to finance the use of an asset for some or all of the asset's economic life. This chapter examines companies' decisions to enter into lease transactions, with an emphasis on the economic theory underpinning lease financing as well as the accounting and financial reporting implications that have evolved in recent years.

Leases are ubiquitous in practice. In addition to the economic motivations for lease financing, accounting and reporting considerations have historically influenced the benefits and costs associated with leases. Indeed, a flourishing stream of academic research has sought to explain the existence of leases and has explored the economics of leasing and the impact of accounting requirements on lease structuring (e.g., Johnson and Lewellen 1972; Gordon 1974; Miller and Upton 1976; Ang and Peterson 1984; Imhoff and Thomas 1988; Eisfeldt and Rampini 2009; Caskey and Ozel 2019). The finance literature has generally focused on explaining the prevalence of lease transactions through the lens of borrowing capacity (e.g., Sharpe and Nguyen 1995; Eisfeldt and Rampini 2009), tax considerations (e.g., Miller and Upton 1976; Myers et al. 1976; Graham et al. 1998), and operational flexibility (e.g., Gavazza 2011). Meanwhile, accounting scholars have generally focused on the impact of accounting and financial reporting requirements in terms of both companies' incentives to structure leases to be off-balance-sheet and the capital market impacts of such structuring decisions (see, e.g., Spencer and Webb 2015). We discuss this body of research throughout this chapter.

In the next section, we define the nature of a lease and discuss the use of lease arrangements across industries. We then provide an overview of the economic theory and assumptions that help explain the existence of leasing as a widely used investment financing option. The fourth section focuses on the accounting standards issued by the Financial Accounting Standards Board and the International Accounting Standards Board that have recently ushered in a new era of accounting and reporting for leases. We discuss how the recent changes in accounting and financial reporting requirements have potentially shifted the expected costs and benefits of some lease arrangements. Although we focus primarily on generally accepted accounting principles (GAAP) in the United States, we also provide a brief discussion of international financial reporting standards (IFRS). The last section concludes this chapter.

86.1.1 Nature and Use

86.1.1.1 General Nature of a Lease Arrangement

Companies lease assets such as land, agricultural products, buildings, plants, retail and office space, and equipment. A lease transaction is guided by a contractual

agreement that specifies the rights and obligations of the contracting parties – the lessor and the lessee. The lessor commonly owns the asset to be leased. The lessee has an obligation to make payments to the lessor in exchange for the exclusive right to control the use of the lessor's physical asset (e.g., property, plant, or equipment) for a specified period of time (the lease term). The lease term is generally less than the expected economic life of the underlying leased asset; otherwise, the transfer of possession of the asset would generally be considered a sale. At the end of the lease term, the underlying leased asset is typically returned to the lessor. The lessor could then, for example, redeploy the asset to another lessee or to a buyer.

86.1.1.2 Use of Leases

Leases are used across the world and, historically, have been used for at least as long as contractual arrangements have been recorded (e.g., Ellickson and Thorland 1995, p. 369; Spencer and Webb 2015, p. 1000). Although the use of leases spans industries, companies in industries such as airlines, retail, and telecommunications tend to rely relatively more on leases as a financing option than companies in other industries do. Present day lease transactions include, for example, retail space leased by companies such as Walgreens Boots Alliance Inc. and CVS Health Corporation. AT&T Inc. and Verizon Communications Inc. both have lease arrangements that cover assets such as towers, retail stores, and buildings. Amazon Inc., FedEx Corporation, and United Parcel Service Inc. lease, for example, aircraft, distribution facilities, and vehicles. Companies in the airline industry, such as United Continental Holdings and Delta Airlines Inc., lease aircraft, buildings, and other assets. According to prior research, slightly more than half of all commercial aircraft are leased (Gavazza 2010, pp. 68–69).

Securities and Exchange Commission (SEC) Form 10-K filings for companies' 2019 fiscal year-end reveal that more than 70% of publicly traded US companies report a lease liability. Similarly, prior research suggests that 80% of all US companies lease assets (Gavazza 2010, p. 62). For the 2019 fiscal year-end, publicly traded US companies report an average lease liability of nearly \$190 million. However, the average lease liability reported by the 100 publicly traded US companies with the largest lease liabilities is approximately \$5.2 billion. Illustration 88.1 below further highlights the magnitude of lease liabilities for the 25 US companies with the largest lease liabilities. As the chart demonstrates, the largest lease liability amounts tend to be reported by companies in the airlines, retail, and telecommunications industries. Note that before 2019, the lease liability reported by the vast majority of companies would have been substantially smaller because companies could previously structure their leases to keep many leases (specifically, operating leases) off their balance sheets. The accounting rules currently in place, which are discussed in Sect. 86.3, require companies to report the vast majority of their leases on their balance sheets, regardless of lease classification.

Illustration 88.1 Total lease liability – that is, finance and operating lease liabilities – as of the 2019 fiscal year-end. The amounts are reported in billions of US dollars. (Source: SEC 10-K filings)

86.2 Motivations for Leasing: Theory and Assumptions

There are several factors that can make leasing an attractive and pervasive financing option for many companies. This section discusses the primary motivations for entering into a lease arrangement, including considerations related to transaction costs, operational flexibility, financing capacity, tax consequences, and financial reporting outcomes. It should be noted, however, that the discussion that follows is not meant to be a blanket endorsement of leasing. There are, of course, many situations in which it makes more sense for a company to purchase – whether using internal funds, debt, or equity – than to lease an asset. The discussion in this section is only meant to highlight considerations that can make leasing comparatively more attractive than purchasing in certain circumstances, thus explaining the observed widespread use of lease financing.

86.2.1 Financing: Lease Vs. Purchase

A natural question that arises is whether and to what extent there is a difference in the economic substance of purchasing an asset through the issuance of long-term debt and purchasing the right to use an asset by entering into a lease agreement. Generally speaking, the economic substance of these two transactions is identical, although the contractual arrangements and contracting parties will differ to some extent. Indeed, following from the Modigliani-Miller theorem (Modigliani and Miller 1958, 1963), Miller and Upton (1976) assert that under certain fairly strict assumptions, the decision to lease an asset rather than borrowing funds to purchase it should be irrelevant to the company (see also, e.g., Smith and Wakeman 1985). However, the assumptions underlying this irrelevance conclusion likely do not reflect reality. For instance, Miller and Upton's assumptions relating to the existence of perfect capital markets, as well as the absence of asymmetries in transaction costs, default risk, and tax consequences between the leasing and borrowing-to-buy decisions, do not generally comport well with realistic institutional settings. The discussion that follows focuses on nonfinancial-reporting incentives first and then turns to financial reporting incentives that could play a role in leasing decisions and in how leases are structured.

86.2.2 Nonreporting Incentives: Transaction Costs, Flexibility, Borrowing Capacity, and Taxes

A benefit of leasing, particularly in the absence of access to perfect capital markets, is that companies obtain the exclusive right to control the use of an asset at a relatively low cost, given that the lease is for less than the expected useful life of an asset. In contrast, a purchase is for the asset's entire useful life. Although a company could purchase an asset and then subsequently sell it to make the cost of leasing and purchasing equivalent (for a given period of time), this argument relies on the assumption of perfect capital markets and no asymmetry in transaction costs. Since a lessor can specialize in leasing and redeploying assets while lessees specialize in utilizing assets, the overall costs associated with using the asset are reduced – more generally, the lessee and lessor can efficiently separate responsibilities. A lessor, for example, can use its expertise in acquiring land, building management, maintenance, and asset disposal and redeployment. Lessees can focus on their competitive advantages, whether that be in retail, manufacturing, or services industries.

Similar to the benefits associated with specialization, leases allow lessees and lessors to split the residual rights of the leased asset and, thus, the risks associated with owning the asset. For instance, the lessee pays for the right to use the asset for a certain period of time while the lessor retains some of the residual rights. In particular, since the lease is for a period less than the expected useful life of the asset, the lessee returns the asset to the lessor at the end of the lease term, which

represents the remaining residual rights in the asset.¹ This protects a lessee, for instance, against the risk of obsolescence and also affords the lessee more operational flexibility since the lessee will not need to use the asset for its entire useful life, nor will the lessee need to incur the costs associated with disposing of the asset (including identifying a buyer for a partially used asset). Leases may also offer flexibility vis-à-vis the option to buy the asset or renew the lease at the end of the lease term, as well as the option to choose a lease term suitable to the needs of the company or terminate the lease early in a relatively low-cost and straightforward manner. Gavazza (2011) suggests that operational flexibility (e.g., the ability to adjust for changes in capacity needs at relatively low costs) is an important factor explaining the use of lease financing.

Furthermore, leases typically require relatively small (or even no) down payment, which can make it more attractive than a secured loan that may require a relatively large down payment, especially for financially constrained companies. Leases also offer greater protections to lessors – for example, with respect to repossessing an asset when a lessee does not make the required lease payments – than protections available to secured lenders (Sharpe and Nguyen 1995; Eisfeldt and Rampini 2009; Beatty et al. 2010). This bankruptcy protection afforded to lessors effectively expands a lessee's borrowing capacity beyond what would be the case in a world without leases and only secured borrowing.

A potential additional benefit of using a lease to finance the use of an asset is the associated tax advantages (Miller and Upton 1976; Graham et al. 1998). Similar to the bankruptcy protections for lessors, the tax benefits of leasing will vary by jurisdiction. A company that borrows to build or buy an asset may enjoy tax savings from the deduction of interest and depreciation. If Miller and Upton's (1976) assumptions hold, the tax advantage associated with leasing will equal the tax advantage associated with the deduction of interest and depreciation. However, interest and depreciation generally can only be deducted insofar as a company has taxable income. In contrast, lease payments can be used as a tax shield in future periods (i.e., in the case of net operating losses). More generally, leases can be advantageous because they allow the contracting parties to structure the arrangement so that the tax benefits are allocated to taxable companies.

86.2.3 Financial Reporting Incentives

Finally, it should be noted that the US and international accounting rules previously allowed for off-balance-sheet reporting for certain types of leases. In particular, until a few years ago, the characteristics of a lease arrangement and, thus, the classification for accounting purposes, substantially impacted the accounting treatment (i.e.,

¹ Naturally, the lessor will be concerned about the condition of the leased asset at the end of the lease term. As such the lessor may monitor the lessee and include in the lease agreement certain clauses about the minimum residual value of the asset at the end of the lease.

on- vs. off-balance-sheet reporting). As a result, many lease arrangements were structured so that the lease was not reported as a liability and corresponding asset on a lessee's balance sheet, while nearly identical lease arrangements may have resulted in the lease-related asset and liability being recognized on the balance sheet. Structuring leases to be off-balance-sheet may have been considered a benefit to lessees, as evidenced by widespread efforts by many lessee companies to keep leases off their balance sheets (e.g., Imhoff and Thomas 1988; SEC 2005). The potential financial reporting incentives arise from a desire to improve the reported financial condition of a company – for example, in anticipation of a debt or equity issuance, to avoid debt covenant violations, or to maximize compensation or other contracting outcomes. However, some have argued that the financial reporting incentives associated with keeping leases off-balance-sheet (i.e., through window dressing) are likely not of primary importance (e.g., Myers et al. 1976, p. 815; Caskey and Ozel 2019), but rather the decision to structure a lease to keep it off-balance-sheet was likely primarily driven by tax and bankruptcy laws.² Regardless, the new accounting rules, which are discussed next, generally no longer allow for off-balance-sheet reporting of leases.

86.3 Accounting for Lease Transactions Under US GAAP and IFRS

In November 1976, the Financial Accounting Standards Board (FASB) issued Statement of Financial Accounting Standards No. 13, *Accounting for Leases*, which required a lease arrangement to be classified as either an operating lease or a capital lease (FASB 1976).³ An operating lease was not required to be reported on a lessee's balance sheet, which was generally considered a desirable accounting outcome for lessees, as indicated in the prior section (such an arrangement was considered a “true lease” or rental agreement). A lessee would instead record lease (or rent) expense in the income statement and disclose the lease commitment in the notes to the financial statements. In contrast, the FASB concluded that, for capital leases, a lease-related asset and liability should be reported on a lessee's balance sheet because substantially all of the risks and rewards associated with the underlying leased asset were considered to be transferred to the lessee (i.e., such an

²The tax and bankruptcy laws in the U.S. and many other countries maintain relatively similar criteria for classifying a lease as either a “true lease” (basically a rental agreement) or a financed purchase (Eisfeldt and Rampini 2009, p. 1626). This is important because the same general criteria that allowed a company to report a lease off-balance-sheet for financial reporting purposes also resulted in tax benefits and bankruptcy protections that make it difficult to determine whether a company was structuring a lease for a desired financial reporting outcome or for the benefits associated with tax consequences or expanded borrowing capacity.

³FASB Statement No. 13, which is now superseded, was codified as Topic 840, *Leases*. Note that prior to Statement No. 13, leases were only disclosed in the notes to the financial statements.

arrangement was considered a de facto financed acquisition of the underlying leased asset).

The FASB's Statement No. 13 lease accounting requirements (the predecessor standard) were frequently criticized by financial statement users because the rules relied on bright-line tests that were used to determine if a lease should be capitalized or not. These tests, which are, to some extent, still used today, are discussed in the next section. Because of the all-or-nothing approach to lease capitalization, it was relatively easy for companies to structure lease arrangements in a way that a preferred financial reporting outcome could be obtained. This resulted in a proliferation of off-balance-sheet operating lease arrangements (e.g., Cornaggia et al. 2013, p. 349) and a lack of transparency regarding a company's financing activities (e.g., Monson 2001; Rapoport 2013). To correct for this deficiency and to aid in the comparison of financial statements across companies with different financing arrangements (e.g., leasing vs. debt financing), investors and analysts routinely used note disclosures to reconstruct financial statements and financial ratios as if operating leases had been capitalized and properly treated as a liability.⁴ This was commonly referred to as constructive capitalization (e.g., Imhoff et al. 1991, 1997). There has been considerable debate about whether the disclosed operating lease amounts were treated similarly to on-balance-sheet liabilities and appropriately factored into equity prices and credit assessments (e.g., Wilkins and Zimmer 1983; Ely 1995; Dhaliwal et al. 2011; Bratten et al. 2013; Altamuro et al. 2014; Kraft 2015).⁵ However, the consensus generally was that the FASB's lease accounting standard was deficient in that it could result in differing accounting outcomes for otherwise similar transactions.

In response to these shortcomings and following a June 2005 report from the SEC (SEC 2005), the FASB initiated a standard-setting project with the International Accounting Standards Board to develop new lease accounting standards.⁶ The new accounting rules were issued in February 2016 in the FASB's Accounting Standards Update 2016–02, which is codified, along with subsequent amendments, in the Accounting Standards Codification (ASC) as Topic 842, *Leases* (FASB 2016). ASC 842 was effective for publicly traded companies beginning after December 15, 2018. Although the new guidance largely retains the prior classification criteria established in FASB Statement No. 13, the accounting treatment corresponding to the different classifications has converged to generally require on-balance-sheet reporting for the vast majority of leases. These accounting rules are discussed next, beginning with the lease classification requirements.

⁴FASB Statement No. 13 required lessees to disclose certain information about operating lease commitments, including the minimum lease payments due in the current fiscal year, the subsequent five fiscal years, and a lump sum amount reflecting the fiscal years thereafter.

⁵We refer readers to Spencer and Webb (2015) for a review of the literature related to lease accounting from the perspective of lessees.

⁶The SEC, for instance, indicated in its report that it estimated there was outstanding a total of \$1.25 trillion in off-balance-sheet operating lease obligations.

86.3.1 Classification of Leases

The FASB defines a lease arrangement in ASC 842 as a contractual arrangement that confers the right to control the use of an identified asset – that is, property, plant, or equipment – for a specified period of time in exchange for consideration paid to the lessor. However, there are some scope exceptions. ASC 842 does not apply to leases of intangible assets, leases for the exploration or use of natural resources, leases of biological assets, leases of assets under construction, or leases of inventory.

Once the underlying asset is identified and it is determined that a lease exists, a company must classify the lease based on the provisions of the contract.⁷ Under the new accounting requirements set forth in ASC 842, lessees classify leases as operating leases or finance leases at the lease commencement date.⁸ Classification as an operating lease or finance lease by the lessee depends on whether the lease arrangement meets any of the five criteria described in ASC 842-10-25-2. If a lease meets any of the five criteria described in ASC 842-10-25-2 (see below), the lease effectively transfers control of the underlying leased asset to the lessee, and the lease is classified as a finance lease.⁹ If the lease does not meet any of the five criteria, the lessee is considered to have obtained the right to use an asset, but not control of the underlying leased asset. Such leases are classified as operating leases. The five criteria stipulated by ASC 842-10-25-2 that are used by a lessee to determine whether to classify a lease as a finance lease are as follows:

1. **Ownership transfer test.** The lease arrangement confers ownership of the underlying leased asset to the lessee before or at the end of the lease term.
2. **Purchase option test.** The lease arrangement provides the lessee with an option to purchase the underlying leased asset, and it is reasonably certain the lessee will exercise the option.
3. **Lease term test.** The lease term (or duration of the lease) is for the major part of the remaining economic life of the underlying leased asset.

⁷For simplicity, we refer to a lease as if it applies to only a single leased asset. In practice, additional complexities can arise. For example, an arrangement could include several lease components as well as nonlease components. ASC 842 requires that a company allocate the contract consideration to each separate component of the contract. Each lease component would have to be classified and accounted for separately. Nonlease components (e.g., for the provision of services, such as maintenance) would also need to be accounted for separately following the appropriate accounting guidance.

⁸The previous lease accounting rules required that a lessee classify a lease at the inception date (e.g., the date the lease is signed). ASC 842 requires that a lessee determine whether a lease exists at the inception date, while the classification determination is made at the commencement date. The commencement date is the date on which a lessor makes an underlying leased asset available to the lessee.

⁹As noted in the section addressing lessor accounting, all else equal, the lessor would classify the lease as a sales-type lease, reflecting the de facto sale of the asset from the perspective of conferring control of the underlying leased asset to the lessee.

4. **Lease payments test.** The present value of the sum of the lease payments and any residual value guaranteed by the lessee (that is not already part of the lease payments) equals or exceeds substantially all of the fair value of the underlying leased asset.
5. **Asset specificity test.** The underlying leased asset is of a specialized nature, such that the leased asset is expected to have no alternative use to the lessor at the end of the lease term.

Again, if any of the five criteria are met, then a lessee would classify a lease as a finance lease. The predecessor lease accounting standards used similar lease classification criteria. However, some changes have been made to the updated classification criteria contained in ASC 842. First, the lease term test and the lease payments test were previously based on bright-line tests. The bright-line tests are now principles-based approaches, as described above. In particular, under the predecessor accounting standards for leases, if a lease term was greater than or equal to 75% of the asset's remaining economic life, the lessee would classify the lease as a finance lease. The new standards no longer use this bright-line test, although the 75% threshold could be used as evidence that the lease term is for the major part of the remaining economic life of the underlying leased asset. In addition, if the present value of the sum of the lease payments and any residual value guaranteed by the lessee was greater than or equal to 90% of the asset's fair value, the lessee would have classified the lease as a capital lease (now called a finance lease) under the predecessor accounting standard. Again, the current rules allow for the 90% threshold as evidence of the lease meeting the lease payments test, but the new standards no longer use the bright-line test as the sole determining factor.

Second, ASC 842 includes a fifth criterion that was not included in the predecessor lease accounting guidance related to the specialized nature of the asset. This additional criterion makes it more difficult to classify a lease as an operating lease. If the underlying leased asset is of a highly specialized nature, such an asset would be prohibitively expensive for the lessor to repurpose for use by another user and would have no alternative use to the lessor. In this case, the lessee would classify the lease as a finance lease (the lessor would generally classify the lease as a sales-type lease, as noted in the section discussing lessor accounting).

Note that the dual classification model primarily impacts how a lessee will report lease expense in its income statement subsequent to the initial recognition of the lease. The distinction between operating and finance leases does not impact the recognition of lease-related assets and liabilities on a lessee's balance sheet. Lastly, there is an exemption that applies to the general requirement that lessees recognize the lease-related assets and liabilities on their balance sheets. In particular, when a lease arrangement has a term of 12 months or less, and it does not include an option to purchase the underlying leased asset that the lessee is reasonably certain to exercise, the lessee does not need to report the lease-related asset and liability on its balance sheet.

Lessors must follow the same five fundamental criteria used by lessees to determine the appropriate classification of a lease. However, under US GAAP,

there also exist additional criteria that apply only to lessors and are used to determine whether a lessor should classify a non-sales-type lease as either an operating lease or a direct financing lease. These additional criteria will be discussed in the section addressing lessor accounting.

86.3.2 Discussion of Important Assumptions, Estimates, and Inputs

The classification, initial recognition and measurement, and subsequent measurement of a lease arrangement require lessees and lessors to make certain assumptions and estimates. For example, accounting for leases requires an estimate of the lease term, an appropriate discount rate to calculate the present value of lease payments and any residual value guarantees, and an estimate of the fair value of the underlying leased asset. These assumptions and estimates are discussed in this section.

86.3.2.1 Lease Term

While the lease term may be explicitly stated in a lease contract, a lessee and lessor must also consider contractual provisions such as renewal and termination options. Only if a renewal or termination option is reasonably certain to be exercised should it be factored into the lease term. ASC 842-10-30-1 considers the lease term to be the noncancellable period of the lease, plus:

1. Lease renewal periods, if the lessee is reasonably certain to exercise an option to extend the lease arrangement.
2. Lease termination periods, if the lessee is reasonably certain not to exercise an option to terminate the lease.
3. Lease renewal and termination periods for which the options to extend the lease arrangement or not to terminate the lease arrangement are controlled by the lessor.

Naturally, the assessment of reasonably certain requires professional judgment based on the facts and circumstances present at the commencement of a lease. Judgment should be based on, for example, historical practices and a lessee's or a lessor's economic incentives to exercise renewal or termination options. The FASB suggests that reasonably certain generally would be considered in the context of a threshold of 75%.

Note also that one of the criteria governing the classification of a lease requires a comparison of the lease term and the remaining economic life of the underlying leased asset. The economic life of an asset is defined in ASC 842 as either the period over which an asset is expected to be economically usable by one or more users or the number of production or similar units expected to be obtained from an asset by one or more users. Estimating the economic life of an asset at lease commencement also requires judgment, similar to estimating the depreciable life of an asset purchased.

86.3.2.2 Lease Payments and Residual Values

The lease payments represent the consideration exchanged by a lessee to obtain the right to control the use of the underlying leased asset. For classification purposes, the lease payments test is satisfied if the present value of the sum of the lease payments and any residual value guaranteed by the lessee (that is not already part of the lease payments) equals or exceeds substantially all of the fair value of the underlying leased asset. As discussed above, and as a general rule of thumb, evidence of satisfying the lease payments test could include situations in which the present value of the sum of the lease payments and any residual value guaranteed by the lessee equals or exceeds 90% of the fair value of the underlying leased asset.

ASC 842-10-30-5 discusses the types of lease payments that should be considered at the commencement date to assess the lease payments criterion for lease classification purposes. These lease payments include the following:

1. Fixed payments, net of any lease incentives that have been or will be paid to the lessee.
2. Variable lease payments (e.g., that depend on a market interest rate), which should initially be measured using the referenced index or rate at the lease commencement date.
3. The exercise price of a purchase option that the lessee is reasonably certain to exercise.
4. Amounts paid as penalties for terminating the lease arrangement if the lessee's option to terminate the lease was reflected in the determination of the lease term.
5. Amounts paid by the lessee to a special-purpose entity to structure the lease arrangement. Importantly, note that these amounts should not be included in the determination of the fair value of the underlying leased asset.
6. Amounts that are probable of being owed under a residual value guarantee (this applies to the lessee only).

The residual value is the estimated fair market value of the leased property at the end of the lease term. The lessor can transfer the risk of loss to the lessee through a guarantee of the estimated residual value. A residual value guarantee is a guarantee made by the lessee to the lessor that the value of the underlying leased asset returned to the lessor will be at least some specified amount at the end of the lease term.¹⁰ A lessor may also obtain insurance for the residual value of the underlying leased asset

¹⁰It is important to recognize that lease classification and lease measurement (e.g., the measurement of the lease liability) are not necessarily the same. For example, the lease payments classification criterion requires a lessee and lessor to consider the present value of the sum of the lease payments and any residual value guaranteed by the lessee. In contrast, for purposes of measuring the lease liability, only lessee residual value guarantees that are *probable* of being paid are considered. In addition, the lease liability reflects the present value of the remaining lease payments, while the lease payments classification criterion considers all payments, including payments made before the commencement date.

from a third party (rather than from the lessee), which would not be considered by the lessee in terms of lease classification or lease measurement.

86.3.2.3 Discount Rate

Lessees and lessors need to determine an appropriate discount rate for lease classification and lease measurement purposes. ASC 842 indicates that a lessor should use the rate implicit in the lease. The basic idea is that the rate implicit in the lease is the rate of interest that sets the present value of the lease payments and the residual value of the underlying leased asset (whether guaranteed or unguaranteed) equal to the sum of the fair value of the underlying leased asset (net of any investment tax credits that can be used by the lessor) and the lessor's deferred initial direct costs (if any).

Thus, the rate implicit in the lease is effectively the internal rate of return. For instance, suppose the lessee and lessor enter into a lease contract that requires the lessee to make ten annual lease payments of \$3,000 at the beginning of each year (the first payment is due on the lease commencement date). The lessor estimates the fair value of the asset to be \$20,000 and expects that the asset has no residual value at the end of the lease term. In addition, the lessor has no deferred initial direct costs.¹¹ The interest rate implicit in the lease is the value r in the following equation:

$$3,000 + \sum_{t=1}^9 \frac{3,000}{(1+r)^t} = 20,000$$

A lessee should also use the rate implicit in the lease, unless the lessee is unable to determine that rate. A lessee often is unable to determine the rate implicit in the lease, for example, because the lessee may not have access to the same information that a lessor has related to the fair value of the underlying leased asset, the lessor's residual value estimate, and the initial direct costs incurred by the lessor. In this case, the lessee should use its incremental borrowing rate. ASC 842 indicates that a lessee's incremental borrowing rate should be based on a collateralized borrowing rate using otherwise similar terms reflected in the lease arrangement (e.g., similar duration, amount, and economic environment). Thus, ASC 842 requires the incremental borrowing rate to be a secured rate. Unsecured sources of funds can no longer be considered in determining the incremental borrowing rate, as was the case under the predecessor lease accounting standards.

86.3.2.4 Fair Value of the Underlying Leased Asset

In evaluating the lease payments criterion for classification purposes, the present value of the sum of the lease payments and any residual value guaranteed by the lessee must be compared to the fair value of the underlying leased asset. Specifically, note that the lease payments criterion requires that the fair value of the underlying

¹¹ The lessor will defer initial direct costs if, at the lease commencement date, the fair value of the underlying leased asset is equal to its carrying value. In such a case, the deferred initial direct costs would be included in the determination of the rate implicit in the lease.

leased asset be used, not the fair value of the right to use the underlying leased asset for a period that is typically less than the economic life of the asset. Thus, the fair value of the leased asset should reflect the price that would be received to sell the asset in an orderly transaction on the commencement date. ASC 842-30-55-3 indicates that in some cases, it may be impracticable to determine the fair value of the underlying leased asset. If that is the case, lease classification can be determined without regard to the lease payments test.

86.3.3 Accounting and Reporting Requirements

Once the appropriate classification is determined by the lessee and lessor, the transaction can be appropriately measured and reported in their respective financial statements. This section briefly discusses the initial and subsequent accounting for a lease arrangement. This section first focuses on lessee accounting, and then turns to lessor accounting.¹² It is important to understand that the lease classification criteria do not impact a lessee's initial balance sheet recognition of the lease arrangement. However, the classification as an operating versus a finance lease will ultimately impact how the lease expense is recognized in the income statement. In contrast, the lease classification will, to some extent, impact a lessor's recognition of the lease arrangement.

86.3.3.1 Lessee

A lessee measures the lease liability on the commencement date as the present value of the *remaining* lease payments, as discussed above and defined in ASC 842-10-30-5. As noted previously, a lessee should use the rate implicit in the lease (if known) or, alternatively, its incremental borrowing rate in its determination of the present value of the remaining lease payments. Note that the lease liability does not include amounts transferred to the lessor before the commencement date, and it only includes residual value guarantees that are probable of being owed by the lessee.¹³

A lessee measures the right-of-use asset in accordance with ASC 842-20-30-5, which indicates that, at the commencement date, the cost of the right-of-use asset consists of the following:

¹²See, for example, Gordon et al. (2019, Chap. 18) and Kieso et al. (2019, Chap. 21) for detailed illustrations of the recognition and measurement of leases from the perspective of both the lessee and the lessor.

¹³As discussed previously, the calculation of lease payments for the lease payments test included in the classification criteria does not necessarily reflect the lease payments included in the lease liability at the commencement date. The lease payments test includes all payments, including payments made prior to the commencement date and a lessee's residual value guarantee, regardless of whether it is probable that the lessee will owe amounts associated with the guarantee (if any).

1. The lease liability at the commencement date
2. Amounts paid to the lessor at or before the commencement date, which are not reflected in the lease liability, net of any lease incentives received
3. The lessee's initial direct costs

Thus, the lease liability and the right-of-use asset may not be the same at the lease commencement date. Note also that ASC 842 changed the criteria for determining initial direct costs for both the lessee and the lessor. ASC 842 defines initial direct costs as incremental lease-related costs that would not have been incurred if the lease had not been obtained. Under the predecessor lease accounting guidance, these incremental costs included items arising before the lease was executed (such as legal fees) that generally are not included as initial direct costs under ASC 842. An example of an initial direct cost that would be included is lease documentation costs such as filing fees. Excluded costs would include items such as advertising, lease negotiation fees, and employee salaries. Specifically, any costs incurred that would have been incurred even if the lease arrangement ultimately failed to materialize would not be included as initial direct costs.

Following the initial measurement of the lease liability and the right-of-use asset, the lessee will make periodic lease payments while amortizing the right-of-use asset and recording interest expense associated with the lease liability. Importantly, the pattern of recognizing amortization and interest expense will differ depending on how the lessee classifies the lease – that is, as either a finance lease or an operating lease.

With a finance lease, the lessee will simply amortize the right-of-use asset on a straight-line basis, generally over the lease term.¹⁴ Interest expense related to the lease liability is determined using the effective interest method (and the same discount rate used to measure the lease liability on the commencement date). As a result, total lease expense typically declines over the course of the lease term – while amortization of the right-of-use asset is constant, interest expense declines as the periodic lease payments reduce the lease liability.

With an operating lease, the annual lease expense is recognized on a straight-line basis and is reflected as a single expense in the income statement and a single item in the operating section of the statement of cash flows. The annual lease expense impounds both interest and amortization expense. The annual lease expense is generally the sum of the total undiscounted cash flows (total lease payments plus initial direct costs minus lease incentives) divided by the lease term. Each period the lessee calculates interest expense (or the portion of the annual lease expense related to interest) using the effective interest method, similar to the approach used for a finance lease. However, the annual amortization of the right-of-use asset is now the difference between the annual lease expense and the portion of the annual lease

¹⁴Note, for example, that if the lease contains a purchase option that the lessee is reasonably certain to exercise, the right-of-use asset would be amortized over the useful life of the asset rather than the lease term.

expense related to interest for the period. As a result, amortization of the right-of-use asset will be higher at the end of the lease term when interest expense is lower. It is important to reiterate that the lessee is not reporting interest expense and amortization expense. Instead, the lessee is reporting a single lease expense that is constant each period. Included in the annual lease expense are interest and amortization. The calculation of interest is simply used to determine the annual accretion to the lease liability and the amortization of the right-of-use asset.

86.3.3.2 Lessor

The accounting rules related to the lessor were generally not impacted by the adoption of ASC 842. Similar to the lessee, a lessor follows the same fundamental criteria contained in ASC 842-10-25-2 (which were discussed in Sect. 86.3.1) when determining the appropriate classification of a lease. If any of the criteria described in ASC 842-10-25-2 are met, the lessor will classify the lease as a sales-type lease, indicating that the lease transfers control of the underlying leased asset to the lessee.

For a sales-type lease, a lessor will derecognize the underlying leased asset and record a financial receivable reflecting the lessor's net investment in the lease at the commencement date. The net investment in the lease reflects the lease receivable and the unguaranteed residual value of the underlying leased asset. The lease receivable is the present value of the remaining lease payments and the guaranteed residual value (whether guaranteed by the lessee or a third party). The unguaranteed residual value is based upon the amount the lessor expects to derive from the underlying leased asset at the end of the lease term that is not guaranteed by the lessee or any third party. As discussed before, these amounts must be discounted using the lessor's implicit rate in the lease. Initial direct costs are expensed at the commencement date unless there is no profit or loss on the lease (i.e., the fair value of the leased asset is equal to its carrying amount), in which case the lessor's initial direct costs are deferred and recognized over the lease term.

ASC 842 indicates that the selling profit or loss on a sales-type lease at the commencement date is equal to the lower of (1) the fair value of the underlying leased asset or (2) the lease receivable plus any lease payments made by the lessee before the commencement date, minus the following:

- (a) The carrying amount of the underlying leased asset net of any unguaranteed residual value related to the underlying leased asset
- (b) The lessor's deferred initial direct costs (if any)

The sales price (revenue) is generally equal to the fair value of the underlying leased asset; however, it could be lower in some circumstances, such as if there is an unguaranteed residual asset. The present value of an unguaranteed residual asset also reduces cost of goods sold so that it is below the asset's cost. Following the initial recognition of a sales-type lease, a lessor will recognize interest income on the net investment in the lease using the effective interest method while collecting lease payments from the lessee (which reduce the lessor's net investment in the lease).

If the ASC 842-10-25-2 criteria are not met, the lessor considers additional criteria described in ASC 842-10-25-3, which determines whether the lessor will classify the lease as an operating lease (like the lessee) or, alternatively, a direct financing lease. Specifically, a lessor will classify the lease as an operating lease unless both of the two following criteria are met (after failing to meet the basic criteria in ASC 842-10-25-2):

1. **Expanded lease payments test.** The present value of the sum of the lease payments and any residual value guaranteed by the lessee (that is not already part of the lease payments) and/or any residual value guaranteed by a third party unrelated to the lessor equals or exceeds substantially all of the fair value of the underlying leased asset.
2. **Collectability test.** The lease payments plus any amounts needed to satisfy a residual value guarantee are probable of being collected by the lessor.

A key feature of the above criteria is that the lessor now includes third-party residual value guarantees in the lease payments test. If the lease payments test is met following the inclusion of third-party residual value guarantees, and payments are probable of being collected, then the lessor will classify the lease as a direct financing lease. Otherwise, the lessor will use the operating lease classification, similar to the lessee.

The accounting for direct financing leases and operating leases is different. At initial recognition for a direct financing lease, a lessor recognizes its net investment in the lease and derecognizes the underlying leased asset, similar to the initial recognition of a sales-type lease. However, unlike a sales-type lease, the lessor of a direct financing lease will include any selling profit and initial direct costs in the net investment in the lease to be recognized over time.¹⁵ To be consistent with the FASB's revenue guidance, ASC 842 precludes the recognition of selling profit at lease commencement for a direct financing lease because the lease does not transfer control of the underlying leased asset. Instead, selling profit is recognized as interest income over the lease term, consistent with the notion that a direct financing lease effectively converts the lessor's risk related to the underlying leased asset into credit risk. Note that a critical difference between a sales-type lease and a direct financing lease is not the amount of income recognized on the net investment in the lease, but rather the timing of income recognition. Another, perhaps less substantial, difference is the timing of the recognition of initial direct costs.

Finally, with an operating lease, the lessor's asset related to the lease remains on the lessor's balance sheet and will be depreciated by the lessor while the lessor recognizes rent revenue associated with the lease. No lease-related asset or liability will be recognized at lease commencement.

In general, a lessee and lessor should arrive at the same conclusion with respect to lease classification outcomes. For example, if a lessee determines that a lease is

¹⁵ A selling loss at the commencement date would be recognized immediately.

appropriately classified as a finance lease, the lessor should generally conclude that the lease is a sales-type lease. However, because of differences in inputs used in determining the classification of a lease, the lessee and lessor could arrive at different conclusions. For example, the lessor may use the rate implicit in the lease while the lessee uses its incremental borrowing rate (see Sect. 86.3.2.3), or the lessee and lessor may arrive at different conclusions with respect to the likelihood of a renewal option being exercised. In addition, a lessee and lessor may not both classify a lease as an operating lease because a lessor will also consider arrangements unrelated to the lessee, such as a residual value guarantee obtained from a third party.

86.3.4 Further Discussion of Lease Arrangements

There are various general forms that a lease arrangement can take. We can think of these general lease forms as (1) direct leases, (2) leveraged leases, and (3) sale and leasebacks. So far, we have generally assumed that a lease is a direct lease, whereby the lessee obtains the right to control the use of a lessor's identified asset for a specified period of time in exchange for consideration paid to the lessor. This relatively simple arrangement may not always be the case.

For example, one type of lease arrangement that was once commonly used is a leveraged lease, as determined by the criteria contained in the predecessor leasing standard – specifically, ASC 840-10-25-43(c). The leveraged lease classification applied only to lessors – the lessee would continue to classify the lease as either an operating lease or a finance lease (previously referred to as a capital lease). From the lessor's perspective, leveraged leases are direct financing leases that involve a lessee, a lessor, and a long-term creditor. ASC 840 required that the financing provided by the long-term creditor (for the lessor to acquire the asset) be nonrecourse as to the general credit of the lessor (although the creditor could have recourse to the specific property leased and the unremitted rentals relating to it). The amount of financing needed to be sufficient to provide the lessor with substantial leverage in the transaction. Such leases were typically desirable for the tax benefits obtained by the lessor (as long as the lessor had a sufficient equity stake in the asset) that typically also reduced the cost of the lease to the lessee. However, tax law changes reduced the desirability of leveraged leases such that few such transactions have been entered into in recent years. In addition, ASC 842 no longer contains guidance for leveraged leases and, thus, does not permit new leases to be accounted for as leveraged leases.

Finally, an arrangement that is frequently used today is known as a sale and leaseback. In a sale and leaseback arrangement, a company (the seller-lessee) sells an asset that it owns to a second party (the buyer-lessor), and the two parties then enter into a lease in which the seller-lessee leases back the asset from the buyer-lessor for some or all of the asset's remaining economic life. The buyer-lessor retains title to the asset and all other benefits of ownership, such as tax credits and depreciation allowance. The seller-lessee receives funds from the sale of the asset along with the right to use the asset and, in exchange, makes periodic lease payments to the buyer-lessor.

Although sale and leaseback accounting applied only to lessees under ASC 840, both lessees and lessors must apply sale and leaseback accounting under ASC 842. In order to qualify for sale and leaseback accounting, first, the transaction has to qualify as a sale in accordance with the FASB's revenue accounting standard. If the transaction qualifies as a sale, then the seller-lessee and buyer-lessor will separately account for the sale (in accordance with the revenue standard) and the leaseback (in accordance with the leasing standard). If the transaction qualifies as a sale, but the seller-lessee classifies the lease as a finance lease and the buyer-lessor classifies the lease as a sales-type lease, the arrangement would be considered a "failed" sale and leaseback. Control of the asset is effectively transferred from the seller-lessee to the buyer-lessor and then back to the seller-lessee. As a result, the guidance in ASC 842-40-25-5 requires a failed sale and leaseback to be accounted for as a financing event by the seller-lessee and as a lending event by the buyer-lessor.

86.3.5 Important Differences between US GAAP and IFRS

While the lease accounting rules developed as part of the joint project between the FASB and International Accounting Standards Board (IASB) have many similarities, the boards came to different conclusions in some aspects. One of the most substantial differences is the fact that the FASB retained its dual model for lessees (operating leases versus finance leases) while the IASB chose to require that lessees apply a single model to all leases. Under the new IFRS standards for leases (i.e., IFRS 16, *Leases*), the lessee does not differentiate between operating leases and finance leases (IASB 2016). Instead, under IFRS 16, lessees treat all leases similar to how a finance lease would be treated for US GAAP purposes. As a result of the dual vs. single model, differences arise not only in terms of lease classification but also in the resulting income statement and statement of cash flow effects due to the fact that, for lessee operating leases under US GAAP, only a single lease expense amount is recognized (on a straight-line basis) with the cash outflow reported as an operating activity in the statement of cash flows.

Although lessees use a single lease model under IFRS, IFRS 16 does contain the lease classification criteria included in ASC 842. However, for IFRS purposes, the lease classification criteria are intended solely for the lessor. Some relatively minor differences exist for lessor accounting. Under US GAAP and IFRS, a lessor may recognize profit on a sales-type lease. However, under IFRS, a lessor can also recognize profit on a direct financing lease if the performance obligations have been met (this is not permitted under US GAAP, as discussed in the section that discusses [lessor](#) accounting).

Like the new US GAAP standards, IFRS also maintains an exemption for reporting leases on the balance sheet if the lease term is less than 12 months in duration. Additionally, under the new IFRS standards, a lessee may elect to treat leased assets with a value of less than \$5,000 as rental agreements. For example, if a

lessee leased a car with a value of \$3,000 and a useful life of 2 years, the lessee does not have to recognize a lease asset or a lease liability on its balance sheet.

86.3.6 Impact of New Leasing Accounting Guidance

As discussed above, ASC 842 was issued in 2016 and effective for publicly traded companies during a company's first fiscal period beginning after December 15, 2018. This means that most companies first implemented the new leasing guidance for their fiscal years beginning on January 1, 2019. As such, researchers have only just begun to explore the effects of the new lease accounting guidance.

The new leasing standards are expected to bring a greater degree of transparency to financial statements than previously available and are expected to significantly impact financial statements and important financial ratios for many companies. For instance, the updated guidance under both US and international accounting standards should enable analysts and investors to compare the credit capacity and leverage metrics of companies with different financing practices much more readily and consistently by eliminating the off-balance-sheet treatment of operating leases. This will impact reported leverage for many companies, as recognizing an asset and liability from leases will cause leverage metrics to increase. The recognition of amounts related to operating leases that were once only disclosed in the notes to the financial statements could impact how investors and lenders perceive the company.

Many questions remain unanswered since the FASB's and IASB's leasing standards became effective. Do the new lease accounting requirements provide decision-useful information to investors and creditors? Have the new leasing standards impacted the comparability of financial information? Have the new leasing standards impacted companies' operating and financing decisions? Has the use or structuring of leases changed as a result of the new guidance? What are the consequences of the FASB's dual classification approach in comparison to the IASB's single model approach? In sum, it remains to be determined whether the standard setters' objectives of increasing the amount of lease-related decision-useful information reported by lessees and lessors have been met, as well as whether there have been any unintended consequences associated with the adoption of ASC 842 and IFRS 16.

86.4 Conclusion

Capital investment decisions are among the most critical decisions made by corporate managers. When confronted with the decision to make capital investments, managers must identify a viable source of financing. Theory suggests that under certain conditions, the lease-versus-buy decision should be irrelevant to a company. However, prior research has explored and provided evidence of the factors contributing to the widespread use of leases.

This chapter focuses on companies' use of leases as a financing mechanism to facilitate capital investments. We discuss the nature and use of leases, as well as the economic theory rationalizing the existence and implementation of lease arrangements. We then turn our attention to recent changes to US and international accounting standards that have ended several decades of off-balance-sheet reporting for many lease transactions. We discuss how the recent changes in accounting and financial reporting requirements have potentially shifted the expected costs and benefits of some lease arrangements. We then conclude by highlighting the need for researchers to study the impact of the new lease accounting standards that have recently been adopted in countries around the globe.

Pension Accounting, Inside Debt, and Capital Structure

87

Cheng-Few Lee and James Juichia Lin

Abstract

This study aims to examine how pension accounting relates to inside debt and capital structure. We introduce basic concepts of pension plans and pension accounting (including the determinants of pension liabilities, assets, and pension expense reported in financial statement) in accordance with U.S. GAAP (FAS 158) and IFRS (IAS 19). We also provide a review of empirical research on the pension accounting associated with earnings management and firm value. Finally, following Alderson and Lee (J Econ Bus, 40:209–228, 1988), this chapter introduces a developed model in which individuals and corporations have an incentive to engage in pension plans to deals with corporate pension funding policy as part of the capital structure decision.

87.1 Introduction

Defined benefit (DB) and defined contribution (DC) plans are the two most common types of pension plans. In a DB plan, the employer guarantees to pay the employee a specific level of benefits for life upon the employee's retirement; whereas in a DC plan (including Individual Retirement Accounts (IRAs) and 401 (k) plans), the employer makes a fixed sum of contribution every year to an employee's account but does not guarantee the payout upon the employee's retirement. That is, only the employer's contribution is guaranteed under a DC plan but not the future benefit payouts. In the USA, the maximum annual retirement benefit allowed under a DB plan is \$195,000 whereas the maximum contribution allowed under a DC plan is \$49,000 in 2010 (Calhoun 2010). At an aggregate level, DC plans are cheaper and involve lower risk for sponsoring firms than DB plans. According to a study by PricewaterhouseCoopers (2005), defined benefit plans cost about 5–6% of payroll while defined contribution plans cost only about 3%. Thus, all these studies suggest that DB plans are more costly to the sponsoring firms (Choy et al. 2014).

In addition to the difference in costs, these two types of plans impose different levels of risk on the sponsors. Since sponsoring firms guarantee the payout of a specific number of benefits for the life of their employees upon their retirement under DB plans, firms with DB plans have to bear various uncertainties and risks associated with the future payouts, such as the market and longevity risks (Munnell et al. 2007; Lin and Werner 2021). DB firms face such risks as fluctuations in the assumption regarding the longevity of employees, interest rate, inflation, and rate of investment return. Any change in these factors can have a significant effect on the required payout or the funds available for distribution, and enhance the contribution required in the current period to meet these expected future payouts.

This study aims to examine how pension accounting relates to inside debt and capital structure. The remainder of this chapter is organized as follows. The next section describes pension plan freeze and termination. Section 87.3 discusses the effects of ERISA and PBGC on Pension Management. Section 87.4 presents accounting for defined pension plans under FAS 158 and IAS 19. Sections 87.5 and 87.6 provide a review of empirical research on the pension accounting associated with earnings management and firm value. Section 87.7 introduces a developed model in which individuals and corporations have an incentive to engage in pension plans to deals with corporate pension funding policy as part of the capital structure decision.

87.2 Pension Plan Freeze and Termination

Traditionally, the occupational pension system was designed and dominated by the DB plans while DC plans were only offered by small firms or as supplementary plans. However, there has been a steady increase in the adoption of DC plans since

1975, the year following the passage of the Employee Retirement Income Security Act (ERISA).¹ In the last two decades, a shift in pension coverage from defined benefit (DB) plans to defined contribution (DC) plans has been underway in the United States and UK (Munnell et al. 2007). According to the 2008 Private Pension Plan Bulletin report, based on the information collected from US firms' Form 5500 filings with the U.S. Department of Labor, the number of DB pension plans decreases by 42.3%, from 20,035 in 1975 to 11,557 in 2005. On the contrary, the number of DC plans multiplies by about 7.8-times from 8,587 in 1975 to 67,678 in 2005.²

During the 1980s and early 1990s, DB pension freeze or termination is limited mostly to firms facing bankruptcy or engaged in merger and acquisition activities (Choy et al. 2014). However, the shift in pension coverage from DB to DC plans has gained popularity among large healthy firms since the early 2000s (Munnell et al. 2007). Watson Wyatt (2010) documents an increase in DB plan freezes among Fortune 100 firms. The number of DB plan freezes rose from 45 in 2004 to 113 in 2006. McFarland et al. (2009) observe 82 US public companies that froze their DB plans in the period 2003–2007. Some firms that froze their plans during the period include Motorola Inc. that froze its pension plan to new employees in 2004; Lockheed Martin, Hewlett-Packard, and Sears Holdings followed suit and froze their DB plan in 2005. In 2006, Coca-Cola Bottling and IBM both decide to impose a total freeze on their DB plans in 2006 (Munnell et al. 2007). These large healthy companies either offer a 401-K plan or improve their existing 401-K plans after the freeze.

87.3 Effects of ERISA and PBGC on Pension Management

Employee Retirement Income Security Act (ERISA) of 1974 improves the protection of retirement benefits for private-sector employees. Two provisions of ERISA affect the firm's decision to terminate the plan or to exercise the pension plan put option. The first provision establishes a rule for determining the minimum benefit level to which employees are entitled. When a pension plan is underfunded, the put option has a positive value. The employee will receive the smaller of the guaranteed vested benefits or the fund's value. A second ERISA provision establishes pension plan termination insurance under the Pension Benefit Guaranty Corporation (PBGC). Assuming a pension fund's value is so low on termination that an addition of 30% of the firm's equity and the guaranteed pension liabilities. This limits the maximum exposure of the firm to 30% of its equity for meeting underfunded pension

¹Source: U.S. Development of Labor Employee Benefits Security Administration, Private Pension Plan Bulletin, February 2008.

²Only pension plans with 100 or more participants are included in the statistics. The statistics include single employer plans, plans of controlled groups of corporations, and multiple-employer non-collectively bargained plans.

Fig. 1 Net liability of firm in pension plan (NLFPP)

liabilities. In exchange for this protection, the value pays a fixed premium based on a per-employee rate.

The effects of the PBGC and the pension fund assets on firm value are shown in Fig. 1. When the value of the pension plan's assets (A) exceeds the accrued liabilities (L), the retirees will receive all of their benefits and the firm has the right to $(A-L)$, or the amount of overfunding of the pension plan. If the value of the plan's asset (A) equals the accrued benefits (L), or $(A-L)$ equals 0, the retirees will receive their guaranteed benefits and the firm has no interest in the pension fund. If $(A-G)$ is less than 0, where G is the level of guaranteed benefits, the firm must make up the difference so that the retirees receive their guaranteed benefits, but only up to assumed 30% of the firm's net worth (NW). The additional funding to meet the shortfall will come from the PBGC when $G > A + 0.3NW$.

87.4 Accounting for Pension Plans Under FAS 158 and IAS 19

Following fair-value pension accounting, U.S. GAAP (FAS 158) and IFRS (IAS 19) recognize the difference between pension asset and pension liability (defined benefit obligation, DBO) as net pension asset or on liability referred to as funded status reported in the statement of financial position. Pension assets are employer contributions and the actual return on plan assets at fair value which increase pension plan assets. Employer's defined pension obligation (DBO or PBO) is the present value of the deferred compensation obligation for vested and non-vested employees at future salaries level under the terms of the pension plan. Actuarial assumptions (i.e., discount rate, salary growth rate, and longevity) are responsible for determining the pension obligation.

Following FAS 158 or IAS 19, all changes in the defined benefit obligation and plan assets in the current period be recognized in comprehensive income (including net income and other comprehensive income). The following items account for the

changes in the defined benefit obligation (Kieso, et al. 2020). (1) service cost: referred to as the increase in DBO from employee service in the current period. (2) past service cost: referred to the change in the DBO resulting from a plan amendment. (3) accrued interest expense based on the yields of high-quality bonds. (4) benefits paid to retired employees (beneficiary). (5) gains or losses related to the DBO reported in the section of other comprehensive income, net of tax. The items that account for the change in pension assets are as follows. (1) employer contributions to plan assets. (2) actual return on the plan assets. (3) benefits paid to retired employees (beneficiary). Pension expense reported in the income statement consists of the service cost and net interest expense. Net interest expense is the difference between the accrued interest expense from PBO and the expected rate of return on pension assets. The difference between the actual return and the expected return is recognized as other comprehensive income³.

87.5 Pension Assumptions and Earning Management

Pension accounting which deals with recognition and valuation of pension-related liabilities, assets, and expense, has been developed for decades but debates on its flexible discretion and information content still remain. If firms intentionally obscure the economic status of DB plans by using pension accounting measurement and recognition guidance to manage the financial statements, inaccurate valuations may result (Hsieh et al. 2021). According to the Statement of Financial Accounting Standards 158, hereafter SFAS 158, the actuarial parameters used to compute projected benefit obligations (such as assumed discount rate) and the periodic pension costs should reflect the rate at which the pension benefits could be effectively settled. Although the standard requires the best estimates, it does allow certain discretion in setting these actuarial pension assumptions. For example, in setting the discount rate, the plan manager could refer to the rates of return on high-quality fixed-income investments with the same maturity as the pension obligation, either currently available or expected to be available in the future. This practice provides management with the discretion to choose a desirable discount rate. Further, relatively small changes in assumed pension rates can have a significant impact on corporate pension value, reported earnings, and firm value (Glaum 2009).² Regulators have also expressed some concern about this issue. The U.S. Securities and Exchange Commission (SEC) has instituted a review process for certain filings with expected rates of return on pension plan assets in excess of 9% (Dale 2003). In

³The major differences between FAS 158 and IAS 19 are as follows. (1) FAS 158 amortizes PSC over the remaining service lives of employees, while IAS 19 recognizes past service cost as a component of pension expense in income immediately. (2) FAS 158 recognizes liability and asset gains and losses in “Accumulated other comprehensive income” and amortizes these amounts to income over remaining service lives. Under IAS 19, companies recognize both liability and asset gains and losses (referred to as re-measurements) in other comprehensive income. (Kieso et al. 2020)

addition, by SEC mandate, the Financial Accounting Standards Board (FASB) incorporated an overhaul of pension accounting that was carried out jointly with the International Accounting Standards Board (IASB).³

In addition to the discount rate, the management can also exercise discretion in choosing the expected salary growth rate and the expected rate of return on plan assets. The expected salary growth rate is used to estimate the future pay level of the plan's active participants, which in turn affects the sponsor's pension obligation. The expected rate of return (ERR) on the pension assets' assumption captures the expected future cash inflow from pension assets. A higher ERR leads to a lower sponsor's current obligation. As ERR is typically determined by managers at the beginning of the fiscal year, the manager evaluates the current plan conditions and the asset plan operating prospects for the current year (Picconi 2006). By altering the pension plan assumptions, the sponsor's management can influence its obligations and the required contribution to the plan (Hsu et al. 2013; Lin and Werner 2021).

The potential impact of DB plan reporting improprieties on company valuations by the capital markets evokes the consideration of factors that might influence managers to intentionally manipulate pension assumptions under pension accounting guidance as a means to manage overall accounting reports. Much of the evidence in this regard reveals that pension accounting assumptions are highly correlated with the achievement of specific pension-related goals as well as larger business activity-related objectives. For instance, Gopalakrishnan and Sugrue (1995) find that leverage and pension plan funding play important roles in the choice of these assumptions, while Godwin et al. (1996) find that managers are likely to increase the interest rate assumption in response to declines in earnings, increasingly restrictive dividend constraints, and tightening debt covenants. Bergstresser et al. (2006) document that managers are more aggressive with the estimated ERR in pension obligation computation before undertaking acquisitions when their earnings are near critical thresholds, and before they exercise stock options. They, however, lower the expected rate assumption to reduce income before CEO option grants. Further, Comprix and Muller (2006) find that managers strategically increase the ERR estimation to boost pension income before the CEO's open market stock sales. Comprix and Muller (2011) suggest that employers bias their accounting assumptions downward to exaggerate their pension burden when they want to freeze their pension plans. Amir and Gordon (1996) find that when a firm is close to violating the debt covenant, the management selects a discount rate, and those health care cost assumptions that understate the post-retirement benefit obligations.

87.6 Pension Accounting Information and Value Relevance

Value relevance studies, also called association studies, are one way of examining whether financial statement information is decisional useful by the explained proportion of variation in stock prices. Landsman (1986) makes the first study to examine the value relevance of pension information. He concludes that pension information which has been disclosed under FAS 36 at the time is value relevant.

Landsman and Ohlson (1990) examine the extent to which stock price fully reflects the off-balance-sheet pension item (net pension liability). They document that the market underprices pension disclosures. Barth et al. (1993) find that the fair value of pension asset and PBO disclosed in the pension note under SFAS 87 are associated with stock price. Coronado and Sharpe (2003) follow a similar research design and show that market tends to pay more attention to the recognized pension information in balance sheet and income statement than to disclosed information. Davis-Friday et al. (1999) also document that recognized post-retirement benefits other than pension liabilities receive greater weight than when those same items are disclosed only. Wiedman and Wier (2004) evidence that investors view under-funded pension plans as liabilities to the sponsoring firm, but do not view over-funded plans as assets to the firm. In addition, Picconi (2006) examines the ability of investors and analysts to fully assimilate available pension information. He finds that neither prices nor forecasts fully reflect the quantifiable future earnings effects of changes in pension information at the time it is released in the firm's 10-K report. Franzoni and Martin (2006) argue that the market significantly overvalues firms with severely underfunded pension plans. The evidence shows that those firms continue to earn lower stock returns than firms with healthier pension plans for at least 5 years after the first emergence of the underfunding. Besides, Hann et al. (2007a) find that the discretionary component of PBO is incrementally value-relevant beyond the non-discretionary component ones.

Accordingly, the examinations and comparisons of value relevance under different accounting standards are also documented in the literature. Coronado et al. (2008) argue that more pertinent information on pension finance is relegated to footnotes, which may not receive much attention from investors and portfolio managers. They suggest that the FASB's reform efforts on pension accounting standards should substantially aid the market's ability to value firms with defined benefit pensions. On the contrary, Hann et al. (2007b) compare the value and credit relevance of financial statements under fair-value and smoothing (U.S.'s SFAS 87) models of pension accounting. The result shows that there are no informational benefits of adopting fair-value pension accounting model.

87.7 Pension Plans and Capital Structure Decisions⁴

Inside debts (e.g., pension and other deferred compensation plans) resemble risky corporate debts in that their values are sensitive to both credit risk and liquidation value of corporate assets in bankruptcy (Sundaram and Yermack 2007). Extant literature widely documents that inside debts motivate executives to lower firm risk in order to alleviate creditors' concern over risk-shifting and asset substitution

⁴The following section is original discussed in the paper titled "Corporate Pension Policy and Capital Structure Decisions" published in *Journal of Economics and Business* by Alderson, M. J. and Lee, C. F. (1988).

problems (e.g., Wei and Yermack 2011; Cassell et al. 2012; Wang and Zhang 2014; Chi et al. 2017; Colonnello et al. 2017; Freund et al. 2018). In recent studies, Borah et al. (2020) and Lee et al. (2021) find that firms paying their CEOs with large inside debt leads to reductions in firms' cost of debt, default risk, systematic risk, and idiosyncratic risk.

Following Amott and Gersovitz (1980), this section deals with corporate pension funding policy as part of the capital structure decision. A model is developed in which individuals and corporations have an incentive to engage in contracts for the deferral of wage income in the form of an unfunded pension.

The model assumes that there are two mutually exclusive and exhaustive groups in the economy: capitalists and labor. Capitalists initiate the firm formation and maintain nonneutral investment positions, while labor holds a monopoly on the sale of specialized services. Both groups operate in a one-period, two-date framework. At the beginning of the period (time 0), firms negotiate an agreement with labor, calling for the payment of $\$w$ immediately, in exchange for services to be rendered over the course of the period. Simultaneously, firms issue a series of claims on their state-dependent (end-of-period) operating earnings.

The opportunity to defer wage income from time 0 to time 1 is available. The pension contract is structured such that employees receive their cash wage ($\$w$) at the beginning of the period and immediately return a portion of that wage to the firm in exchange for an unfunded, vested pension claim. From an economic standpoint, the wage deferral arrangement makes the employee a creditor of his/her firm. That relationship serves as the foundation for the integration of corporate pension policy with the capital structure decision.

Both firms and labor are motivated to engage in a pension contract for several reasons. Employees benefit from the deferral of current income, especially if their present marginal tax rate exceeds the rate at which they expect to pay in retirement. Payroll taxes (i.e., FICA) are also a significant source of tax saving because they are levied on current wages and not on pension income. Defined-benefit pension plans also provide nontax advantages to labor by enforcing the discipline to save for retirement and shielding the employee from the investment risk to his/her retirement saving.

The employer firm also recognizes several advantages to the deferral of wage income. One advantage derives from giving labor a stake in the profitability of the firm. Ippolito (1985) has developed a model in which pension contracts reduce the incentive of labor to exploit its monopoly in specialized skills in the short run, at the expense of the long-run survival of the firm. By making employees creditors of the firm, a congruence of goals between capitalists and labor is established. In a separate vein, firms that sponsor defined-benefit pension plans also realize tax advantages. Employer contributions to the pension fund are tax-deductible and are exempt from payroll taxes. Finally, borrowing from employees may be a more flexible source of financing than selling bonds.

The model incorporates the heterogeneous nature of the federal personal income tax. Let $t(pd, i)$ and $t(pe, i)$ represent the constant marginal tax rates on debt and equity income for individual i . The opportunity to defer the recognition of capital

gains indefinitely causes the tax rate on debt income to exceed the effective rate on equity income, implying that $t(pd, i) > t(pe, i)$. That relationship creates a personal tax bias against debt income which will ultimately influence the equilibrium pension benefit.

The corporate tax rate is a constant $t(c)$. Marginal tax rates on investment income are assumed to be progressive in nature, with at least one investor in each of the following mutually exclusive and exhaustive tax brackets:

Bracket 1 $(1 - t(pd, i)) > (1 - t(c))(1 - t(pe, i))$

Bracket 2 $(1 - t(pd, i)) = (1 - t(c))(1 - t(pe, i))$

Bracket 3 $(1 - t(pd, i)) < (1 - t(c))(1 - t(pe, i))$

At the end of the one-period time frame, corporations are assumed to receive state dependent operating earnings of $X(s)$ in state s ; $X(s)$ is monotonically increasing in s with $0 < X(S1) < X(S5)$. The face value of debt (B), certain noncash charges (D) such as depreciation and depletion, and pension contributions (VP) are excludable from taxable income. Firm specific tax credits of G dollars exist, but consistent with the tax code only $\theta\%$ of a firm's tax liability can be offset by these credits.

87.7.1 Aggregate Pension Demand and Differential Taxation

This section explains the characteristics of the demand for pension income in the model. That demand is determined in the market for the nonrecourse debt securities that are collateralized by pension income. The model mirrors the fundamental structure of the market for corporate debt and equity claims developed by Miller (1977) and DeAngelo and Masulis (1980).

To begin, recall that $t(pd, i)$ and $t(pe, i)$ represent the constant marginal personal tax rates on pension collateralized debt and equity income, respectively, for the i th individual. The opportunity to defer the recognition of capital gains introduces a bias into the tax code, so that $t(pd, i) > t(pe, i) > 0$ for all i . That implies that the state-contingent personal after-tax cash flow per unit of state s equity income exceeds that per unit of state s debt income, so that $(1 - t(pe, i)) > (1 - t(pd, i))$ for all individuals.

Let $P(d, s)$ equal the current time ($t = 0$) price in the market of \$1 of pretax state s income from an investment in pension collateralized debt. The term $P(e, s)$ represents the current time market price of \$1 of pretax state s income from an equity investment. Their reciprocals, $1/P(d, s)$ and $1/P(e, s)$, are pretax current yields; $(1 - t(pd, i))/P(d, s)$ and $(1 - t(pe, i))/P(e, s)$ are accordingly the after-tax yields to the i th individual. Utility maximizing investors will adjust their portfolio holdings of states claims in order to maximize these after-tax yields. In making their portfolio selection, investors will prefer pension collateralized debt to equity if $(1 - t(pd, i))/P(d, s) > (1 - t(pe, i))/P(e, s)$; equity will be preferred to debt if the inequality is reversed; finally, the individual will be indifferent between the two when after-tax yields are equal.

Individual members of the labor pool function as intermediaries in the pension contracting process. Let $g(t(w, i))$ represent the value of deferring \$1 of income from time 0 to time 1, for the i th individual with a time 0 marginal wage tax rate of $t(w, i)$. The schedule of marginal tax rates on wage earnings ($w(i)$) is progressive, such that $t(w, i)$ increases with $w(i)$. Define r to be the opportunity cost of funds. The value of deferring the tax on \$1 of wage income is $g(t(w, i)) = t(w, i) * (r/(1 + r))$. The function $g(t(w, i))$ is nonnegative, and is monotonically increasing in $t(w, i)$.

The intermediation process operates in the following way. Individuals are willing to exchange $\$1/(1 + r)$ of time 0 wage income for \$1 of pension income at the end of the period. As members of the labor group, however, they desire to neutralize the financial holding (i.e., pension obligation) created by that exchange. To accomplish this, each individual must pay a certification premium of $\$c$ to establish credentials in the capital market. Once certified, any individual may sell a personal debt claim (collateralized by the pension benefit) on a nonrecourse basis. The sale of debt by the employee offsets the holding of the pension claim, leaving him/her with a (desired) zero net investment position.

The cross-sectionally constant corporate tax rate is represented by $t(c)$. It is assumed that progressive personal tax rates are such that at least one investor is in each of the following mutually exclusive and exhaustive tax brackets:

Debt Preferring $(1 - t(pd, i)) > (1 - t(c))(1 - t(pe, i))$

Debt Indifferent $(1 - t(pd, i)) = (1 - t(c))(1 - t(pe, i))$

Debt Adverse $(1 - t(pd, i)) < (1 - t(c))(1 - t(pe, i))$

Investors are risk neutral and homogeneous in their belief that each state will occur with probability $p(s)$. In the course of constructing a portfolio, every investor will select the security of his/her tax preference (pension collateralized debt or equity) with the highest expected yield. Given that all claims must be held in equilibrium, it follows that the markets must set prices for their state contingent claims so that pretax expected yields are equal. If $P(d)$ and $P(e)$ are the current market prices of the pretax cash flows from debt and equity, respectively, this implies that $1/P(d) = p(s)/P(d, s) = p(s)/P(e, s) = 1/P(e)$ for all s . Applying the results of DeAngelo and Masulis (1980), it is possible to examine both (1) the pension collateralized debt and equity demand decisions of individuals, and (2) the pension and equity supply decisions of firms by examining only two markets: the one for pretax cash flows to equity (with current price $P(e)$) and the one for pretax cash flows to pension collateralized debt (with current price $P(d)$). Let the superscript u denote investors who are indifferent between investing in debt or equity. Exactly which investors are marginal in this sense is established by the market prices $P(d)$ and $P(e)$, when they equate the pretax personal yields of pension collateralized debt and equity for certain groups of investors. This occurs when, for individual u :

$$p(s)(1 - t(pd, u))/P(d, s) = (1 - t(pd, u))/P(d) = (1 - t(pe, u))/P(e) = p(s)(1 - t(pe, u))/P(e, s).$$

Equivalence of personal after-tax yield causes individuals to be indifferent between investing their next dollar of capital in pension collateralized debt or equity.

87.7.2 Firm Valuation

This section describes the one-period state preference valuation model that will be used in the subsequent discussion of optimal corporate pension policy. The model is an adaptation of the theoretical work of DeAngelo and Masulis (1980). It is from this valuation model that the supply function for pension income emerges.

Let $X(s)$ represent cash operating earnings before pension expenditures. This variable is monotonically increasing in s , with $X(S1) < X(s) < X(S5) < \infty$. From $X(s)$, certain noncash charges (D), the interest expense on bonds (B), and vested pension benefits (VP) are deducted to arrive at corporate taxable income. Firms pay a tax of $t(c)$ on taxable earnings. They can offset their liability with any tax credits (G) which they possess, subject to the limitation that the offset does not exceed $\theta\%$ of the total liability. The firm-specific variables B , VP , D , and G define the subintervals over the $[S1, S5]$ range that describe the potential pretax dollar returns which the holders of pension collateralized debt and equity face. Table 1 describes those returns, which will be referred to as $VP(s)$ and $E(s)$, respectively.

In the first interval, $[S1, S2]$, the operating stream is sufficient to compensate regular bondholders but is insufficient or just sufficient to pay pension benefits. The pension beneficiaries will receive from zero to VP dollars, while the holders of the nonrecourse debt sold on those claims will receive the after-tax proceeds to the beneficiaries. The firm will pay no taxes, thereby wasting all deductions and credits.

When $(X(s) - B) < X(s) < (B + VP + D)$, then $s \in [S2, S3]$. In this interval, both bondholders and retirees are paid in full. No corporate taxes are paid, however, as earnings fail to exceed total tax deductions. Excess deductions and all tax credits are consequently unutilized. When $(VP + B + D) < X(s) < (VP + B + D) + G/\theta t(c)$, $s \in [S3, S4]$. This interval is similar to the prior one, except that the firm now has earnings that exceed all available deductions, resulting in a tax liability that can be partially offset by available tax credits. The limitation on the offset exists because the total credits available exceed the maximum percentage of the gross liability allowed by law. Thus, all deductions and a fraction of available credits are utilized. In the final interval, when $s \in [S4, S5]$, the returns to both parties reflect the full utilization of all tax deductions and tax credits by the firm.

The optimal deferred wage occurs when the current time firm value is maximized, that is when the market value (V) of the claims of labor (VP) and equity (E) are greatest in total. VP and E are valued by discounting their cash flows in every state nature by the appropriate state-contingent unit price, $P(d, s)$ and $P(e, s)$, respectively. Thus,

Table 1 State Contingent Dollar Returns

State	$VP(s)$	$E(s)$
$S1-S2$	$X(s) - B$	0
$S2-S3$	VP	$X(s) - B - BP$
$S3-S4$	VP	$S(s) - B - VP - (1 - \theta)t(c)[X(s) - B - VP - D]$
$S4-S5$	VP	$S(s) - B - VP - t(c)[X(s) - B - VP - D] + G$

$$\begin{aligned}
V &= VP + EV = \int_{S1}^{S2} VP(s)P(d, s)ds + \int_{S1}^{S5} E(s)P(e, s)ds \\
&= \int_{S1}^{S2} [X(s) - B]P(d, s)ds + \int_{S2}^{S5} [VP]P(d, s)ds \\
&\quad + \int_{S2}^{S3} [X(s) - B - VP]P(e, s)ds \\
&\quad + \int_{S3}^{S4} [(X(s) - B - VP) - (1 - \theta)t(c)(X(s) - VP - B - D)]P(e, s)ds \\
&\quad + \int_{S4}^{S5} [X(s) - B - VP - t(c)((X(s) - B - VP - D) + G)]P(e, s)ds \quad (1)
\end{aligned}$$

The objective of the firm is to select the VP^* value that maximizes V . The appropriate first-order condition is:

$$\begin{aligned}
\partial V / \partial VP &= \int_{S2}^{S3} [P(d, s) - P(e, s)]ds \\
&\quad + \int_{S3}^{S4} [P(d, s) - P(e, s)(1 - (1 - \theta)t(c))]ds \\
&\quad + \int_{S4}^{S5} [P(d, s) - P(e, s)(1 - t(c))]ds \quad (2)
\end{aligned}$$

Equation (2) shows that the level of unfunded pension liabilities which a firm possesses is relevant to valuation because $\partial V / \partial VP$ is not equal to zero for all pension policies if D , B , and/or G are positive. That implies that some values of VP are strictly preferred to others.

Under the assumption that investors are risk-neutral and have homogeneous beliefs, Eq. (2) reduces to

$$\begin{aligned}
\partial V / \partial VP &= [P(d) - P(e)] \int_{S2}^{S3} P(s)ds \\
&\quad + [P(d) - (1 - (1 - \theta)t(c))P(e)] \int_{S3}^{S4} P(s)ds \\
&\quad + [P(d) - (1 - t(c))P(e)] \int_{S4}^{S5} P(s)ds \quad (3)
\end{aligned}$$

In the aggregate, Eq. (3) represents the present value of the expected corporate after-tax cash flow that results at the margin when unfunded pension liabilities are substituted for equity in the firm's financial structure. Further, this marginal present value contains three distinct components whose magnitudes depend on the degree to

which the marginal pension deduction is utilized. The first term, $P(d) - P(e)(1 - t(c))$, is the present value of the unfunded pension for equity substitution when the marginal corporate tax deduction resulting from the increased pension liability is fully utilized. The corresponding integral represents the probability of full utilization of the marginal pension deduction. The second term $P(d) - P(e)(1 - (1 - \theta)t(c))$, is a lower present value due to the partial loss of the corporate tax shield caused by the statutory 0 ceiling on usable tax credits. The corresponding integral is the probability of the partial loss of the marginal pension deduction due to the 0 ceiling. Finally, the third term, $P(d) - P(e)$, represents the present value of the unfunded liability substitution when available deductions already exceed total earnings. The third integral is the probability of the total loss of the deduction for the marginal pension.

87.7.3 Equilibrium with No Tax Shield Risk

To show the contribution of this model to the body of pension theory, this section will adapt the DeAngelo and Masulis market equilibrium in a way that allows for the derivation of analytic results similar to those obtained by Sharpe (1976). When there are no tax shields other than the pension contribution, the partial or total loss of the marginal tax benefits of sponsoring a plan is impossible. If $D = B = G = 0$, then $S2 = S3 = S4$, and Eq. (3) reduces to

$$\partial V / \partial VP = [P(d) - (1 - t(c))P(e)] \int_{S2}^{S5} P(s) ds \quad (4)$$

Equation (4) allows for the derivation of the aggregate supply curve for pension income.

Turning briefly to the demand side, marginal investors must be in bracket 2 at market equilibrium. As pointed out in Sect. 87.7.1, marginal investors are those for whom personal after-tax expected yields on debt and equity are equal: $(1 - t(pd, u))/P(d) = (1 - t(pe, u))/P(e)$. When $P(d) = P(e)(1 - t(c))$, marginal investors are in bracket 2 with tax rates satisfying $(1 - t(pd, i))(1 - t(pe, i))(1 - t(c, i))$.

Substituting the marginal investor's tax rate condition $P(d) = P(e)(1 - t(pe, u))/(1 - t(pd, u))$ into the marginal value of debt Eq. (4) yields irrelevant to firm value.

$$\begin{aligned} \partial V / \partial VP[VP^*] &= \left[\frac{P(d)}{1 - t(pd, u)} \right] * [1 - t(pd, u)) - (1 - t(pe, u)) \\ &\quad \times (1 - t(c))] \int_{S2}^{S5} p(s) ds \end{aligned} \quad (5)$$

In equilibrium, the expression in brackets is zero because marginal investors are in bracket 2. The market in an intuitive sense endogenously determines the relative

marginal personal tax rates on debt and equity so that the corporate pension advantage exactly offsets the disadvantage of pension collateralized debt to investors at any debt level.

The model, therefore, shows that pension funding policy will be irrelevant to firm value when pension contributions are always deductible. This is because, at the margin, the constant corporate tax advantage of providing more pension income is offset by the personal tax disadvantage of doing so. While an optimal level of unfunded pensions will exist in the economy, there are no individual optimums which obtain that are unique to each firm. In this instance, the equilibrium characteristics are the same as those found in Sharpe (1976). The next section will explain how the existence of non-pension tax shields affects the analysis.

87.7.4 Tax Shield Risk and Optimal Corporate Pension Policy

When corporate tax shield substitutes exist ($D, B, G > 0$), corporate pension policy is no longer irrelevant. Instead, relative market prices will adjust until each firm has a unique interior optimum pension level, in equilibrium. Similar to the previous section, there is a constant expected marginal personal tax disadvantage to debt. The existence of tax shield substitutes, however, causes the expected marginal corporate tax benefit to decline as more pension income is contracted. At VP^* , the expected marginal corporate tax benefit just equals the expected marginal personal tax disadvantage of the pension collateralized debt. Similar to the findings of DeAngelo and Masniis, unique interior optimums exist when firms have different amounts of debt substitutes.

To begin, the aggregate supply curve for pension income will be derived, under the assumption that the pension income stream is riskless. When pension contributions are not the firm's only tax shield, both individual and aggregate supply curves will consist of a perfectly elastic section, after which they will smoothly slope upward. The curve is perfectly elastic at relative prices $P(d) = P(e)(1 - t(c))$ over the levels of pension income which allow for the full utilization of all corporate tax shields. The supply curve is upward sloping beyond the full utilization level because firms are willing to supply more pension income to labor only if they are compensated (for the greater likelihood of a partial or total loss of the additional tax shield) with higher unit pension collateralized debt prices $P(d) > P(e)(1 - t(c))$. The supply curve represents the schedule of $(P(d), VP)$ combinations at which the firm has unique interior optimum pension levels. In market equilibrium, the point at which the aggregate demand curve intersects the aggregate supply curve (in its upward sloping section, under weak assumptions on the personal tax code) sets relative prices $P(d) > P(e)(1 - t(c))$. These prices in turn determine the unique interior optimum pension policy for each firm.

A formal derivation of the supply curve proceeds as follows. When D, B , and $G > 0$, $S_4 > S_3 > S_2 > 0$, and the first-order condition is once again represented by Eq. (3). If relative prices are such that $P(d) < P(e)(1 - t(c))$, $\partial V / \partial VP < 0$ for

all values of VP , and the firm will supply no pension income. When $P(d) = P(e)(1 - t(c))$, the supply curve is perfectly elastic to the point where the selected pension contribution just allows for the full utilization of all tax shields in every state of nature. Referring to this amount as $PMAX$, $PMAX$ occurs when θ times the gross tax liability is greater than or equal to G . This is written in equation form as

$$\theta t(c)[X(S1) - D - B - PMAX] > G$$

which, when solving for $PMAX$ implies

$$PMAX = X(S1) - D - B - \frac{G}{\theta t(c)} < X(S1)$$

When VP is such that $0 < VP < PMAX$, $S2 = S3 = S4$ because all corporate tax shields are fully utilized in every state of nature. The first-order condition reduces to

$$\partial V / \partial VP = P(d) - P(e)(1 - t(c)) \text{ for } 0 < VP < PMAX$$

At relative prices $P(d) = P(e)(1 - t(c))$, the firm is indifferent to all pension levels that allow for the full utilization of all corporate tax shields. Consequently, the supply curve is perfectly elastic at relative prices $P(d) = P(e)(1 - t(c))$ over the interval $0 < VP < PMAX$.

No pension income will be provided beyond $PMAX$ at relative prices $P(d) = P(e)(1 - t(c))$. That is because when $PMAX < VP < X(S1)$, $S4 > S3 > S2$. If $P(d) = P(e)(1 - t(c))$, $\partial V / \partial VP < 0$, because the second and third terms are negative, while the first is zero. Firms will only provide pension income beyond $PMAX$ if $\partial V / \partial VP > 0$. In the context of Eq. (3), that is possible only if $P(d) > P(e)(1 - t(c))$. From an economic perspective, the higher pension price (rendered in the form of greater wages returned) is necessary in order to compensate shareholders for the loss of the corporate tax shield which they will incur on marginal units of pension contribution when $s \in [S3, S4]$. For all prices $P(d) > P(e)(1 - t(c))$, there exists a VP^* which sets $\partial V / \partial VP = 0$. As $P(d)$ rises relative to $P(e)$, Eq. (3) will become positive, and the firm will find it advantageous to supply more pension income. The supply curve is thus smoothly upward

sloping beyond $PMAX$.

As DeAngelo and Masulis (1980) point out, market equilibrium will occur on the upward sloping portion of the pension supply curve under a set of weak assumptions. First, the perfectly elastic section of the supply curve must be short. This is reasonable because few pension levels are both riskless to the employee and which have a zero probability of tax shield loss, as the range $0 < VP < PMAX$ does. Second, investors in bracket 1 must be sufficient in number to demand larger quantities of debt than $PMAX$ in the aggregate, at relative prices $P(d) = P(e)(1 - t(c))$. If both of these conditions hold, then the aggregate demand curve will intersect the aggregate supply curve at relative prices $P(d) > P(e)(1 - t(c))$. These prices will dictate a unique

interior optimum pension policy for each firm, and imply that investors are in bracket 1 with tax rates satisfying $(1 - t(pd, i)) > (1 - t(pe, i))(1 - t(c))$.

Following DeAngelo and Masulis, the first-order condition can be used to intuitively show the trade-off that determines the optimal pension policy. For the sake of simplifying the analytics, it is assumed that $t(pe, i) = t(pe, u) = 0$, and that VP^* occurs over the range $PMAX < VP^* < X(S1)$. Evaluating the first-order condition at VP^* and substituting the simplified marginal personal tax rate condition $P(e) = P(d)/(1 - t(pd, u))$ yields

$$\frac{\partial V}{\partial VP[VP^*]} = \left[\frac{P(d)}{1 - t(pd, u)} \right] * \left[t(c) \int_{S4}^{S5} p(s) ds + (1 - \theta) \int_{S3}^{S4} p(s) ds \right] - t(pd, u) \quad (6)$$

The first term in square brackets represents the expected corporate tax advantage of an additional dollar of pension income substituted for equity. Notice that this term is higher when the probability of losing any or all of the marginal tax shield is lower. The second term in square brackets, $t(pd, u)$, quantifies the expected marginal personal tax disadvantage of riskless debt. This is because, under the simplifying assumptions made, an increase in VP of one unit raises the personal tax liability by $t(pd, u)$ in all states of nature. At low levels of pension income, the first term exceeds the second term because there is a higher probability that the additional pension contribution can be fully utilized to reduce the firm's tax liability, and investors purchasing the corresponding debt are in the lower tax brackets. As the quantity of pension income provided rises, so does the likelihood that any or all of the marginal tax benefit will be lost. At equilibrium, the declining marginal corporate advantage of pension contributions just equals the marginal personal disadvantage of the debt sold on pension income. At VP^* , it is not advantageous for firms to supply more pension income or for labor to demand more.

As is the case in the DeAngelo and Masulis model, the use of a one-period framework necessarily precludes the consideration of the carry-back and carry-forward (CB-CF) provisions in the tax code. The effect of the inclusion in a multi-period model is not difficult to predict. Both reduce the probability that a corporate tax shield will be lost. CB provisions allow any unused shields to be applied to reduce the tax liability of up to three prior years. CF provisions allow the firm to apply any shields which cannot be carried back to up to 15 years in the future. Because both involve a time-value loss, however, they reduce but do not eliminate, the expected value of the corporate tax shield loss on the marginal unit of pension. Firms would therefore require less price compensation for increasing the supply of pension income. As a result, the supply curve in a multi-period model would be more elastic in its upward sloping portion than the one presented here.

Finally, it should be noted that our analysis of pension policy can be generalized to the case when corporate bonds are risky. Under that assumption, the returns to the contributors of capital are described in Table 2, given that bondholder claims outrank those of unfunded pensions in a liquidation. Following Table 2, if $P(b, s)$ represents

Table 2 State Contingent Dollar Returns

<i>State</i>	<i>B(s)</i>	<i>VP(s)</i>	<i>E(s)</i>
<i>S1-S2</i>	<i>X(s)</i>	0	0
<i>S2-S3</i>	<i>B</i>	<i>X(s) - B</i>	0
<i>S3-S4</i>	<i>B</i>	<i>VP</i>	<i>X(s) - B - VP</i>
<i>S4-S5</i>	<i>B</i>	<i>VP</i>	<i>X(s) - B - VP - (1 - θ)t(c)[X(s) - B - VP - D]</i>
<i>S5-S6</i>	<i>B</i>	<i>VP</i>	<i>X(s) - B - VP - t(c)[X(s) - B - VP - D] + G</i>

the price per unit of state-contingent income to corporate bonds, then the valuation expression can be written as

$$\begin{aligned}
 V = & \int_{S1}^{S2} [X(s)P(b, s)]ds + \int_{S2}^{S4} [B]P(b, s)ds + \int_{S2}^{S3} [X(s) - B]P(d, s)ds \\
 & + \int_{S3}^{S6} [VP]P(d, s)ds + \int_{S3}^{S4} [X(s) - B - VP]P(e, s)ds \\
 & + \int_{S4}^{S5} [X(s) - B - VP - (1 - \theta)t(c)(X(s) - B - VP - D)]P(e, s)ds \\
 & + \int_{S5}^{S6} [X(s) - B - P - t(c)(X(s) - B - P - D) + G]P(e, s)ds
 \end{aligned}$$

and the appropriate first-order condition is

$$\begin{aligned}
 \partial V / \partial VP = & \int_{S5}^{S6} [P(d, s) - P(e, s)(1 - t(c))]ds \\
 & + \int_{S4}^{S5} [P(d, s) - P(e, s)(1 - (1 - \theta)t(c))P(e, s)]ds \\
 & + \int_{S3}^{S4} [P(d, s) - P(e, s)]ds
 \end{aligned}$$

Under the special conditions of risk neutrality and homogenous beliefs,

$$\begin{aligned}
 \partial V / \partial VP = & [P(d) - P(e)] \int_{S3}^{S4} p(s)ds + [P(d) - P(e)(1 - (1 - \theta)t(c))] \int_{S4}^{S5} p(s)ds \\
 & + \left[P(d) - P(e)(1 - t(c)) \right] \int_{S5}^{S6} p(s)ds
 \end{aligned}$$

The first-order condition is of the same form as in the case of riskless debt but differs with regard to the probabilities of the respective state intervals. That is

because $\int_{s1}^{s2} p(s) ds > 0$ in the case of risky conventional debt, implying that the supply curve has a greater slope than when conventional debt is riskless.

87.8 Conclusion

This study examines how pension accounting relates to inside debt and capital structure. First, as defined benefit (DB) and defined contribution (DC) plans are the two most common types of pension plans, we demonstrate that DC plans are cheaper and involve lower risk for sponsoring firms than DB plans. Therefore, the shift in pension coverage from DB to DC plans has gained popularity among large healthy firms since the early 2000s (Munnell et al. 2007). Second, by using an illustration with Fig. 1, we explain how Employee Retirement Income Security Act (ERISA) of 1974 improves the protection of retirement benefits for private-sector employees and offers a put option for sponsoring firms. Third, we provide a review of empirical research on the pension accounting associated with earnings management and firm value. We highlight that institutional settings difference leaves rooms for future empirical research on pension accounting. Finally, following Alderson and Lee (1988), this chapter introduces a developed model in which individuals and corporations have an incentive to engage in contracts for the deferral of wage income in the form of an unfunded pension as part of the capital structure decision.

The Role of Earnings Management in Equity Valuation **88**

Guanming He, April Zhichao Li, and Dongxiao Shen

Abstract

The intrinsic value of a firm's equity is determined by the present value of future payoffs to equity-holders. Thus, to estimate equity value, one needs to identify and process a series of information that is relevant to the present value of expected future payoffs. Among the value-relevant information, earnings pertain to a summary measure of firm performance and thus play a key role in the equity valuation. Nevertheless, it is not uncommon in practice that firm managers either intentionally or unintentionally misreport earnings, making valuation challenging for outsiders. This chapter aims to explore the role earnings management plays in equity valuation, and how market participants may detect and adjust for misreported earnings, if any, in their forecasts and valuation for a firm. The chapter is organized to comprise the following sections: (i) varied managerial incentives for earnings management; (ii) various tactics of earnings management via accruals manipulation; (iii) various tactics of earnings management via real activities manipulation; (iv) consequences and determinants of earnings management; (v) trade-off between accruals manipulation and real activities manipulation to manage earnings; (vi) how to discern and measure earnings management; (vii) introduction of various equity-valuation models; and (viii) how to adjust for the effects of accruals-based and real earnings management in equity valuation.

88.1 Varied Managerial Incentives for Earnings Management

Investors tend to focus on earnings to make their investment decisions (e.g., Biddle et al. 1995; Francis et al. 2003; Graham et al. 2005). Therefore, managers can manipulate earnings to mislead investors' perception about the firm's future prospects. There are various scenarios in which managerial incentives for earnings management are aligned with shareholders' interests. We classify these scenarios by upwards *vis-à-vis* downwards earnings management, and expatiate on them below.

To facilitate external financing, managers manage earnings upwards prior to initial public offerings or seasoned equity offerings (Rangan 1998; Teoh et al. 1998; Shivakumar 2000; Haw et al. 2004). In so doing, managers can boost the market expectation of a firm's future performance, thereby selling shares at a higher price and raising more capital at a lower cost.

Prior to the announcements of stock-for-stock mergers, managers in both acquirers and acquirees are inclined to manipulate earnings upwards to increase acquisition premium which is tied to stock price (Erickson and Wang 1999; Louis 2004). The higher the stock prices of acquirers before the stock mergers, the fewer stocks acquirers need to swap with acquirees, and vice versa.

Most debt covenants that firms are required to meet are contingent on financial ratios (e.g., interest coverage ratio) that involve earnings numbers. Violation of the covenants can trigger penalties, including acceleration of debt repayment and increases in interest rates, for the firms. Thus, when firms are close to violating debt covenants, managers have an incentive to manage earnings to avoid covenant violation (DeFond and Jiambalvo 1994; Sweeney 1994; Beneish et al. 2012).

Firms missing the earnings thresholds such as zero earnings or consensus analyst earnings forecasts would likely have a stock-price plunge. On the contrary, firms consistently meeting or beating the earnings thresholds would likely receive a price premium (e.g., Barth et al. 1999; Kasznik and McNichols 2002; Myers et al. 2007; Bhojraj et al. 2009). Therefore, managers have a propensity to manipulate earnings upwards to meet or beat the earnings thresholds (Burgstahler and Dichev 1997; Robb 1998; Schilit 2010).

Given the limited amount of internal funds available for investments or operations, financially constrained or financially distressed firms need more external funds (He and Ren 2021). To facilitate external financing for relieving financial constraints or distress, managers have a tendency to manage earnings upwards (Loebbecke et al. 1989; Maksimovic and Titman 1991). Firms in financial constraints or distress are often poorly performing and thus have less to lose from getting caught with financial misconduct (Amiram et al. 2018); this further strengthens managers of these firms to inflate earnings.

Before firms repurchase stocks from open stock markets, managers of these firms have an incentive to deflate earnings to suppress the price paid for the repurchase (e.g., DeAngelo 1986; Gong et al. 2008). The deflated repurchase price transfers wealth from the shareholders who sell (i.e., the leaving shareholders) to those who hold onto their shares (i.e., the remaining shareholders). The lower the price firms manage to suppress through earnings deflation, the more benefits the remaining shareholders would obtain through this wealth transfer; so too is for the executives who hold a substantial amount of stocks or stock options. The likelihood of obtaining import relief and the amount of relief granted by governments will increase if a firm can show that its profitability was adversely tainted by foreign competition. As such, firms seeking import relief have a tendency to make profit-decreasing accounting discretion (Jones 1991). Firms are also likely to make profit-decreasing accounting choices to tone down their performance to outsiders when facing fierce industrial product market competitions or high threats of new entrants (Cheng et al. 2013; Balakrishnan and Cohen 2013; Dhaliwal et al. 2014).

Earnings management could be merely in the managers' own interests and not be aligned with the interests of incumbent shareholders. In such cases, managers' incentives for earnings management are notably stronger. For instance, the value of stocks (stock options) held by managers is contingent on the level (volatility) of stock prices (Coles et al. 2006; Low 2009; Armstrong et al. 2013). Thus, managers holding stocks and stock options have an incentive to manipulate earnings to maximize the value of their equity-based compensation (Cheng and Warfield 2005; Bergstresser and Philippon 2006; Burns and Kedia 2006; Erickson et al. 2006; Efendi et al. 2007; Cheng and Farber 2008; Cornett et al. 2008; Armstrong et al. 2010; Jiang et al. 2010; Feng et al. 2011; Armstrong et al. 2013). The amount of bonus pay is often tied to reported earnings in excess of a pre-specified earnings level. The higher the earnings reported by managers, the higher bonus pay they can get from their companies. This incentivizes the managers to manage earnings to enlarge bonus pay (Healy 1985; Holthausen et al. 1995).

Given high stock holdings by managers, they have an incentive to manage earnings upwards to inflate stock prices before selling shares they own (Ke et al. 2003; Beneish 1999; Park and Park 2004; Darrough and Rangan 2005; Beneish and Vargus 2002; Sawicki and Shrestha 2014). In the same vein, managers are prone to manipulate earnings downwards to deflate stock prices before purchasing shares from open stock markets (Sawicki and Shrestha 2014). Awards of call options on stocks can also induce managers to understate earnings. The stock options are typically granted with a fixed exercise price equal to the stock price on the grant date. The value of call options on stocks is inversely related to the exercise price of the stock options. Therefore, managers have an incentive to deflate earnings prior to option grants to lower the exercise prices of the stock options (Baker et al. 2003; Bartov and Mohanram 2004). In line with this notion, Coles et al. (2006) find evidence of downwards earnings management in the periods following announcements of cancellations of executive stock options up to the time the options are reissued.

In essence, to the extent that investors rely on reported earnings in forming beliefs about future earnings and to trade stocks (Stein 1989), stock prices are likely to be distorted by earnings management, thereby fulfilling various foregoing opportunistic incentives of managers.

88.2 Various Tactics of Earnings Management via Accruals Manipulation

To make earnings well capture a firm's real performance, accounting standards allow firm management to have discretion in making accounting policies and estimates on various noncash business transactions/items, such as allowance for doubtful receivables, impairment losses on inventories, depreciation of tangible assets, which are often uncertain in terms of their actual amount accruing.¹ Such choices of accounting policies and estimates by managers result in accruals, which are part of earnings. Accruals are largely subject to managers' estimation of the nature and amount of a firm's noncash business transactions/events, and therefore can be manipulated by managers for the purpose of distorting reported earnings.

Below we set forth the methods, which we believe are common in practice, of manipulating accruals to inflate earnings. First is the understatement of depreciation (amortization) expense for long-term (in)angible assets. Accounting rules require that firms recognize depreciation or amortization expense on an annual basis for the reduction in the book value of long-term assets. Upon acquiring a long-term asset, managers may overestimate its economic useful life or overestimate its salvage value, such that depreciation or amortization expense for the asset will be understated. Managers may also change the depreciation method from the straight-line (or accelerated) method to the deceleration (or straight-line) method, such that the depreciation or amortization expense at the early stage of the asset's economic useful life will be understated.

The second common tactic is the capitalization of expenditures as assets recognized in the balance sheet, which should be expensed according to the related accounting standards; this would lead to inflations of both reported earnings and assets. For instance, when acquiring a long-term asset, managers capitalize costs (e.g., fine for wrong parking of trucks that transport the asset) not necessarily incurred to bring the asset to its intended use. After acquisition of a long-term asset, managers capitalize the expenditures (e.g., those incurred for repairs, maintenance, additions, or litigation costs) even though these outlays are expected to benefit the firm only for the current year. Managers may even capitalize expenditures on research and development, software development layouts, and brands and membership bases that are created through advertising and promotions; the benefits

¹Throughout this chapter, all the accounting standards and policies mentioned are based on the general accepted accounting principle (GAAP).

associated with these expenditures are highly uncertain, hence the expenditures should be expensed rather than capitalized.²

The third common strategy is to delay the write-down of current or long-term assets. Once the value of the assets (e.g., intangible assets, inventories, property, plant, and equipment (PPE)) is impaired, firms are required to recognize impairment losses. Managers might not do so even when the fair value of an asset falls substantively below its book value. When managers over-buy or over-produce products in excess of market demand for the products, the value of inventories is likely to decrease; when PPE fail to sustain the production of products that meet the changing needs, preferences, and tastes of customers, the value of the PPE will decrease for the firm; when a firm is discovered by the public to have been involved in environmental, social, and governance scandals, the firm will suffer from reputational losses, and its goodwill will be impaired as a result. In all these cases, managers should write-down the book values of the assets to their fair values on a timely basis. Delayed write-down of the assets will lead to the overstatement of reported profits and total assets.³

The fourth common maneuver is to accelerate the recognition of revenues. Managers should recognize revenues only when products (services) have been delivered (provided) to customers and when cash collection is reasonably likely. Nonetheless, managers may recognize revenues when they receive cash but have not delivered products, or render services, to customers. Firms that bundle product sales with service contracts are particularly prone to, either intentionally or unintentionally, advance recognition of revenues for the services that have not yet been provided, especially for long-term service contracts. Managers may also make the advance recognition of revenues in cases when invoicing for the product delivery or service rendering has not yet occurred.

The fifth ordinary approach to boost earnings via accruals is the understatement of allowance for doubtful receivables or loan losses. Firms are required to estimate their expected customer defaults on trade receivables or loans. Managers might underestimate the amount of likely default payment by customers. As a consequence, allowance for doubtful accounts (loan losses), which are contra-accounts to receivables (loans) in

²It is worth noting, though, that unlike GAAP, the International Financial Reporting Standards (IFRS) No. IAS 38 stipulate that research and development expenditures that meet certain specified criteria can be capitalized as an intangible asset. Further details can be found via the link: <https://www.ifrs.org/issued-standards/list-of-standards/ias-38-intangible-assets/#about>

³Pursuant to IFRS No. IAS 2, inventories are measured at the lower of costs and net realizable value, the latter of which equals the estimated selling price minus the estimated costs of completion and the estimated costs to sell. Details can be found via the link: <https://www.ifrs.org/issued-standards/list-of-standards/ias-2-inventories/>. According to IFRS No. IAS 36, if the carrying value of noncurrent assets (e.g., goodwill, PPE) exceeds their recoverable value, the assets should be impaired to their recoverable value, which is the lower amount of (i) fair value less costs to sell and (ii) value in use. The impairment losses can be reversed for the assets, except for goodwill, under the guidance of IFRS, whereas the reversion is not allowed if a firm follows GAAP. Further details can be found via the link: <https://www.ifrs.org/issued-standards/list-of-standards/ias-36-impairment-of-assets/>

the balance sheet, and the associated bad-debt-provision expense will be understated, leading to inflation of both reported earnings and total assets.

The sixth common device to inflate accruals and earnings is to underestimate various provisions (e.g., warranty coverage for products sold, provision for legal fees, provision for environmental clean-up fees) or put the provisions off balance sheet. To illustrate, the degree of future expenditures on warranty coverage for products (services) sold (rendered) is often uncertain. Managers may underestimate provisions on warranty coverage and thereby inflate earnings. Accounting standards prescribe that a firm recognizes a provision when the obligation is unavoidable, is likely to lead to a future outflow of cash, and can be reliably estimated. Managers may understate, or even not recognize, the provision, even when a liability meets all the requirements for recognition. In consequence, the associated provision expense will be understated, and earnings will be overstated.

The last common means to prop up earnings via accruals is the understatement of pension and postretirement benefit obligations. Managers are required to estimate and report the present value of the pension benefits and other postretirement benefits that will have been earned by employees over their years of working and services for their firm. These benefits pertain to the firm's liability to its employees, which is offset by any assets (comprised mainly of cash) that the firm set aside in the postretirement plan. The pension and postretirement benefit obligations are estimated based on forecasts of future wages, employee attrition rates, and the expected lives of retirees. Managers can make the forecasts to be pessimistic, such that the firm's pension obligation and associated pension expenses are understated, thereby achieving the end of inflating reported earnings.

Managers normally have the best information on the uncertainties surrounding accruals recognition. The estimation and reporting of accruals involving the foregoing seven common tactics of accruals manipulation are hard to be challenged by outsiders who do not have access to private corporate information and are generally constrained in their abilities to process value-relevant information. This strengthens managerial incentives to make use of the accruals-manipulation tactics to boost reported earnings. By the same token, managers can manage earnings downwards by (i) overstating depreciation for noncurrent assets, (ii) delaying recognition of revenues, (iii) accelerating write-down of noncurrent or current assets, (iv) overestimating pension and postretirement benefit obligation, (v) overestimating allowance for doubtful receivables, loan losses, or inventory obsolescence, and (vi) overestimating various provisions (e.g., warranty coverage for products sold, provision for legal fees, provision for environmental clean-up fees).

88.3 Various Tactics of Earnings Management via Real Activities Manipulation

Real earnings management is the purposeful action of managers to manipulate reported earnings by altering real business activities strategically. Unlike accruals-based earnings management, which changes the accounting methods and/or

estimates, real activities manipulation is achieved by way of manipulating the timing and structuring of real business transactions.

There are three common ways of manipulating recurring business activities to inflate earnings (Roychowdhury 2006). First is to accelerate the timing of sales through increased price discounts or more lenient credit terms to increase sale revenues for the current fiscal year. Second is to report lower costs of goods sold through overproduction during the current fiscal year. Per unit fixed overhead cost would be reduced as a result of overproduction, resulting in a reduction of costs of goods sold, and thus an increase in net income, for the current period. But the costs of unsold goods would increase as a result and be eventually realized into the recognition of higher costs of goods sold in future years. Third is to reduce the current advertising, research and development, maintenance and repair, and other selling, general, and administrative expenditures that would benefit a firm in the long run.

There are other ways of real earnings management, which are through nonrecurring business activities. First, the number of shares outstanding would decrease as a result of stock repurchase, resulting in an increase in earnings per share (EPS). Thus, managers can launch stock repurchases for the purpose of increasing EPS (Hribar et al. 2006; Burnett et al. 2012). Second, managers make advance sales of an asset, which can still create value for a firm, to increase reported profits for the current fiscal year (Bartov 1993; Herrmann et al. 2003). Third, a firm would not have to pay interest expense any longer after the debt is swapped by equity by the firm with its creditors. Thus, managers may advance debt-equity swaps to inflate reported profits, though their firm is not in financial constraints or distress and thus does not have to make the debt-equity swaps for the purpose of relieving the constraints/distress (Hand 1989). Fourth, securitized accounts receivables should be sold at a point when the expected likelihood of default payments by the customers is the lowest, such that the associated securitization expense will be lowest. Managers may delay the sales of securitized accounts receivables to boost reported profits (Dechow and Shakespear 2009). Fifth, managers advance sales of securities that are aimed for long-term investments and for taking control of related business parties.

Last but not least, real earnings management could be done via profit-shifting among related parties inside a business group. For example, real profits can be transferred between a parent company and its subsidiaries, among subsidiaries, or between a firm and its main, non-subsidiary suppliers or customers by means of getting products transacted at a price different from the market price. Or rather, a firm may manage earnings upwards by buying (selling) products from (to) its related business parties at a price lower (higher) than the market price, and may manage earnings downwards by making the purchases (sales) at a price higher (lower) than the market price. Even without transacting products at a price different from the market price, managers may shift income from a parent company to its not-wholly-owned subsidiaries to lower the net income of the consolidated income statement of the parent company, as earnings shared by minority investors of its subsidiaries would not be recognized in the consolidated income statement. Likewise, managers

may shift income from the not-wholly-owned subsidiaries to their parent company to make its consolidated net income higher.

88.4 Consequences and Determinants of Earnings Management

Were managers to inflate (deflate) earnings via accruals in the current year, the inflated (deflated) accruals would be reversed downwards (upwards) in subsequent years, leading to a fall (rise) in earnings and thereby plausible suspicion by outsiders for accruals manipulation (He et al. 2020b). There is no cost to managers for accruals manipulation if it goes undetected by outsiders. Nevertheless, if accruals manipulation is uncovered by the public, the firm will lose reputational capital, defined as the present value of improvements in net cash flows that arise when a firm's stakeholders trust that the firm will uphold and abide by its explicit and implicit contracts and will not act opportunistically to the detriment of stakeholders (Amiram et al. 2018). The misconduct firm would be subject to higher costs of capital, lower sales, or higher operating costs, as the revelation of accruals manipulation changes the terms of contracts or tacit agreements by which varied stakeholders are willing to do business with the firm. The misconduct firm might also be subject to regulatory fines, class-action settlements, and legal expenses. The legal costs rest on the extent of accruals manipulation and the degree of losses it causes to investors and other financial statement users. As a result of the reputational losses and threat of litigation, it will be difficult or costly for the firm to finance and/or contract for investments and operations in the future, thus reducing firm value and increasing corporate default risk (Ball and Shivakumar 2008; He 2015, 2016). There is an array of evidence (e.g., Dechow et al. 1996; Beneish 1999; Burns and Kedia 2006; Karpoff et al. 2008; Gande and Lewis 2009) to suggest that a drop in firm value as a consequence of the discovery of accruals inflation is substantively larger than the original stock price inflation.

The manipulation of accruals might also have adverse impact on the firm's business activities. For instance, companies often make investment decisions in the current period based on their past performance (He et al. 2020a). The inconsistency between the current period's investments and the previous periods' manipulated earnings might induce investors' suspicion of accruals misreporting. To lower the risk of detection, managers may adjust their firm's investments to be in line with the managed earnings. As such, accruals inflation might lead managers to overinvest in risky projects that increase corporate default risk (e.g., McNichols and Stubben 2008; Kedia and Philippon 2009; Kumar and Langberg 2009); in a similar vein, accruals deflation might cause managers to underinvest in positive-net-present-value projects that could guard against financial distress for the firm in the long run (e.g., McNichols and Stubben 2008; Kedia and Philippon 2009; Kumar and Langberg 2009; He 2015). Put differently, managers who *unintentionally* inflate (deflated) reported earnings believe the misreported growth trend and would overinvest (underinvest) accordingly in the financial markets and product markets; those who *intentionally* boost (lower) reported earnings would seek to overinvest (underinvest)

as well to maintain consistency between misreported earnings and investments so as to avoid outsiders' suspicions of earnings management (Sadka 2006; McNichols and Stubben 2008; Kedia and Philippon 2009). In addition, managers might lose their jobs and compensations once accruals manipulation is discovered by the public.

Unlike accruals-based earnings management, real earnings management is based on the manipulation of real activities in ways that deviate from optimal business strategies and normal business practices (Roychowdhury 2006; Zang 2012). Therefore, real activities manipulation, even if not detected by outsiders, will have a profound, negative influence on the firm's future performance. The larger the deviation of manipulated real activities from normal business practices, the more adverse the influence for the firm. If the manipulation is detected by outsiders, the adverse influence will be even stronger, as the detection will bring about reputational costs to the firm just as the discovery of accruals-based earnings management does.

Whether managers will manage earnings, either via real activities manipulation or accruals manipulation, depends fundamentally on whether the benefits from the earnings management are perceived by managers to be higher than the costs. Accordingly, the determinants of earnings management are related to the perceived benefits versus costs of managing earnings. Taking the benefits as given in the foregoing settings in which managers have incentives to manage earnings, we may take the costs as varying on different firm characteristics. Larger firms, higher-growth firms, financially healthier firms, lower-risk firms, better-performing firms, and firms that face fierce industrial product market competition are less likely to manage earnings, as the reputational costs of doing so are higher for these firms. Firms with stronger internal governance, firms with more intense external monitoring, and firms whose financial statements are subject to high-quality audits are less prone to manage earnings, as the risk of detection of earnings management tends to be higher for these firms.

Below we set out a review of literature on the determinants of earnings management.

Firm size: A great deal of research provides evidence to suggest that firm size is negatively associated with the magnitude of earnings management. Large firms are more likely to have good internal control, since they normally have more assets and business transactions that need be monitored well, and have more resources to invest in internal control systems. In contrast, small firms tend to have weaker internal controls and are more likely to manipulate earnings (e.g., Kinney and McDaniel 1989; Ge and McVay 2005; Doyle et al. 2007; Ashbaugh-Skaife et al. 2007; Haw et al. 2004).

Growth prospect: Some prior research finds that high-growth firms have lower earnings persistence (Nissim and Penman 2001; Penman and Zhang 2002), which makes investors vigilant of potential earnings management, and have fewer earnings management opportunities (Richardson et al. 2005), and that high-growth firms have strong internal control in place to curb potential financial misconduct that impedes growth (Doyle et al. 2007; Ashbaugh-Skaife et al. 2007). In low-growth firms which often have surplus free cash flow and associated agency problems, managers tend to

purposefully manage earnings to avoid reporting any loss that results from rent extraction (Chung et al. 2005).⁴

Financial constraints: Financially constrained firms are those that do not have sufficient internal funds for investments and are subject to high costs for accessing capital markets (Korajczyk and Levy 2003). Financially constrained firms have incentives to prop-up reported earnings so as to raise external capital at a lower cost. Consistent with this notion, Campello et al. (2010) find that, when facing tight economic conditions, financially constrained firms tend to boost earnings through real activities such as a reduction in expenditures on technology and marketing. Linck et al. (2013) show that, given valuable investment opportunities, firms that are in financial constraints tend to use accruals to highlight good news.

Financial distress: Financially distressed firms are referred to as those that are unable to fulfil debt obligations in the foreseeable future. If financial distress of the firms is prolonged, they would be likely to go bankrupt. Prior studies find that financially distressed firms are likely to manage earnings upwards to conceal deteriorating performance and to avoid reported losses (Graham et al. 2005; Jaggi and Lee 2002; Saleh and Ahmed 2005; Rosner 2003).

Risk: One motivation for earnings management is to alleviate the market's perception about firm risk. An increase in firm risk could be associated with a higher likelihood and extent of earnings management. We classify firm risk into business risk and information risk, the former of which includes operational risk and financial risk.

Operational risk: Previous research (Rountree et al. 2008; Hunt et al. 1997) shows that operational risk, proxied by earnings volatility or cash flows volatility, is valued negatively by investors. They would charge a higher premium for investing in a firm that has high operational risk. Therefore, managers are likely to manipulate accruals to smooth earnings so as to mitigate any adverse impact of volatile operating performance of their firm and thereby lower its cost of capital (Francis et al. 2004).

Financial risk: Financial risk refers to the risk associated with external financing, and hinges largely on the level of capital structure. Theory (e.g., Modigliani and Miller 1958, 1963; Mayers and Majluf 1984; Desai et al. 2007) suggests that a good capital structure requires a good trade-off between debt and equity in the way a firm is financed. This theory has been examined in the firm-level, cross-sectional empirical analyses, with results revealing that smaller, riskier firms and those with more intangible assets, higher profitability, and stronger growth prospect are more suited for using equity rather than debt to finance their investments (e.g., Hovakimian et al. 2001; Frank and Goyal 2009; Kayhan and Titman 2007; Adam and Goyal 2008). A firm's optimal capital structure can be determined by estimating the fitted value from a regression of financial leverage on its typical determinants (i.e., firm size, risk, asset tangibility, profitability, and growth). Any deviation from the optimal capital

⁴Surplus free cash flows might induce agency problems in which managers use the cash flows for self-serving purposes.

structure might increase the firm's financial risk (Leland 1998). If financially risky firms wish to obtain new loans, the lenders will likely set tight covenants. To avoid debt-covenant violations, the firms are likely to manipulate earnings upwards. This has been documented extensively by the extant literature (e.g., Sweeney 1994; Dichev and Skinner 2002; Beatty and Weber 2003).

Information risk: Bhattacharya et al. (2003) define information risk as the risks that investors may confront due to the insufficient, imprecise, or even biased information on which to base their investment decisions. A large body of studies show that the cost of capital increases with increased information risk (Bhattacharya et al. 2003; Francis et al. 2005; Bhattacharya et al. 2011; Bharath et al. 2008; Qi et al. 2010). These studies use accruals quality as the proxy for information risk, suggesting that accruals-based earnings management would induce high information risk to a firm.

Performance: Firms that are not performing well have incentives to inflate earnings to conceal the unsatisfactory performance (Petroni 1992; Dechow et al. 1995; DeFond and Park 1997; Balsam et al. 1995; Keating and Zimmerman 1999; Doyle et al. 2007; Kinney and McDaniel 1989). On the other hand, the opportunity costs (i.e., personal reputational losses and compensation losses) for managers to engage in earnings management are likely to be higher for better-performing firms, hence they are less likely to get involved in earnings management.

Competition: Prior studies have investigated the relation between industrial product market competition and earnings management, but document mixed views and evidence on the relation. Some researchers argue that competition might incentivize firms to inflate earnings to attract customers and fund providers (Shleifer 2004; Bagnoli and Watts 2010; Markarian and Santalo' 2014; Karuna et al. 2015). However, some argue that industrial competition has a deterrence effect on managers' misconduct (e.g., Giroud and Mueller 2011; Guadalupe and Pérez-González 2010) and earnings management behavior (Balakrishnan and Cohen 2013), because the reputational costs are higher for firms subject to fierce competition. Some studies also find that competition would impact a firm's trade-off between different tactics of earnings management. For instance, Zang (2012) finds that (non-)market leaders in an industry are more likely to resort to real activities (accruals) to inflate earnings. Shi et al. (2018) find evidence that competition is positively (negatively) associated with accruals-based (real) earnings management.

External monitoring: Extensive evidence suggests that external monitoring from auditors, financial analysts, and institutional investors mitigates earnings management. Auditing is an important external governance mechanism, which provides assurance of earnings quality to external stakeholders by monitoring the financial reporting process and curbing any misreporting therein. The existing literature (e.g., Becker et al. 1998; Francis et al. 1999; Balsam et al. 2003; Krishnan 2003) documents that high-quality auditing reduces accruals-based earnings management. However, real earnings management is less likely to be detected by auditors, thus managers tend to engage in real activities to inflate earnings when the accruals manipulation is constrained by higher-quality audits (Chi et al. 2011).

Financial analysts and institutional investors tend to monitor earnings management because they need to rely on high-quality financial reports for purposes of valuation and/or performance evaluation. Analysts generally have the training and industrial background in accounting and finance, and are thus advantageous in monitoring via collection and analysis of various firm-specific information and in uncovering accounting distortions (e.g., Jensen and Meckling 1976; Healy and Palepu 2001; He et al. 2019a). Miller (2006) and Dyck et al. (2010) offer evidence to suggest that analysts play a critical role in detecting corporate frauds in the financial marketplace. Yu (2008) and Degeorge et al. (2013) show that earnings management is negatively associated with analyst coverage. As to the role institutional investors play in monitoring earnings management, prior research shows that institutional stock ownership is negatively associated with both accruals-based earnings management (Chung et al. 2002; Mitra and Cready 2005) and real earnings management (Bushee 1998; Bange and De Bondt 1998).

Corporate governance: Corporate governance helps reduce the agency problem between shareholders and managers through internal monitoring mechanisms such as board governance, ownership structure, and various governance-related committees (Jensen and Meckling 1976). Prior studies find that firms with higher board independence (e.g., Jensen and Meckling 1976; Dechow and Dichev 2002), dispersed stock ownership structure (e.g., Leuz et al. 2003; Nenova 2003; Dyck and Zingales 2004), and effective internal audit committees (e.g., Carcello et al. 2006; Bedard and Johnstone 2004) have less opportunistic earnings management.

Executive compensation: As noted previously in Sect. 88.1, one incentive for earnings management arises from stock and stock option holdings by executives. A vast literature provides evidence that executive equity compensation is positively associated with earnings management (e.g., Larcker et al. 2007; Bergstresser and Philippon 2006). He (2015) finds that CEOs holding large inside debt are less likely to manipulate accruals. Kohlbeck and Luo (2019) extend He (2015) by showing that CFO inside debt is negatively associated with accruals-based earnings management.

There are various empirical measures of the determinants of earnings management that are documented in prior research. We summarize these measures in Table 1.

88.5 Trade-Off Between Accruals Manipulation and Real Activities Manipulation to Manage Earnings

As noted earlier, whether managers are inclined to manage earnings hinges crucially on whether the expected benefits of doing so outweigh the expected costs. Since the costs of managing accruals differ from those of managing real business activities, managers will have to trade-off between accruals manipulation and real activities manipulation to manage earnings. Manipulating earnings via accruals does not affect the underlying business activities and cash flows of a firm, whereas managing earnings via real business activities does, and thereof will impose negative economic

Table 1 Measurements of the determinants of earnings management

Determinants	Measurements
Firm size	The natural logarithm of the market or book value of total assets or equity
Growth prospect	The book-to-market ratio; sales growth; assets growth; the ratio of capital expenditures to sales; the price-to-book (P/B) ratio
Financial constraints	SA index (Hadlock and Pierce 2010); WW index (Whited and Wu 2006); KZ index (Kaplan and Zingales 1997); dividend payout ratio (Denis and Sibikov 2010; He et al. 2021); retained earnings scaled by total equity; cash and cash equivalents scaled by total assets; cash flows from operating activities scaled by total assets
Financial distress	Distance-to-default and expected default frequency (Campbell et al. 2008); Altman Z-score (Altman 1968); liquidity ratios (e.g., current ratio, quick ratio, cash ratio); solvency ratios (e.g., financial leverage, interest coverage ratio; cash coverage ratio)
Business risk	The standard deviation of earnings, sales, stock returns, or cash flows from operating and investing activities; the standard deviation of return on assets (ROA), return on equity (ROE), or return on sales (ROS)
Performance	Return on assets (ROA); return on equity (ROE); return on sales (ROS); gross profit margin ratio; stock returns; the natural logarithm of sales; Tobin's Q (Kaldor 1966); total factor productivity (Sickles and Zelenyuk 2019)
Competition	Herfindahl-Hirschman index on sales of varied firms in an industry (Harris 1998); product substitutability, market size of competing products, entry costs (Karuna 2007; He 2018; He et al. 2019b)
External monitor	Analyst coverage; institutional stock ownership; audit quality (the presence of big-4 audits, the presence of internal audit committee, the ratio of audit fees to sales revenues of a firm, auditor tenure, auditor switches; auditor industrial specialization; total audit revenues of an audit firm)
Corporate governance	Board independence (e.g., the portion of independent outside directors on the board); CEO power (e.g., whether CEO is also the chairman of the board); ownership structure (e.g., Herfindahl-Hirschman index on shares of different shareholders in a company)
Executive compensation	Executive equity compensation (stocks and stock options of executives scaled by total shares outstanding; equity delta; equity vega); executive debt-like compensation (pension and deferred compensation of executives scaled by total assets)

consequences on a firm. Nonetheless, accruals manipulation is subject to scrutiny from regulators and auditors, and entails a risk of detection and litigation by financial statement users. In contrast, real earnings management, which departs a firm from normal business practices without altering the accounting methods and/or estimates, entails relatively lower detection risk and is not subject to any legal discipline or legal cost. Therefore, given a desired level of earnings, managers tend to use accruals-based earnings management and real earnings management as substitutive instruments to manipulate earnings (e.g., Cohen et al. 2008; Bhojraj et al. 2009; Zang 2012; Cohen and Zarowin 2010; Badertscher 2011; Gunny 2010; Burnett et al. 2012; Chan et al. 2014; Kothari et al. 2016).

Accounting standards need to trade-off between granting financial-reporting discretion, which leaves room for accruals-based earnings management, and imposing mechanical, rigid reporting criteria, which creates opportunities and incentives for real earnings management. Such a trade-off seeking a good balance between the discretion *vis-à-vis* rigidity should lead to a minimization of latitude for overall earnings management, which is a challenging yet pressing task for accounting-standard setters nowadays.

88.6 How to Discern and Measure Earnings Management?

Earnings consist basically of cash and accruals. The reported amount of cash cannot be altered without changing real business activities, but the reported numbers of accruals can, simply by changing the associated estimations such as allowance for trades receivables, impairment losses on assets, pension obligations. Therefore, one way of assessing earnings quality is to estimate abnormal levels of accruals. Before we introduce the approaches of estimating abnormal accruals, we first expatiate on the definitions and measurements of varied accruals.

Accruals are formally defined as involving changes in noncash assets or noncash liabilities of a firm, which denote its future cash inflows or outflows. Positive (negative) accruals reflect future benefits (obligations), or future cash inflows (outflows), for a firm. Aggregate change in noncash assets net of aggregate change in noncash liabilities represents the net change in expected future benefits. We thus refer to this amount as comprehensive accruals, which we calculate as change in common stockholders' equity less change in cash and cash equivalents. Comprehensive accruals are composed of operating accruals (i.e., accruals relating to operational and investing activities) and financial accruals (i.e., accruals relating to financing activities such as investments in marketable securities, interest-bearing lending or borrowing). Specifically, financial accruals are defined as change in financial assets (e.g., cash, security investments, lending) net of change in financial liabilities (e.g., debt) and of change in cash. All assets other than financial assets, and all liabilities other than financial liabilities, relate to operations of a firm (which are, in a broad sense, inclusive of investment activities).⁵ Accordingly, operating accruals are computed as change in net operating assets exclusive of cash and cash equivalents, or as net operating profits after taxes and before interests less free cash flow. Operating accruals can be further categorized into working capital accruals (e.g., inventories, accounts receivables, accounts payables, which are short-term in nature and expected to reverse, and result in cash inflows or outflows, within a year) and long-term operating accruals (e.g., property, plant, and equipment (PPE), pension obligations, which reflect long-term future benefits or obligations). Working capital accruals are computed as: (change in current assets – change in cash and short-term

⁵Throughout this chapter, we take operating activities as, in broad sense, including investing activities. As such, operating accruals are in themselves inclusive of investing accruals.

investments) – (change in current liabilities – change in debt included in current liabilities); long-term operating accruals are then calculated as operating accruals minus the working capital accruals.

Apart from categorizing accruals into working capital accruals, long-term operating accruals, and financial accruals (Richardson et al. 2005), we may also decompose accruals based on whether they articulate across both balance sheet and statement of cash flows. All the changes in assets or liabilities in balance sheet, which are caused by regular operating transactions, should eventually go through statement of cash flows either in the current year or in future years. However, some “non-articulating” events, such as noncash acquisitions and divestitures, foreign currency translation adjustments, lead to changes in the balance sheet but do not cause any change in the statement of cash flows in the current or future years. As such, the non-articulating events will bring about a difference between accruals measured using the balance sheet approach (i.e., taking changes in noncash assets or liabilities in the balance sheet) and accruals measured using the cash flow approach (i.e., subtracting operating and investing cash flows and accrued interests from net operating income before interests and after taxes). Such a difference in accruals arises from the “non-articulating” events and is thus termed non-articulating accruals. The rest of accruals are articulating accruals, which are calculated, under the cash flow approach, as net operating income before interests and after taxes less operating and investing cash flows and accrued interests.

To estimate the abnormal level of operating accruals, we run the following modified Jones regression model by industries and years, with at least 20 firms required for each year and industry (Dechow et al. 1995):

$$\frac{OPACC_{i,t}}{Ass_{i,t-1}} = \alpha_0 + \frac{\alpha_1(\Delta REV_{i,t} - \Delta REC_{i,t})}{Ass_{i,t-1}} + \alpha_2 \left(\frac{PPE_{i,t}}{Ass_{i,t-1}} \right) + \varepsilon_{i,t} \quad (1)$$

where $OPACC_{i,t}$ = operating accruals of firm i at year t ; $\Delta REV_{i,t}$ = change in revenues of firm i for year t ; $\Delta REC_{i,t}$ = change in accounts receivable of firm i at year t ; $PPE_{i,t}$ = the net value of property, plant, and equipment of firm i at year t ; and $Ass_{i,t-1}$ = total assets of firm i at year $t-1$. Under normal operating circumstances, higher growth in cash revenues and less PPE (denoting lower depreciation expense) are associated with more operating accruals. Therefore, it is expected that α_1 (α_2) is positive (negative) and statistically significant at a conventional level.⁶ Abnormal accruals of firm i at year t would be the residual value (i.e., the actual value of $\frac{OPACC_{i,t}}{Ass_{i,t-1}}$ less the predicted value of $\frac{OPACC_{i,t}}{Ass_{i,t-1}}$) estimated from the regression model. Significantly positive (negative) abnormal accruals denote upwards (downwards) earnings management by a firm. The assumption underlying the model used to measure the

⁶The parameter estimation for Model (1) (as well as the follow-up Models (2, 3, 4, 5, 6, and 7) used to estimate various types of earnings management) may incorporate a scaled intercept to mitigate potential heteroskedasticity attributed to the variation in the scaling variable (i.e., total assets) (e.g., Kothari et al. 2005; He 2016).

degree of accruals manipulation is that accruals are innately determined by operational fundamentals regarding cash-revenue growth and fixed assets, and that any deviation from such fundamentals is attributed to managerial accruals manipulation. In the presence of non-articulating events (typically, mergers and acquisitions) for a firm, operating accruals (*OPACC*) should be replaced by articulating operating accruals (*A_ACC*) in Model (1) to estimate the abnormal articulating operating accruals.

Working capital accruals can be manipulated by managers at any year they wish, but the manipulated accruals will be likely reversed in the next year, exposing a firm to a relatively higher risk of detection by outside investors. In contrast, long-term operating accruals cannot be manipulated at any year in which managers wish for a higher or lower level of earnings. For instance, at year *t*, managers wish for inflated earnings. But the market values of operating fixed assets are all higher than the book values of the assets, hence there is no way for managers to delay or underestimate the asset write-off in order to inflate earnings. Alternatively, managers can time their opportunistic incentives for inflating earnings to be at the point when they can manipulate the long-term operating accruals upwards. Therefore, compared with working capital accruals, long-term operating accruals are less flexible for managers to manipulate in order to achieve opportunistic objectives. That said, any manipulated long-term operating accruals tend to reverse in the distant future, and thus are less likely to be detected by outsiders. If we seek to assess whether and to what extent managers use working capital accruals (*WCACC*) to manipulate earnings, then Model (1) should be replaced with the following model to estimate abnormal working capital accruals:

$$\frac{WCACC_{i,t}}{Ass_{i,t-1}} = \alpha_0 + \frac{\alpha_1(\Delta REV_{i,t} - \Delta REC_{i,t})}{Ass_{i,t-1}} + \varepsilon_{i,t} \quad (2)$$

If we wish to assess whether and to what degree managers use long-term operating accruals (*LTACC*) to manage earnings, then Model (1) should be replaced with the following model to estimate abnormal long-term operating accruals:

$$\frac{LTACC_{i,t}}{Ass_{i,t-1}} = \alpha_0 + \alpha_1 \left(\frac{PPE_{i,t}}{Ass_{i,t-1}} \right) + \varepsilon_{i,t} \quad (3)$$

It is worth noting (i) that the abnormal accruals estimated from Model (1) might be attributed to the differences in accounting methods adopted by firms in or between different industries, rather than to managerial accruals manipulation and (ii) that cash flows from operations (*CFO*) in the past, current, and future years are also potential innate determinants of operating accruals for the current year. To account for these concerns in the assessment of accruals manipulation by firms, Francis et al. (2005) develop the following modified Dechow and Dichev model, which is estimated by industries and years and with at least 20 firms required of the sample for each year and industry:

$$\begin{aligned} \frac{OPACC_{i,t}}{Ass_{i,t-1}} = & \alpha_0 + \alpha_1 \left(\frac{CFO_{i,t+1}}{Ass_{i,t-1}} \right) + \alpha_2 \left(\frac{CFO_{i,t}}{Ass_{i,t-1}} \right) + \alpha_3 \left(\frac{CFO_{i,t-1}}{Ass_{i,t-1}} \right) \\ & + \frac{\alpha_4(\Delta REV_{i,t} - \Delta REC_{i,t})}{Ass_{i,t-1}} + \alpha_5 \left(\frac{PPE_{i,t}}{Ass_{i,t-1}} \right) + \varepsilon_{i,t} \end{aligned} \quad (4)$$

The standard deviation of the residual values estimated from Model (4) for years t-4 to t is used as the refined measure of a firm's accruals manipulation. The premises underlying such a measure are that (i) any measurement error in determining accruals is attributable to either noise or management errors and (ii) that noise is time-invariant from year t-4 to year t. Operating accruals and operating cash flows tend to be positively correlated across different years in a time-series but negatively correlated for a given year in the cross-section. Therefore, α_1 and α_3 should be positive and statistically significant at conventional levels, while α_2 should be significantly negative. High-quality accruals should well reflect future, current, and past operating cash flows, after controlling for PPE and changes in cash revenues. As with Model (1), α_4 (α_5) should be significantly positive (negative).

As mentioned earlier, three common ways of manipulating recurring business activities to inflate earnings are (i) accelerating the timing of sales through increased price discounts or more lenient credit terms, (ii) lowering costs of goods sold through overproduction, and (iii) reducing advertising, research and development, maintenance and repair, and other SG&A expenditures. Price discounts and grants of lenient credit terms would result in abnormally low cash flows from operations (CFO). To estimate the resulting abnormal CFO, we run the following regression model by industries and years, with at least 20 firms required of the sample for each year and industry:

$$\begin{aligned} \frac{CFO_{i,t}}{Ass_{i,t-1}} = & \alpha_0 + \alpha_1 \left(\frac{Sales_{i,t}}{Ass_{i,t-1}} \right) + \alpha_2 \left(\frac{\Delta Sales_{i,t}}{Ass_{i,t-1}} \right) + \alpha_3 \left(\frac{Prod_{i,t}}{Ass_{i,t-1}} \right) \\ & + \alpha_4 \left(\frac{Disexp_{i,t}}{Ass_{i,t-1}} \right) + \varepsilon_{i,t} \end{aligned} \quad (5)$$

where $CFO_{i,t}$ = cash flows from operations of firm i in year t; $Sales_{i,t}$ = sales revenues of firm i in year t; $Ass_{i,t-1}$ = total assets of firm i in year t-1; $Prod_{i,t}$ = costs of goods sold + change in inventories; and $Disexp_{i,t-1}$ = advertising expenses + research and development expenses + selling, general, and administrative expenses of firm i in year t. As with Roychowdhury (2006) and Cohen and Zarowin (2010), we control for sales and change in sales for the current period, as they are the innate determinants of the current period's CFO, with larger sales and higher sales growth associated contemporaneously with more CFO. Any deviation from the two determinants is attributed to real activities manipulation by managers. Because real earnings management in terms of overproduction (reduction of discretionary expenses) has a negative (positive) impact on contemporaneous abnormal CFO too, we also include production costs and discretionary expense in Model (5). It is

expected that α_1 and α_2 are positive and statistically significant at conventional levels, and that α_3 and α_4 are significantly negative. The abnormal CFO attributed to price discounts and/or grants of lenient credit terms is measured by the residual value (i.e., the actual value of $\frac{CFO_{i,t}}{Ass_{i,t-1}}$ minus the predicted value of $\frac{CFO_{i,t}}{Ass_{i,t-1}}$) estimated from Model (5). The abnormal CFO being significantly negative denotes upwards real earnings management in respect of price discounts and/or grants of lenient credit terms.

Real earnings management in terms of overproduction would lead to abnormally high production costs. To estimate the abnormal production costs, we run the following regression model by industries and years, with at least 20 firms required of the sample for each year and industry (Dechow et al. 1998; Roychowdhury 2006):

$$\frac{Prod_{i,t}}{Ass_{i,t-1}} = \alpha_0 + \alpha_1 \left(\frac{Sales_{i,t}}{Ass_{i,t-1}} \right) + \alpha_2 \left(\frac{\Delta Sales_{i,t}}{Ass_{i,t-1}} \right) + \alpha_3 \left(\frac{\Delta Sales_{i,t-1}}{Ass_{i,t-1}} \right) + \varepsilon_{i,t} \quad (6)$$

Abnormal production costs of firm i at year t are equal to the residual value (i.e., the actual value of $\frac{Prod_{i,t}}{Ass_{i,t-1}}$ minus the predicted value of $\frac{Prod_{i,t}}{Ass_{i,t-1}}$ estimated from the regression model). Production costs comprise costs of goods sold and change in inventories, with the former (latter) positively associated with the current year's sales (with the current and previous years' sales growth) (Dechow et al. 1998; Roychowdhury 2006). Accordingly, we expect α_1 , α_2 , and α_3 to be positive and statistically significant at conventional levels. The rationale underlying this modeling is that production costs are innately determined by the sales and sales growth, and that any deviation from the innate determinants is attributed to real earnings management as to overproduction. Significantly positive abnormal production costs denote upwards real earnings management via overproduction by a firm.

Real earnings management via strategic reduction in discretionary expenditures would result in abnormally low discretionary expenses. To estimate the resulting abnormal expenses, we run the following regression model by industries and years, with at least 20 firms required of the sample for each year and industry (Dechow et al. 1998; Roychowdhury 2006):

$$\frac{Disexp_{i,t}}{Ass_{i,t-1}} = \alpha_0 + \alpha_1 \left(\frac{Sales_{i,t-1}}{Ass_{i,t-1}} \right) + \varepsilon_{i,t} \quad (7)$$

Abnormal discretionary expenses of firm i at year t are equal to the residual value (i.e., the actual value of $\frac{Disexp_{i,t}}{Ass_{i,t-1}}$ minus the predicted value of $\frac{Disexp_{i,t}}{Ass_{i,t-1}}$) estimated from Model (7). The current period's advertising expenses, research and development expenses, selling, general, and administrative expenses are incurred largely based on the previous period's sales revenues. The higher the sales for the previous year, the high discretionary expenses incurred for the current year. Therefore, we expect α_1 to be positive and statistically significant at a conventional level. A significantly downward deviation from the innate determinant of discretionary expenses (i.e., sales lagged for 1 year) is attributed to managers strategically cutting down on discretionary expenditures for the purpose of propping up reported earnings.

Lastly, we may aggregate the three real earnings management measures into one proxy either by subtracting the abnormal discretionary expenses and the abnormal CFO from the abnormal production costs, or by using common factor analysis to construct a composite measure.

In addition to the foregoing regression analysis, we may use various red flags regarding abnormal accounting changes to appraise potential earnings management by a firm. We summarize a host of red flags, which can be commonly used in practice, in Table 2.

It should be noted that the red flags might be merely reflective of a firm's changed business strategies and/or circumstances, rather than attributed to earnings management motives. For example, a firm which has abnormal increases in its inventories relative to sales might have been introducing a new, better product or product line, rather than overproducing the existing type of products. Abnormal decreases in the allowance for uncollectible receivables relative to sales might be due to a firm changing customer base in ways that cover more financially healthy customers, rather than the firm understating its allowance for uncollectible receivables. Thus, it is important to appraise a firm's potential red flags in the context of its business strategies and/or circumstances. When a firm has high business risk, it will be difficult for us to distinguish whether red flags are attributed to unexpected changes in a firm's business conditions or to questionable accounting numbers. In such a case, we had better use the foregoing regression analysis rather than the red flags to assess the firm's accounting quality.

88.7 Introduction of Various Equity-Valuation Models

The intrinsic value of a firm or stock is determined based on the present value of expected future payoffs from the firm or stock to an investor. The future expected payoffs are discounted at a rate reflecting the time value of money and the uncertainty of these payoffs. The stock price which represents the market expectation of a firm's intrinsic value does not necessarily equal the value of a stock at any point in time. Therefore, analyzing whether and to what degree the stock price deviates from its intrinsic value provides a reliable basis for investors and financial analysts to assess the investment potential of a firm or stock. Investors could gain by buying (selling) the stock if its price is lower (higher) than its intrinsic value. However, unlike the observable price, the value of a firm is invisible and can only be estimated. To this end, we need to first identify what kind of information is relevant to, and has implications for, the present value of the expected future payoffs, and then utilize the value-relevant information to forecast the future payoffs from the firm. Depending on how the payoffs are measured, four primary equity valuation models can be used: (i) dividends valuation model (DVM) which requires forecasts of future dividends (e.g., Gordon 1962), (ii) residual earnings valuation model (or abnormal earnings valuation model (AEVM)) which requires forecasts of future residual earnings (e.g., Edwards and Bell 1961; Peasnell 1982), (iii) free cash flows valuation model (FCFVM) which requires forecasts of future free cash flows (e.g., Damodaran

Table 2 Red flags on different types of earnings management

Types of earnings management	Red flags
Accelerated recognition of revenues	An abnormal increase in credit sales or trades receivable towards the end of the year
Understatements of allowance for doubtful receivables or loan losses	An unusual increase in trades receivables relative to sales increases; significantly growing days' receivable; business downturns for a firm's major customers; significantly growing loan delinquencies
Understatements of pension and postretirement obligations	An abnormally large or increasing pension deficit (i.e., the case in which the funds set aside in the pension benefit plans are significantly less than the pension obligations)
Capitalization of expenditures which should otherwise be expensed	A substantive decline in relevant operating asset turnover ratio
Delayed write-down of current operating assets such as inventories	An unusual increase in inventories relative to sales increases; significantly growing days' inventory; significant write-down of inventories by noncompetitors in the same industry; business downturns for a firm's major clients
Delayed write-down of long-term operating assets	A substantive decline in the long-term operating asset turnover ratio; declines in return on assets (return on equity) to a level lower than the weighted average cost of capital (cost of equity capital); significant write-down by noncompetitors in the same industry which have also suffered from deterioration of long-term operating assets; overpayments for, or unsuccessful, mergers and acquisitions
Understatements of depreciation or amortization on long-term operating assets	An unusual decrease in the overall depreciation (amortization) rate of long-term (in)tangible operating assets; a substantive decline in the long-term operating assets turnover ratio
An inflation of overall operating accruals	Operating accruals of a firm is abnormally higher than the industrial average/median of operating accruals; an abnormal increase in the gap between a firm's reported earnings (operating income) and its cash (cash flows from operations)
Acceleration of the timing of sales in terms of increased price discounts or more lenient credit terms	A significant reduction in the gross profit margin ratio; an abnormal increase in trades receivables relative to sales
Reduction of costs of goods sold through overproduction	Production costs of a firm are abnormally higher than the industrial average/median of production costs; an abnormal increase in production costs
Reduction of discretionary expenses (e.g., advertising, research and development, maintenance and repair, and other SG&A expenditures) that would benefit a firm in the long run	Discretionary expenses of a firm are abnormally lower than the industrial average/median of discretionary expenses; an abnormal decrease in discretionary expenses

2002), and (iv) residual operating income valuation model (ROIVM) (or abnormal operating profits valuation model (AOPVM)) that requires forecasts of future abnormal operating profits. The forecasts involving the application of the four valuation models are based on the value-relevant information, which comes primarily from the audited financial statements.

Dividends are the primitive form of shareholder payoffs, as they represent the income received by shareholders for holding a firm's stocks. Nonetheless, to maintain a clean surplus relationship (i.e., change in book value of equity for shareholders equals earnings after dividends) for accurate valuation of the shareholders' equity, the dividends used in the valuation model encompass all cash flows distributed from the firm to shareholders through not only regular dividend payments but also liquidating dividends, stock repurchases, and the stock issuances in which cash collected from shareholders are considered as negative dividends. In applying the dividend valuation model to value a firm's stocks, we discount all the expected future dividends to their present values over the expected life of the firm in the following way (e.g., Gordon 1962):

$$V_0 = \frac{D_1}{(1 + \rho_E)} + \frac{D_2}{(1 + \rho_E)^2} + \dots = \sum_{t=1}^{\infty} \frac{D_t}{(1 + \rho_E)^t} \quad (8)$$

where V_0 is the intrinsic value of a firm or stock, which refers to the present value of expected future payoffs measured by net dividends; and D_t refers to net dividends, computed as cash dividends minus cash from share issuances plus cash from share repurchases, and representing overall net cash flows to shareholders. D_t and V_0 can be either net dividends per share and equity value per share, respectively, or net dividends and equity value, respectively. ρ_E is the cost of equity, which is computed as: $r_f + (r_m - r_f) * \beta$, where r_f is the risk-free rate, $r_f - r_m$ is the market risk premium, and β is the firm's beta. Before being used as the discount rate for the model, ρ_E needs to be adjusted for the effect of any potential accruals-based earnings management (denoting high information risk), of any significant change in the firm's liquidity and solvency positions, and of any substantial change in operational risks of the firm, in the current period as well as the foreseeable future. This adjustment also applies to the discount rate used for the other three valuation models.

Dividend valuation model measures shareholder payoffs by the cash distribution in the form of dividends paid by the firm to shareholders. Free cash flows (i.e., cash flows that are available for distribution to shareholders and debtholders after capital expenditures on investments and operations) can also be used to measure the expected shareholder payoffs for the valuation of a firm or stock. In such a case, the free cash flow valuation model should be used, with the firm's value estimated as (e.g., Damodaran 2002):

$$V_0 = \frac{FCF_1}{(1 + WACC)} + \frac{FCF_2}{(1 + WACC)^2} + \dots = \sum_{t=1}^{\infty} \frac{FCF_t}{(1 + WACC)^t} \quad (9)$$

where V_0 is the intrinsic value of net operating assets, including equity and debt, of the firm; and FCF is free cash flows, calculated as cash flows from short-term

operations before interests and after taxes (CFO) minus capital investments (CI). Free cash flows can also be calculated as net operating profits after taxes and before interests (NOPAT) minus change in net operating assets (ΔNOA), and in specific as: [net income + (after-tax interest expense – after-tax interest income)] – { $\Delta\text{working capital} + [(\text{expenditures for noncurrent operating assets} - \text{sales of noncurrent operating assets}) - \text{depreciation and amortization expense}]$ }. Since free cash flows are for distribution to both shareholders and debtholders, the discount rate we use to divide the free cash flows is the weighted average of the cost of equity and cost of debt, expressed as follows:

$$WACC = \frac{\rho_E * E + \rho_D * (1 - T_c) * D}{E + D} \quad (10)$$

where ρ_E is the cost of equity; ρ_D is the cost of debt which is calculated as net interest expense before taxes (NIE) divided by net debt (ND) (also named net financial obligation). If net financial assets are larger than net financial obligation, or if interest income is larger than interest expense, NIE/ND of an industrial peer firm that has the same credit rating as the firm being valued could be used as the alternative proxy for the firm's expected cost of debt (ρ_D); T_c is corporate income tax rate; E is the book value of equity; and D is the book value of debt.

Earnings are a summary measure of firm performance and thus form an essential basis for investors to make investment decisions (e.g., Biddle et al. 1995; Francis et al. 2003; Graham et al. 2005). It is thus reasonable for valuers to use future earnings as a proxy for the future payoff that an investor expects to get from the firm. Accordingly, we have the residual earnings valuation model (e.g., Edwards and Bell 1961; Peasnell 1982), in which the value of a firm is estimated based on the future residual earnings as follows:

$$V_0 = B_0 + \frac{AE_1}{(1 + \rho_E)} + \frac{AE_2}{(1 + \rho_E)^2} + \dots = B_0 + \sum_{t=1}^{\infty} \frac{AE_t}{(1 + \rho_E)^t} \quad (11)$$

where ρ_E is the cost of equity; B_0 is the book value of common shareholders' equity at the point of doing the equity valuation; V_0 is the intrinsic value of a firm's equity and represents the present value of expected future shareholder payoffs measured by residual earnings; and AE_t is the residual earnings, also known as residual income or abnormal earnings, at year t, and is computed as: $E_t - \rho_E * B_{t-1}$. An alternative way of writing AE and Model (11) is (e.g., Ohlson 1995; Lee et al. 1999):

$$V_0 = B_0 + \sum_{t=1}^{\infty} \frac{(ROE_t - \rho_E) * B_{t-1}}{(1 + \rho_E)^t} \quad (12)$$

where $ROE_t = \frac{E_t}{B_t}$ is the return on equity, representing the expected return on the book value of equity in year t. Model (12) suggests two key value drivers, which are return on equity (ROE) and growth in equity (as reflected in B_t relative to B_{t-1}); when the

expected return on equity is larger (smaller) than the cost of equity, the firm will experience value-added (–destroying) growth.

The residual earnings valuation model values a firm on the basis of the book value of equity with any excess of required earnings added to the book value, and emphasizes the excess earnings created from the equity. It is worth noting that financial activities do not create value for a firm, if financial assets are traded at a fair price, and if this trading does not pertain to a firm's main business. Therefore, it is important to distinguish the operating activities (inclusive of investing activities) from financing activities for valuation purposes. Given that value is created primarily from operating activities, it is reasonable to measure the expected payoffs from a firm by the residual income from net operating assets, namely, residual operating income. Accordingly, we have the residual operating income valuation model expressed as:

$$V_0 = NOA_0 + \sum_{t=1}^{\infty} \frac{AOP_t}{(1 + WACC)^t} \quad (13)$$

where V_0 is the intrinsic value of net operating assets, including equity and debt, of the firm; NOA_0 is the net operating assets at the point of doing the asset valuation; WACC is the weighted average cost of capital, defined as previously; and AOP is the abnormal operating income, also known as residual operating income. It is defined as: $AOP_t = NOPAT_t - WACC * NOA_{t-1}$, where NOPAT refers to the net operating profits after taxes and before interests, and equals net income plus after-taxes net interest expenses. An alternative way of writing AOP and Model (13) is as follows:

$$V_0 = NOA_0 + \sum_{t=1}^{\infty} \frac{(RNOA_t - WACC) * NOA_{t-1}}{(1 + WACC)^t} \quad (14)$$

where $RNOA_t = \frac{NOPAT_t}{NOA_{t-1}}$, representing the expected return on net operating assets at year t . A firm will add (lose) value in year t in which the expected return on net operating assets is larger (smaller) than the weighted average cost of capital.

The dividends valuation model and residual earnings valuation model value the equity of a firm, while the free cash flows valuation model and residual operating income valuation model value the assets of a firm. So, when using the latter two models, the estimated value of net operating assets needs to be further deducted by the market value of net financial obligation, which approximates its book value due to the fixed interest income/expenses stipulated in the debt contracts, to get the value of the firm's equity.

Equity valuation is done by way of estimating the present value of expected future payoffs from investing in the stocks of a firm. Which of the four valuation models will be the best for use in the valuation depends critically on which form of future payoffs is best-founded yet easiest to forecast. Future dividend payouts depend on future cash adequacies, future investment opportunities, future operational needs, and future debt repayments. Future free cash flows hinge on future cash adequacies,

future investment opportunities, and future operational needs. Forecasts of future residual earnings involve forecasts of future financial obligations such as future interest income or expenses and future financial leverage. Future abnormal operating profits rest exclusively with the future operational activities and performance, from which firm value is created. Therefore, the residual operating income valuation model offers the most reliable and scientific ground on which to estimate the intrinsic value of a firm in a relatively accurate manner, compared with the other three valuation models. Below we set forth more details on the application of the residual operating income valuation model.

The residual operating income valuation model anchors the expected shareholders-and-debtholders payoffs on future residual operating income that is fundamentally determined by three main factors. First is a firm's competitive advantage established via differentiation or cost-leadership strategies and against industrial competitive forces or threats. Second is the industrial growth rate which reflects the growing market demand for a firm's products or services. Third is the rate of return required by capital providers, which will be reduced if the uncertainty of future payoffs in terms of business risk, information risk, or market risk decreases. AOP in year t can be expressed in an alternative way as: $AOP_t = NOPAT_t - WACC * NOA_{t-1} = NOPM_t * sales_t - WACC * \frac{sales_t}{ATO_{t-1}}$, where NOPM is the net operating profit margin ratio, and ATO is the operating asset turnover ratio. As such, the forecast of future AOP can be transformed into a job of the forecasts of future sales, NOPM, ATO, and WACC, which are grounded on analyses of a firm's sales performance, operational efficiency, investment efficiency, and financing, respectively.

To facilitate accurate valuation under the residual operating income valuation model, we typically take three steps to forecast future AOP. First, we choose a finite forecast horizon (usually, 5–10 years) within which the specific trends of future sales, NOPM, and ATO can be reasonably forecasted. Second, we forecast future sales, NOPM, and ATO at the chosen forecast horizon. These forecasts should be made based on (i) the analyses of a firm's business strategies and industrial competitive forces, (ii) time-series and cross-sectional analyses of historical sales, NOPM, and ATO, and (iii) real earnings management, if any. Third, we make some simple assumptions for our long-term forecasts of AOP at years after the end of the chosen forecast horizon. For instance, if we believe that the firm can enlarge its abnormal profits beyond the short run, we may make a simple assumption that, after the end of the forecast horizon, AOP will grow at a constant rate (which we term terminal growth rate) in perpetuity. We then refine the residual operating income model as:

$$V_0^{NOA} = NOA_0 + \frac{AOP_1}{(1 + WACC)} + \frac{AOP_2}{(1 + WACC)^2} + \dots + \frac{AOP_T}{(1 + WACC)^T} + \frac{CV_T}{(1 + WACC)^T} \quad (15)$$

where V_0^{NOA} is the value of net operating assets, standing for the value of a firm to both shareholders and debtholders. The value of equity is then estimated via: $V_0^E = V_0^{NOA} - V_0^{NFO}$, where V_0^{NFO} is the value of net financial obligation. The subscript

T in Model (15) represents the number of years over the finite forecast horizon; CV_T is the continuing value beyond the chosen forecast horizon. Provided that AOP will grow permanently at a rate of g beyond the short-term forecast horizon, $CV_T = \frac{AOP_{T+1}}{WACC - g} = \frac{AOP_T * (1+g)}{WACC - g}$. On the other hand, if we assume AOP to be zero after the end of the forecast horizon, $CV_T = 0$; if we presume that AOP will remain constant and perpetual since the final year of the forecast horizon, $CV_T = \frac{AOP_{T+1}}{WACC} = \frac{AOP_T}{WACC}$. To facilitate more accurate forecasts of the terminal growth rate, we may further assume that, after the end of the finite forecast horizon, NOPM and ATO remain constant, and sales will grow at a constant rate or remain unchanged. Under such an assumption, AOP is a linear function of sales, thus the terminal growth rate in AOP equals the terminal growth rate in sales. As such, forecasts of the terminal growth in AOP are equivalent to forecasts of the terminal growth in sales, yet the latter will be more feasible for us.

After we apply the residual operating income model and estimate the equity value per share, we compare it with the stock price to aid in our investment decision-making. If the estimated equity value per share is significantly higher (lower) than the stock price, stock purchases (sales) are recommended. If the estimated equity value per share is insignificantly different from the stock price, it is advised to hold the stocks. Various risks which a firm is exposed to will make its future sales, ATO, NOPM, WACC, and terminal growth rate differ from the forecasted ones, increasing the uncertainty of, and error in, our forecasts and valuation. Thus, we need to perform sensitivity analysis in the meantime to see how sensitive the estimated equity value per share is to the changes in the forecast inputs across a certain range.⁷ Provided that the estimated equity value per share is highly sensitive to the forecast inputs and that we are uncertain about the accuracy of our forecasts, then a high upwards (downwards) sensitivity of the estimated equity value per share should lead us towards making buy (sell) decisions, *ceteris paribus*, while a high symmetric sensitivity should lead us towards holding the stocks, *ceteris paribus*. With all that said, the investment decisions made based on the foregoing analysis of fundamental values of stocks are premised on investors holding long-term investment horizons. If investors hold short-term investment horizons and seek to arbitrage on stock return anomalies, the fundamental value of stocks will be of less relevance for making profitable stock trades (He 2021).

88.8 How to Adjust for the Effects of Accruals-Based and Real Earnings Management in Equity Valuation?

Upwards accruals-based earnings management is just like borrowing future earnings for current use, thus earnings would be reversed and decline in the subsequent periods. Say, firms that delay writing-off assets in the current year would have to

⁷For example, if we speculate that the firm's liquidity and solvency positions will plausibly deteriorate in the near future, we need to first gauge the extent to which WACC will increase in consequence, and then estimate how large the estimated equity value per share will decrease as a result of the increase in WACC. On the other hand, if we are certain that the firm's liquidity and solvency positions will deteriorate, we should factor this into our estimation of discount rate (i.e., WACC) rather than in the sensitivity analysis.

write them off in the future years. In cases when we discern a firm's accruals manipulation in our valuation, we need to ensure that our forecast horizon is long enough (often at least 5 years and preferably 8–10 years) to allow accruals manipulation to play out by itself, even if the firm is in a mature industry with a well-established product line, stable prices of input products, robust production technologies, and stable market demand. Meanwhile, because accruals manipulation subjects a firm to a risk of detection and thereof to the related negative economic consequences, such risk needs to be factored into our estimation of the weighted average cost of capital (WACC) or into the test of the sensitivity of our estimated equity value per share to the WACC. Also, we need to adjust the weight we put on the current figures that are used in our forecasting.

Suppose we use the residual operating income model to value a firm's equity. If we spot that a firm has accelerated recognition of sales revenues in the current year, we should put less weight on the current sales revenues (current NOPM) that are used in the forecasts of future sales (future NOPM), and put more (less) weight on the current ATO that is used for forecasting future ATO if current ATO is higher (lower) than 1. If we detect an inflation of operating accruals via asset or liability distortion, we should put less (more) weight on the current NOPM (current ATO) when using it to forecast future NOPM (future ATO). Figure 1 illustrates how we should adjust the weight put on the current value-oriented figures when using them to forecast their future figures.⁸

Real earnings management subjects a firm to a relatively low risk of detection. As such, we don't need to adjust the discount rate (i.e., WACC) for the effects of real earnings management. However, unlike accruals-based earnings management, real earnings management that deviates a firm's optimal business strategies has negative real effects on a firm's future sales, NOPM, and ATO. Hence, our forecasts of future sales, NOPM, and ATO need to be adjusted downwards for the effects of the real earnings management; in the meantime, we need to put less weight on some of the current figures (i.e., sales and NOPM) used to forecast their future figures. Figure 2 portrays how to do these in the case when we use the residual operating income model to value a firm's equity.⁹

In specific, when we discern that managers have accelerated the timing of sales through giving increased price discounts or more lenient credit terms to customers, we should put less weight on the current sales that are used for forecasting future sales; then for the future sales forecasted based on current sales, we further adjust the future sales downwards. When we spot that a firm strategically reports lower costs of goods sold by virtue of overproduction, we should put less weight on the current NOPM that is used in the forecasts of future NOPM, and further, adjust the forecasted future NOPM downwards. When we discover the

⁸The same rationale and approach can be applied when we assess the role of downwards accruals manipulation in our forecasting and valuation.

⁹We may use the similar approach to assess the role the downwards real earnings management plays in the forecasting and valuation.

Fig. 1 Adjustment of accruals-based earnings management in equity valuation

Fig. 2 Adjustment of real earnings management in earnings management

strategic reduction of advertising, research and development, maintenance and repair, and other selling, general, and administrative expenditures that would benefit a firm in the long run, we do not need to adjust the current ATO that is used for the forecasts of future ATO, but we need to adjust our forecasted future ATO downwards.

What if we see through real earnings management that is achieved via nonrecurring business activities (e.g., asset sales, debt-to-equity swaps, sales of securities that should have been aimed for long-term investments)? We don't need to make any adjustments in our forecasting, provided that the current value-oriented figures (e.g., ATO, NOPM) used for the forecasting are purged of nonrecurring operating items.

The Applications of Machine Learning in Accounting and Auditing Research

89

Hanxin Hu and Ting Sun

Abstract

The term “machine learning” has become a buzzword in the past few years. In accounting and auditing area, while this technology has been used in major accounting firms such as Big 4 s, its research is still evolving. Increased use of machine learning and other artificial intelligence techniques will allow accountants to focus on providing better decision support instead of on data gathering and manual analyses. This chapter introduces machine learning as compared to traditional statistical modeling, discusses its current applications in accounting and auditing research, and provides directions for future research.

89.1 Machine Learning Technology

Machine learning is an application of artificial intelligence (AI) that enables computer systems to automatically learn patterns and regularities from historical data and improve from past experience without human intervention or adjust actions

(Alpaydin 2020; Expert.ai 2020). The identified patterns and regularities can help one make predictions for future unseen data, assuming that the future will not be much different from the past when the data was collected (Alpaydin 2020).

A machine learning model is created directly from data by an algorithm. It is often called by researchers “black box” because it cannot explain how input variables are being combined to make predictions in a way that humans can understand. Most machine learning models, however, are not designed with interpretability constraints. Instead, their goal is to make accurate predictions. In his book “Introduction to Machine Learning,” Ethem Alpaydin (2020) states that:

“We may not be able to identify the process completely, but we believe we can construct a good and useful approximation. That approximation may not explain everything, but may still be able to account for some part of the data. We believe that though identifying the complete process may not be possible, we can still detect certain patterns or regularities. This is the niche of machine learning.”

In 1949, Donald Hebb, in his book titled “The Organization of Behavior” (Hebb 1949), developed a model of brain cell interaction, which established a foundation for the development of machine learning. The AI pioneer, Arthur Samuel, first came up with the term “Machine Learning” in 1952 and popularized it. He invented the first computer program for playing checkers at IBM. The program was among the world’s first successful self-learning program (Wiederhold et al. 1990). Using the positions of the pieces on the checkerboard, he designed a scoring function that is capable of measuring the winning chances for each side. The checkers-playing program decides its next move by employing a minimax strategy, which eventually evolved into the minimax algorithm. It records all positions that have been shown and combines each position with the values of the reward function (Foote 2019). In 1957, Frank Rosenblatt related Donald Hebb’s model of brain cell interaction to Arthur Samuel’s machine learning concept and created the Perceptron, which was a simple classifier for image recognition in an artificial neural network. It was initially designed for IBM 704, a 5-ton computer with the size of a room. With perceptions, IBM704 can learn by itself to distinguish punch cards marked on the left from those marked on the right. Rosenblatt (1957) called it “a machine capable of perceiving, recognizing and identifying its surroundings without any human training or control (Lefkowitz 2019).” Due to the limitation of hardware and technology at that time, perceptions could not recognize many kinds of visual patterns such as human faces, then there were several years of stagnation of the neural network area until a resurgence during the 1990s (Foote 2019).

Machine learning regained its popularity because the intersection of computer science and statistics generated probabilistic approaches in AI in the 1990s. The basic idea behind it is that learning can be considered as inferring plausible models for explaining observed data and making predictions. Nevertheless, there is an uncertainty regarding which model is appropriate, given the observed data is uncertain. Likewise, predictions about future unseen data are uncertain. Probability theory provides a framework to represent and manipulate uncertainty about models and predictions (Ghahramani 2015), and, thereby, emerges as one of the principal approaches for machine learning, shifting the focus of this technology toward data-driven approaches (Provalis Research 2017).

With large-scale data available as well as the advances in computing and the rapid growth of data storage techniques, machine learning enters its golden eras in recent decades. Machine learning algorithms such as deep learning have been evolved to be capable of analyzing big data. As a highlight, DeepMind’s AlphaGo defeated a world champion of Go game, which is known as the most challenging classical game for AI because of its complexity.

89.2 Differences Between Machine Learning and Statistical Modeling

Machine learning is built upon statistics. While closely related to each other, machine learning and statistical modelling are distinct in many aspects. Table 1 summarizes major differences between them. The biggest distinction is the principal goal: machine learning models are developed to make accurate predictions whereas statistical modeling is designed for inference about the relationships between input variables (Healthcare.ai 2020). In other words, statistical modeling draws population inferences from a data sample, whereas machine learning identifies generalizable predictive patterns (Bzdok et al. 2018). While statistical modeling does make predictions, the accuracy of those predictions made by statistical modelling is lower than those generated by machine learning approaches. Similarly, certain machine learning models like Lasso regression provide high level of interpretability; nevertheless, others like support vector machine are very difficult to explain.

In contrast to statistical modeling such as linear regression, machine learning approach does not require the data to follow any prior assumptions about the underlying relationships between the variables, such as normality of residuals, homoscedasticity, linearity of residuals, no multicollinearity, etc. This feature enables machine learning to make more accurate predictions because data in the real word does not always follow those rigid assumptions.

Machine learning performs excellently with high-dimensional data sets. The bigger the data size, the higher the accuracy of predictions. For example, deep neural networks typically cannot make good predictions when the sample size is limited, but the prediction accuracy improves with the increase of sample size. In contrast, statistical models generally predict accurately on hundreds or even dozens of data points but improve little with the addition of more observations (Healthcare.ai).

In traditional statistics, we typically do not want to include too many variables to avoid issues like multicollinearity. We use techniques such as estimates of the variance inflation factor (VIF) to identify the multicollinearity. However, the

Table 1 Machine learning versus statistical modeling

	Machine learning	Statistical modeling
Purpose	Prediction	Interpretation
Assumptions	No	Yes
Data	Big data	Small data
Variables	Many	Few

predictive power of a machine learning model will not be affected by the existence of highly colinear variables. Furthermore, machine learning algorithms have mechanisms to rule out irrelevant information. For instance, support vector machine allows more predictors than features because the kernel trick used by the algorithm allows the system to operate solely on the inner product of those feature vectors.

89.3 Machine Learning Algorithms

Machine learning algorithms are considered the engines of machine learning due to automatically transforming a dataset into a model (Heller 2019). Implementing machine learning algorithms can efficiently extract information and detect significant patterns underlying the data (Shalev-Shwartz and Ben-David 2014). As illustrated in Fig. 1, five categories of learning algorithms exist, including supervised learning, unsupervised learning, ensemble learning, neural networks and deep learning, and reinforcement learning.

The running of supervised learning algorithms can be expressed as a mapping function $y(x)$ that takes a new observation x as the input and generates a predicted output y (Bishop 2006). In a supervised learning paradigm, the dataset is divided into three compartments: the learning (training) set, validation set, and test set, separately for developing machine models, tuning the parameters in models, and examining the models' generalization effects. According to the nature of outputs, supervised learning algorithms can be further partitioned into two types: regression and classification. The outputs are real values within the regression scenario, where the algorithms, such as linear and polynomial regressions, are commonly applied. For instance, the New York City Airbnb listing prices can be predicted by using regression algorithms.¹ Unlike the regression, the dependent variables of classification models (e.g., logistic regression, support vector machine, and Naïve Bayes classifier) are in the form of categories. Consider the MNIST database of handwritten digits² as a classification example, where the input variables are pixel values, and the output is the identity of digits.

By contrast with supervised learning, no outputs correspond to input variables under the circumstance of unsupervised learning (Shaw 2017). That is, it is employed to explore the potential patterns hidden in the data without prior labels. There are three types of unsupervised learning algorithms: clustering, association rule learning, and dimensionality reduction. The clustering techniques' insight is to group a part of data samples based upon the essential principle: maximizing the intraclass similarity and minimizing the interclass similarity (Chen et al. 1996). It can be used in the marketing campaign by categorizing customers with similar

¹The data source is <https://www.kaggle.com/dgomonov/new-york-city-airbnb-open-data>. In this application case, explanatory variables including room types, geographical availability, and the number of reviews per month are treated as the independent variables to predict prices.

²The data source is <http://yann.lecun.com/exdb/mnist/>

Fig. 1 The roadmap of machine learning algorithms

consumption behaviors and establishing appropriate segmentation strategies.³ Regarding the association rule learning that was initially developed by Agrawal et al. (1993), it attempts to capture meaningful associations and causal structure among items in the database (Zhao and Bhowmick 2003). One application for this kind of algorithms (e.g., Apriori association rule learning algorithm) is the construction of recommendation systems. For example, a customer has ordered diapers from the Amazon website; perhaps next time, powdered milk will be exhibited in his or her recommendation list due to the meaningful relationship between those two items mined by the association rule learning. As implied by the name, dimensionality reduction algorithms aim to reduce the number of predictors in the dataset but remain critical information in the meantime. This objective can be achieved either through feature selection or extraction (Khalid et al. 2014). Specifically, feature selection refers to the process where redundant and noisy attributes are filtered out, and the best subset of predictors are selected to represent the original high-dimensional dataset (e.g., backward or forward stepwise regression); while feature extraction, such as principal component analysis (PCA) and t-distributed stochastic neighbor embedding (t-SNE), involves several linear or nonlinear transformations of the original features to generate new attributes that contribute to latter learning tasks (i.e., classification or regression) (Khalid et al. (2014) and Van Der Maaten et al. (2009)).

The nature of the learning algorithms described above is searching a hypothesis space (i.e., training set) to find the best single learner (Dietterich 2002). Instead of only using one unique learner, ensemble learning combines the approximation results generated from multiple base learners (e.g., decision tree) (Zhou 2009). One of the effective and representative ensemble learning methods is bagging, in which each base learner is trained from a different bootstrap replicate of the learning set,⁴ and the final output aggregates their prediction results when predicting the numerical outcome and voting for the majority class (Breiman 1996). Relative to the single learner, ensemble learning usually achieves lower-generation errors on the previously unseen dataset, because they can partially overcome three problems afflicting the unique learning algorithm: the statistical problem,⁵ the computational problem,⁶ and the representation problem⁷ (Dietterich 2002).

³One of the examples in this domain is in <https://www.kaggle.com/vjchoudhary7/customer-segmentation-tutorial-in-python>. The task of this data set is to segment customers based on their behavioral related attributes by applying the K-means clustering algorithms.

⁴A bootstrap replicate is accessed by randomly sampling the training set with replacement. This operation will generate a new training set with size equal to that of the original one.

⁵The statistical problem means that the training set fails to provide adequate information to select one single learner within the circumstance that multiple unique learners can achieve the same accuracy on the training set.

⁶Searching for the best hypothesis (e.g., neural network) that fits in the training data may be computationally intractable.

⁷The approximations to the real target function, which are generated from single learners, may not be ideal.

In the recent two decades, neural networks and deep learning are increasingly popular for applications ranging from stock price prediction to face recognition (Anthony and Bartlett 2009). These methods are considered the branch of machine learning algorithms: obtaining a nonlinear approximation to the true target function by learning successive layers of significant representations (Chollet 2017). Compared with traditional supervised learning algorithms, neural networks and deep learning can more accurately capture intricate patterns underlying the large datasets with the implementation of back-propagation algorithms to update the internal parameters contained in every layer (Lecun et al. 2015). Particularly, convolutional neural networks dramatically contribute to speech recognition and visual object recognition; recurrent neural networks are universally used in the field of text processing (Lecun et al. 2015).

Finally, reinforcement learning attempts to “maximize a numerical reward signal by mapping situations into actions” (Sutton and Barto 2018). In other words, this subfield of machine learning algorithms allows the agent to determine the best subsequent strategies given the current status by learning interactive behaviors that maximize the reward (Shaw 2017). Dissimilar with supervised and unsupervised learning, these algorithms’ goal is neither to obtain the optimal data representation nor find the hidden structure on unlabeled datasets (Bishop 2006; Sutton and Barto 2018). In practice, they can be applied in contexts like autonomous driving and robotics (Sallab et al. 2017; Kober et al. 2013).

89.4 Applications of Machine Learning in Accounting Research

Machine learning has been increasingly integrated into empirical accounting research to gauge information content of accounting amounts and qualitative disclosures, evaluate the corporations’ bankruptcy or default risks, and enhance accounting estimates & fundamental analytics (Bertomeu 2020).

89.4.1 The Evaluation of Information Content

Machine learning algorithms excel at adopting a flexible approach to efficiently extract meaningful information from various data formats, including numerical attributes and raw texts. This intrinsic nature sheds light on the evaluation of information content. Barth et al. (2021) use the nonlinear learning algorithm CART (i.e., classification and regression tree) to examine the relationship between equity prices and accounting amounts (e.g., net income, equity book value, research and development expenses, etc.). They discover that CART’s out-of-sample performance significantly outperforms that for the traditional linear regression model, suggesting that accounting amounts tend to map into future cash flows and equity prices nonlinearly. By comparing the model’s explanatory power over calendar years, this study contradicts the conclusion generated from prior research that the relevance between accounting information and equity prices gradually decays with the new economy’s development in the recent five decades.

Instead of focusing on quantitative accounting information (e.g., accounting amounts shown in financial restatements), some researchers derive insights from qualitative disclosures, such as the company's annual reports, earning call conference transcripts, and analyst reports. However, manually analyzing and classifying substantial amount of raw textual data are incredibly strenuous (Van Den Bogaerd and Aerts 2011). In this sense, machine learning algorithms are efficient and convenient in extracting meaningful information from voluminous texts. Li (2010) construct a Naïve Bayesian classifier to identify the tone of forward-looking statements (FLS) in the Management Discussion and Analysis section (MD&A) of 10-K and 10-Q reports. Even though the conditional dependence assumption behind this learning algorithm does not align with reality, the prediction accuracy yielded from cross validation is 67%, saliently better than random guessing. This chapter demonstrates the informativeness of MD&A by discovering the positive association between the average tone of the FLS and future earnings performance. Note that the author also uses dictionaries to obtain the tone but fails to forecast the company's future performance, indicating that machine learning algorithms may process corporate filings better than the traditional dictionary approach. Analogous to Li (2010), Huang et al. (2014) also exploit Naïve Bayesian to predict the opinion (i.e., positive, negative, and neutral) at the sentence level, yet based on another corpus analyst reports. This chapter demonstrates that after controlling the effects of quantitative items derived from analyst reports (e.g., earnings forecasts and stock recommendations), investors react significantly to qualitative information contained in this corpus. Concentrating on the qualitative disclosures of MD&A, Frankel et al. (2016) build a support vector regression (SVR) model to predict firm-level accruals given the occurrence frequency of the entire one- and two-word phrases used as independent variables. After incorporating this numerical output into the accrual model (Dechow and Dichev 2002), they find that the explanatory power of the modified model augments by around 24.8%, reflecting that the information content in MD&A interprets accruals in a way distinguished from that of Dechow and Dichev (2002) model.

Li (2010), Huang et al. (2014), and Frankel et al. (2016) all employ supervised learning techniques to obtain the real functions' approximations and predict the target labels or numbers. Nevertheless, manually labeling outcomes in the training set is time-consuming and vulnerable to programmers' subjective judgments (e.g., the taxonomy of risk factors disclosed on 10-K reports varies from person to person) (Bao and Datta 2014). Aiming at mitigating these issues, some other studies apply unsupervised learning algorithms to unravel the underlying structure of textual data. Huang et al. (2018) employ a Bayesian-parametric topic model latent Dirichlet allocation (LDA) to compare the thematic contents of conference call transcripts with those discussed in analyst reports instantly released after calls. Two critical findings of this study establish both the discovery and interpretation roles played by analyst reports during the information intermediary process: (1) investors significantly and economically react to the new and exclusive topics covered in analyst reports, especially when managers are confronted with greater incentives to conceal value-relevant information (e.g., undergoing undesirable financial performance) in earning call disclosures; (2) within the contexts where earning calls are demanding in comprehensibility, the explanations offered in analyst reports are particularly valuable to investors. With the contextual

assumption that words appearing in one sentence only refer to one risk factor, Bao and Datta (2014) modify the original topic model and implement a novel sent-LDA model to automatically capture risk categories embraced in section 1A of 10-K reports. This study then investigates whether and how risk perceptions proxied by stock volatilities respond to these risk-related disclosures. It is intriguing to observe that two-thirds of risk types exert insignificant influence (e.g., competition risks and volatile stock price risks). Only three informative risks related to systematic and liquidity risks tend to increase the risk perceptions of investors.

89.4.2 The Estimation of Bankruptcy or Default Risks

For credit risk management, there has been considerable research attempting to estimate the likelihood of bankruptcy or default events. Ohlson (1980) is one of the most seminal literature by applying the machine learning algorithm logistic regression to predict potential debtors' default probability. Afterward, a variety of more advanced learning methods are exploited in this domain to alleviate some unpreferable nature of logistic regression, such as (1) the incapability of capturing the nonlinear association between the target outcomes and predictors, (2) and the ineffectiveness when working on high-dimensional datasets. Table 2 summarizes representative bankruptcy or default prediction papers published in the recent three decades from the angles of dataset, dependent variables, predictors, machine learning algorithms, and out-of-sample performance. It is manifest that a wealth of studies emphasizes the improvement of model fitting by applying a wide range of machine learning algorithms (e.g., artificial neural networks, support vector machine, and ensemble learning methods) to achieve better prediction accuracy (Odom and Sharda (1990), Yang et al. (1999), Shin et al. (2005), Kim and Sohn (2010), Tsai et al. (2014), and Barboza et al. (2017)).

Nevertheless, this set of models is considered a "black box" due to the lack of transparency (Adadi and Berrada 2018). To mitigate this issue, Olson et al. (2012) employ the decision tree algorithm to generate interpretative rules during the bankruptcy prediction process. After controlling the decision tree algorithm's complexity,⁸ it can achieve a higher classification accuracy relative to support vector machine and artificial neural networks models.

It is worth noting that most literature shown in Table 2 solely uses quantitative financial items as the inputs of machine learning models. However, certain qualitative disclosures are also predictive of potential bankruptcy. Having complemented bankruptcy-relevant financial ratios with the token count vectors derived from MD&A sections, Cecchini et al. (2010a) find the prediction accuracy saliently improves.

⁸"Complexity" means that the decision tree model generates a plethora of rules, resulting the overfitting issues.

Table 2 Summary of the papers

Paper	Dataset	Dependent variables	Independent variables	Algorithms	Out-of-sample performance
Odom and Sharda (1990)	Moody's Industrial Manuals	Whether the firm went bankrupt between 1975 and 1982	Five financial ratios used by Altman (1968)	Artificial neural networks with three layers	ANN can achieve a consistently high true positive rate ^a with varying class ratio.
Yang et al. (1999)	US oil and gas industry data	Whether the firm went bankrupt between 1984 and 1989	Five financial ratios used by Platt et al. (1994)	Probabilistic neural networks with four layers	Neural networks have the best performance concerning the overall classification accuracy, but not in Type II errors ^b .
Shin et al. (2005)	Provided by Korea Credit Guarantee Fund	Whether the firm went bankrupt or not between 1996 and 1999	Ten financial ratios including total asset growth and contribution margin	Support vector machine and back-propagation neural networks with three layers	As the size of the training set gets smaller, SVM has higher classification accuracy than neural networks.
Kim and Sohn (2010)	Korean dataset	Whether small and medium enterprises defaulted or not between 1997 and 2002	Eight attributes of small and medium enterprises; 9 financial ratios; 16 technology evaluation factors; 10 economic indicators	Support vector machine, back-propagation neural networks with three layers, and logistic regression	SVM has the highest classification accuracy among the three learning algorithms.
Olson et al. (2012)	Compustat, LexisNexis databases	Whether the firm went bankrupt between January 2006 and December 2009	Sixteen financial items derived from prior research	Decision tree, support vector machine, back-propagation neural networks with three layers, and logistic regression	After controlling the complexity of the decision tree algorithm, it can achieve the highest classification accuracy.

(continued)

Table 2 (continued)

Paper	Dataset	Dependent variables	Independent variables	Algorithms	Out-of-sample performance
Tsai et al. (2014)	Taiwan Economic Journal	Whether the firm went bankrupt	Ninety-five relevant financial ratios	Bagging and boosting ensemble learning with different base classifiers	Decision tree ensemble by boosting outperforms other models according to prediction accuracy.
Barboza et al. (2017)	Compustat, NYU's Salomon Center databases	Whether the firm filed for bankruptcy between 1985 and 2014	Eleven quantitative financial items used by Altman (1968) and Carton and Hofer (2006)	Logistic regression, artificial neural networks, support vector machine with different kernels, boosting, bagging, and random forest	Random forest generates the highest AUC ROC score ^c compared with other algorithms.
Cecchini et al. (2010a)	Edgar, Compustat/CRSP databases	Whether the firm filed for bankruptcy between 1994 and 1999	The token count vectors generated from MD&A sections, financial items used by Altman (1968) and Beneish (1999)	Support vector machine	After merging the quantitative items with textual information, the prediction accuracy of bankruptcy improves.

^aTrue positive rate is defined as the likelihood that the actual positive instances (i.e., bankruptcy cases in this chapter) will test positive.

^bType II errors produce false negatives, where the bankrupt firms are wrongly classified into the non-bankruptcy group.

^cThe area under the curve (AUC) measures the performance of classification models at various cut-off settings.

89.4.3 The Enhancement of Accounting Estimates and Fundamental Analytics

By exerting the predictive role, machine learning algorithms can support judgments and decision-making processes (Cho et al. 2020). Specifically, they inherently fit in the contexts of accounting estimates and fundamental analytics, in which the likelihood of manager manipulation or subjective judgments is non-trivial. Grounded upon the data obtained from the insurance industry, Ding et al. (2020) apply four kinds of machine learning algorithms (i.e., linear regression, random forest, gradient boosting regression, and artificial neural networks) to

predict the amount of loss reserves. This study shows that compared with managers' subjective estimations, the approximations generated from machine learning algorithms are closer to real loss reserve values. To alleviate the problem that the out-of-sample performance of traditional regression models in predicting profitability does not significantly outperform that generated from random walking, Anand et al. (2019) use the random forest learning algorithm to forecast the directional changes of five profitability proxies (i.e., return on equity, return on assets, return on net operating assets, cash flow from operations, and free cash flow). By incorporating a minimum number of independent variables into the classification model (i.e., the firm identifier, fiscal year, and the contemporaneous value of the target profitability measure), this study substantiates that machine learning algorithms can achieve better prediction accuracy than the random walking benchmark over forecast windows ranging from 1 to 5 years. This finding is meaningful to the improvement of fundamental analytics, where the profitability prediction is one of the key procedures.

89.5 Applications of Machine Learning in Auditing Research

In the context of auditing, researchers have explored various machine learning's applications in audit processes, detecting financial misstatements, predicting audit quality, and etc.

89.5.1 Auditing Processes

There are many possible applications of machine learning in audit procedure from planning to reporting. Using automation for large volumes of data both structured and unstructured can help delivering high-quality audits, which allows auditors to focus more on tasks that require higher level of human judgment. For example, advanced machine learning techniques such as deep learning can analyze unstructured data such as audit working papers to identify potential errors and risks. Sun (2019) focuses on deep learning technique and proposes a framework for applying it to all audit phases. The proposed framework identifies that deep learning has the capabilities of text understanding, speech recognition, visual recognition, and structured data analysis, which can be fit into the audit environment. It also illustrates that audit processes like substantive testing can be automated by deep learning through its functions of information identification and judgment support. Examples include examining business contracts, emails, recordings, or minutes of board meetings to collect audit evidence. The implementation of machine learning is leading the accounting profession to greater connectivity and transparency and as a result, greater stakeholder confidence (Sidhu 2019).

89.5.2 Financial Misstatements/Misreporting/Frauds

Predicting financial misstatements or frauds is another direction for the research of machine learning's applications in auditing. One of the early research is conducted by Cecchini et al. (2010b). Instead of using financial ratios, they analyze basic financial data to detect management frauds with support vector machine. A finance-specific kernel that constructs features from existing literature is developed to increase the power of the learning. The developed model outperforms the traditional fraud prediction models and is able to successfully identify 80% of the frauds and 90.6% of the nonfraudulent observations.

With a dataset consisting of 51 fraud observations and 15,934 nonfraud cases between 1998 and 2005, Perols (2011) compares the performance of six machine learning algorithms (i.e., artificial neural networks, support vector machine, decision tree, logistic regression, bagging, and Stacking) in detecting financial statement fraud. The results show that logistic regression and support vector machines outperform other algorithms. The research finds that six predictors are consistently important for all algorithms: auditor turnover, total discretionary accruals, Big 4 auditor, accounts receivable, meeting or beating analyst forecasts, and unexpected employee productivity. Based on the Perols (2011) dataset, Perols et al. (2017) increase the number of explanatory variables to 109. The variables are primarily derived from prior literature (i.e., Cecchini et al. 2010b; Dechow et al. 2011; Perols 2011). More than 10,000 prediction models are developed with three data analytics preprocessing methods. Their results indicate that two of these three methods improve fraud prediction accuracy by approximately 10%.

Recently, Bao et al. (2020), following Cecchini et al. (2010), use raw financial data items from financial statements of US public companies between 1991 and 2008. They apply ensemble learning to predict frauds and find that an ensemble learning model produces more accurate predictions relative to the two benchmark models (i.e., Dechow et al. 2011 and Cecchini et al. 2010b). Bertomeu et al. (2020) use the Audit Analytics Advanced Non-Reliance Restatement database to collect samples of material misstatements from 2001 to 2014. In total, the sample in this literature consists 3,599 misstatement observations and 54,354 Compustat observations, with financial ratios as predictors as well as a wide range of other variables from governance and auditing datasets, etc. The main machine learning algorithm is gradient boosted regression tree (GBRT), which is a regression method that explains the probabilities of misstatements. It finds that, as opposed to traditional methods, machine learning approaches improve the prediction accuracy of out-of-sample test. The literature also employs a number of alternative methods and documents that the classification algorithms generally perform well at predicting misstatements especially when the sample size is big enough.

On the same topic, Brown et al. (2020) focus on the thematic content of financial reports. They utilize Bayesian topic modeling algorithm to identify and quantify the topic content of 10-K filings spanning from 1994 to 2012 and document that this information is useful for predicting misstatements. This literature extends the

research stream by exploring the semantic meaning of management disclosure and how disclosure themes point to misreporting. Similar work includes Cecchini et al. (2010a), Goel et al. (2010), and Purda and Skillicorn (2015). They all use support vector machine to classify misstatements. Thanks to this technique, there is no need to require predefined word dictionaries and the results show that their models provide better prediction performance than prediction models and those based on quantitative financial measures.

89.5.3 Audit Quality

Audit quality is a complex problem and there are a variety of measures used by existing literature which generate mix results. Hu et al. (2020) propose a machine learning approach to measure audit quality by constructing “surprise” scores based on traditional proxies of audit quality: audit adjustments, nonclean audit opinions, and restatements. They assert that the proposed measure of audit quality is capable of capturing unobservable factors that drive audit quality because it is the difference between the predicted probability of an event (e.g., the issuance of a modified audit opinion) and the actual value. It is the first archival research applying multiple types of audit adjustments and utilizing a comprehensive characteristics of audit firms and individual audit partners in addition to financial variables for audit quality measuring. They demonstrate the application of the proposed audit quality measures for auditing research by examining the relationship between the constructed measure and audit failure.

Yang et al. (2020) implement the double machine learning (DML) approach that relies on machine learning methods to examine the Big N audit quality effect. They demonstrate that the gradient boosting method outperforms other machine learning algorithms (e.g., decision tree, random forest, and support vector machine) for DML. They apply the DML approach with gradient boosting to estimate the Big N effect and evidence that Big N auditors have a positive effect on audit quality.

Different from prior studies, Hunt et al. (2021) employ machine learning techniques to predict the likelihood of auditor switches using data samples from 2002 through 2016. They compare the accuracy of predictions generated by multiple machine learning models including gradient boosting, random forest, artificial neural networks, support vector machines, and logistic regression. The results show that gradient boosting consistently outperforms the other algorithms. They use the probability of switching auditors estimated by the gradient boosting model and investigate whether increased probability of auditor switches affect audit quality as proxied by misstatements and abnormal accruals. This chapter finds that lower audit quality among companies that are more likely to switch auditors but remain with their incumbent auditor.

89.6 Machine Learning Tools

There is a series of publicly available tools that effortlessly implement machine learning algorithms.

89.6.1 Scikit-Learn Module in Python

Aiming to bring machine learning to nonspecialists in programming, Scikit-learn is a python module that incorporates various machine learning techniques ranging from data preprocessing to supervised and unsupervised learning (Pedregosa et al. 2011). Examples, source codes, and documentation of specific learning algorithms can be found on the official website <https://scikit-learn.org/stable/>. When employing Scikit-learn to perform supervised learning tasks, the core method is fit, referring to training the machine learning models (e.g., decision tree classifier) based on data samples from the train set. After training, the predict method can infer the target labels or numerical outcomes of previously unseen data points. Concerning the unsupervised learning algorithms, such as K-means clustering, the transform method can be exploited to acquire the modified versions of data sets. Furthermore, Scikit-learn offers the cross-validation method⁹ to help users tune the parameters of machine learning algorithms and evaluate models' performance by using task-relevant metrics.

89.6.2 PyOD Module in Python

Recently, some outlier detection methods, such as isolation forest, local outlier factor, and one-class SVM, are incorporated into the audit process. These techniques empower auditors to analyze the entire ledger/transaction sets and find high-risk areas that deserve further investigation (Analyticsai 2020). PyOD is an open-source Python toolkit for identifying anomalies existing in multivariate data (Zhao et al. 2019). It embraces a wide range of outlier detection algorithms, from traditional K-nearest neighbors to the newly invented AutoEncoder. Researchers may use this toolbox to explore which set of outlier detection methods fits in the audit context.

89.6.3 TensorFlow Platform

Invented by the Google Brain team, TensorFlow is an open-source library that supports fast numerical computations. This toolkit can be applied in the construction of traditional machine learning and deep learning models.¹⁰

⁹For details of the cross-validation method, check the website: https://scikit-learn.org/stable/modules/cross_validation.html

¹⁰More details are presented on the website: <https://www.tensorflow.org/>

89.7 Conclusions: Perspectives for Future Research

The research on the applications of machine learning in accounting and auditing is still evolving. There are numerous promising areas that have not been explored. One of these areas is using machine learning to estimate uncollectable bad debts. The current method to determine the allowance for doubtful accounts is to estimate the percentage of receivable based on the age of outstanding accounts receivables or to use a percentage based on prior years' actual uncollectible accounts to prior years' credit sales percentage of sales. We are expecting a machine learning model trained with history data that describing the business, the auditor, the clients, as well as the economic and social environment to make better predictions.

While the vast majority of existing research is centered on the problem of financial misstatements or frauds, other topics are of great potential for the implementation of machine learning to improve the quality of financial information. Examples of those topics include material internal control weaknesses, real earnings management (i.e., management operational activities to change reported earnings in a particular direction by overproducing inventory to lower the cost of goods sold or cutting discretionary expenses to improve reported margins (Huang and Sun 2017)), and accrual-based earnings management deserve investigation (i.e., management actions of altering the accounting methods, such as the depreciation method for fixed assets, or estimates, such as the estimate for provision for doubtful accounts, used when presenting a given transaction in the financial statements (Zang 2012)).

We are now in the era of big data. Audit methodologies and practices need to be aligned with the development of cutting-edge technologies and make sufficient use of the exogenous data from a variety of sources to improve the effectiveness and efficiency of accounting work. Exogenous data refers to "data from third-party sources rather than internal accounting records of corporate entities (Brown-Liburd et al. 2019)." The exogenous data, such as posts on social media, location data collected from Internet of Things, weather data, and google search data, can be analyzed with machine learning techniques to extract informative data like the sentiment, topic, entity, and keywords. Future research can utilize those exogenous data as a supplement to endogenous financial data to develop prediction model to support audit decision-making.

To make the results understandable and transparent to humans, future research needs to take effort to explore the interpretability of "black box" models of machine learning. While feature importance (i.e., a technique for determining which variable(s) contribute(s) most strongly to a model's output) has been used frequently in prior studies, other techniques are rarely used in accounting and auditing literature to interpret the results. For instance, accumulated local effects (ALE) (Apley and Zhu 2020) provides global explanations for machine learning models by using an ALE plot to describe how features influence the prediction of the model on average. The Shapley value¹¹ is a concept in cooperative game

¹¹Shapley, Lloyd S. (August 21, 1951). "Notes on the n-Person Game -- II: The Value of an n-Person Game" (PDF). Santa Monica, Calif.: RAND Corporation.

theory,¹² which assigns a unique distribution (among the players) of a total surplus generated by the coalition of all players. When the Shapley value is used in machine learning, we assume that each value of the input variable for a given sample is a player in a cooperative game where the prediction is the payout. So Shapley value helps us explain how much each value of the input variable has contributed to the prediction compared to the average prediction (Roth 1988). Local interpretable model-agnostic explanations (LIME) can be applied to any machine learning model to help us understand the model by training local surrogate models¹³ to explain predictions for each single data sample. Specifically, it modifies a single data sample by adjusting the feature values and observes the resulting impact on the prediction.

Besides archival research, behavior studies can be conducted to explore questions like how the decision-making of humans affected by the implementation of machine learning technologies, to what extent human auditors rely on the results generated by machine learning models, what the performance of machine learning techniques is when they are adopted to conduct structured and repetitive tasks as opposed to unstructured tasks that need higher level of professional judgment, and how investors or other stakeholders perceive and evaluate the quality of financial reports if they know the reports are prepared/audited with the help of machine learning techniques.

Future research could discuss that the increased use of machine learning and other AI techniques will require human accountants to identify and manage risks with this technology through systematic governance and internal controls. It is also very important that future research examines the inherent bias in machine learning and how it can be addressed in practice. The bias comes from multiple sources, such as the data-driven bias due to the flaws or skewness in the data we collected for model training purpose and the interaction bias between human and machine as machines learn the biases of the people who train them (Hammond 2016). Furthermore, providing solutions to data privacy and security issues is another direction for future research. There is still a long way to go for machine learning applications in the context of accounting auditing. Scholars, practitioners, and policy-makers need to cooperate more closely to foster the development of the accounting profession with the help of innovative technology and provide guidance for the best use of machine learning to make accounting and auditing more effective and efficient.

¹²Read “Cooperative game theory assumes that groups of players, called coalitions, are the primary units of decision-making, and may enforce cooperative behavior.” (Choudhary 2019). <https://www.analyticsvidhya.com/blog/2019/11/shapley-value-machine-learning-interpretability-game-theory/>

¹³Local surrogate models are interpretable models that are used to explain individual predictions of black box machine learning models.

Internal Capital Budgeting and Allocation in Financial Firms

90

Woo-Young Kang

Abstract

Internal capital budgeting for financial firms differs from that for nonfinancial firms. Financial firms are highly leveraged, risk-sensitive, and possess limited equity capital to cover their illiquid risks compared to nonfinancial firms. Thus, some issues regarding internal capital budgeting – such as type of firm, financial shock, and capital budgeting methodologies – are somewhat different in case of financial and nonfinancial firms, while almost all their other characteristics including agency problem, optimal timing for capital budgeting, relative dependence on the external capital market, firm boundary, and market type remain near identical. Internal capital budgeting for financial firms aims to maximize their risk-adjusted performance measured by risk-adjusted return on capital (RAROC), return on risk-adjusted capital (RORAC), risk-adjusted return on risk-adjusted capital (RARORAC) and so on, leading to the maximization of shareholder value. On the other hand, internal capital budgeting for nonfinancial firms is largely affected by the traditional standard discounted cash flow (DCF) method. Financial firms are required to reflect regulatory capital requirements in their internal capital budgeting process, and using RORAC or RARORAC performance measures, which emphasize the risk component of capital, can be quite helpful for this.

90.1 Backgrounds of Internal Capital Budgeting

In the economy, a firm has access to two types of markets as its source of financing – external and internal. When a firm engages with the external capital market, it interacts with external capital suppliers such as the stock market, the bond market, financial intermediaries, etc. On the other hand, a firm interacting with the internal capital market tries to conduct its business with the headquarter, which allocates its limited capital to the business units it owns. Therefore, both the external and the internal capital market can be a source of capital for a firm and its business units (Gertner et al. 1994). However, there are certain problems that firms need to solve in order to efficiently utilize the internal capital market for capital budgeting, and a financial firm's approach to do so is very different from and more specific than that of a nonfinancial firm. This chapter aims to analyze the issues and approaches regarding internal capital budgeting for financial firms in comparison with those for non-financial or general firms.

Firms can create value through capital budgeting in the internal capital market. A firm's headquarters selects optimal investment projects from the various divisions and reallocates capital by moving it from relatively low-return projects to high-return projects or by using one division's assets as collateral to fund another division based on various criteria. These criteria include industry or business unit characteristics (e.g., Bardolet et al. 2011), desires for growth (e.g., Arrfelt et al. 2015), opportunities for creating synergies (e.g., Bower and Gilbert 2005), and need to reduce corporate risk to increase returns (e.g., Liebeskind 2000). There are three major motives behind the internal capital allocation according to Busenbark et al. (2017). First is the winner picking motive (e.g., Stein 1997), which selects and allocates capital to business units with the best performance prospects and maximize the overall firm growth (e.g., Arrfelt et al. 2015; Duchin and Sosyura 2013; Wulf 2009). Risk mitigation (e.g., Matvos and Seru 2014) is the second motive, which involves diversification. Corporate managers can allocate capital to their related or unrelated business units such that their firm can limit exposure to exogenous shocks to its business unit and/or maximize the variety of its product offerings (e.g., Lang and Stulz 1994; Liebeskind 2000; Shin and Stulz 1998). The third motive is the exploitation of synergies through leveraging and sharing of capabilities and assets across business units (e.g., Bower and Gilbert 2005). In other words, internal capital allocation may share, lend, and leverage resources, capabilities, and expertise among business units with disparate characteristics (e.g., Cremers et al. 2011; Williamson 1991).

Capital budgeting in the internal capital market depends on both the absolute and relative merits of the investment projects. For instance, if a company has two unrelated projects and the relative merit of investing in one of them is higher, this

implies that the investment in the other project, despite the fact that its net present value (NPV) may be positive, should decrease. Although important, the NPV is not the only relevant benchmark for internal capital budgeting decisions. There are also other important criteria that determine the budgeting decision, including the project's strategic fit, its cash flow structure, market share, past performance, and the business unit CEOs reputation, confidence, and gut feel behind the project (Graham et al. 2015; Glaser et al. 2013). The size and scope of the internal capital market also affects its value creation when there is a trade-off. If the size and scope of the internal capital market increases, the absolute amount of investment will increase as well. Consequently, financial constraints will loosen and a firm can raise more capital. However, a side effect of this is that the monitoring costs to the headquarters also increase and it becomes more difficult to select an optimal project (Stein 1997).

The capital budgeting of the internal capital markets has both bright and dark sides. The bright side views the internal capital allocation as a result of pooling internally generated cash flows optimally distributed to business units as funds determined by their investment prospects (Weston 1970; Williamson 1975; Matsusaka and Nanda 2002; Maksimovic and Phillips 2002), a necessary condition to make the right investments over time (Lovallo et al. 2020). This winner-picking process creates value by making more allocations to units with better investment opportunities (Stein 1997). On the other hand, the dark side views the hierarchy within a firm as disproportionately impacting internal policies and leading to inefficient capital budgeting decisions (Coase 1937). The business unit or divisions run by more powerful or better connected managers may secure more internal funding than their justified amount based on their investment opportunities and outlooks (Meyer et al. 1992; Scharfstein and Stein 2000; Rajan et al. 2000; Wulf 2009). These managers may prefer larger capital allocations for rent-seeking or empire-building purposes and exert more influence to secure more funds, which are costly and induce inefficient investment decisions for the firm (Glaser et al. 2013).

90.2 Issues Related to Internal Capital Budgeting

I start by discussing issues relevant to capital budgeting in the internal capital market derived from the extant literature in the context of general firms. These issues include the agency problem, optimal timing for capital budgeting, relative dependence on the external capital market, firm type, firm boundary, market type, financial shock, capital budgeting methodologies, etc. Many of these issues also relate to financial firms' internal capital budgeting, although they may still need some adjustments on account of their highly leveraged and risk-sensitive characteristics.

90.2.1 The Agency Problem

The agency problem is an internal capital budgeting issue that mainly comprises managerial issues and information asymmetry.

90.2.1.1 Managerial Issues

Managerial issues are a major part of the agency problem. In the internal capital market, the CEO's opinion of the divisional manager is the second most influential factor after the NPV rule (Graham et al. 2015). In other words, the power balance and connection between the CEO and divisional managers can distort the internal capital budgeting. Specifically, managers who have good relationships with their bosses receive more capital through the "appointment channel" or the "capital allocation channel." The appointment channel designates connected managers to divisions with more capital and, following this, connected managers receive more capital than other nonconnected ones through the capital allocation channel. The effect of the capital allocation channel is approximately two times greater than that of the appointment channel. However, these managers' connections with the CFOs or board members have a weaker effect on internal capital budgeting compared to those who have connections with CEOs (Duchin and Sosyura 2013). The misalignment of investment incentives between divisional managers and headquarters may result in inefficient investments, which may be either over or under investments (Lamont 1997; Shin and Stulz 1998; Rajan et al. 2000; Hund et al. 2010; Ozbas and Scharfstein 2010; Roper and Ruckes 2012). CEO duality can also be a source of incentive misalignment between the role as a CEO and a chair of the board. This may result in inefficient investments by allocating more capital to business units with low growth prospects over units with high growth prospects (Aktas et al. 2019), and CEO's equity-based compensation can ameliorate this negative impact (Datta et al. 2009; Aktas et al. 2019). The investment inefficiencies resulting from managerial power and connections occur especially in case of a firm-wide financial slack (Glaser et al. 2013).

There are also other agency problems related to managerial issues. These include insiders' voting rights exceeding their cash flow rights (Hoechle et al. 2012), managers' rent-seeking activities (Duchin and Sosyura 2013), empire building tendencies (Xuan 2009; Hoechle et al. 2012), over-confidence (Hoechle et al. 2012) or voluntary risk-adversity (Stoughton and Zechner 2007) from different risk appetites, the relationship between managers' incentives and compensation (Huang et al. 2012), managers' behavioral biases or cognitive limitations (Bardolet et al. 2011; Arrfelt et al. 2013), sociopolitical forces on managers within the organization (Bernardo et al. 2006; Xuan 2009; Glaser et al. 2013; Hoang and Ruckes 2015), etc.

90.2.1.2 Information Asymmetry

Information asymmetry is another major part of the agency problem. It is mostly caused by divisional managers' monopoly over business information such as changes in customer demands, the likelihood of market entry or exit, quality or pricing adjustments of competitors, and new technologies for product development. Information asymmetry among divisions can generate a coordination problem since all the divisions compete to receive capital budgets from headquarters as early as possible, simultaneously. It also affects the strategic behavior of headquarters when moving resources from divisions with a high degree of information asymmetry to divisions with more information transparency (Roper and Ruckes 2012). When external financial shock negatively causes some high-ability agents (or divisional managers) to

abandon their investment projects, other low-ability agents use this opportunity as shelter to hide their private information by delaying abandoning their poor investment projects until the high-ability agents abandon theirs (Grenadier et al. 2014).

90.2.2 Optimal Timing for Capital Budgeting

The optimal timing for capital budgeting has been discussed mostly in the context of real options. This includes competition among divisional managers for securing capital allocation, past financial shocks, investment-signaling incentives, and others. Competition among divisional managers affects the optimal time for capital budgeting. Divisional managers compete with each other to secure capital allocation as soon as possible, since headquarters would have a limited budget that all the managers would strive to secure as soon as possible, simultaneously. This results in a coordination problem resulting from uncertainty in investment opportunities and the actions of other divisions. Under conditions of such severe financial constraints, it is optimal to reduce the probability of significant capital allocation in the second period if a significant capital allocation takes place in the first period – this is known as the dynamic rationing policy (Roper and Ruckes 2012).

The traditional approach to achieve optimal timing in capital allocation for investment demonstrates the importance of “the option to wait” in the real-option context due to uncertainty regarding future shocks to cash flows. However, lessons from past financial shocks, called “option to learn,” is another way to determine the timing of investment. When a firm faces a financial shock and it is not yet clear whether it is temporary or permanent, it will want to wait to learn more about the nature of the shock. If the firm continues to see high cash flow in the next period, the past shock is likely to reflect a positive fundamental change. On the other hand, if it witnesses a decrease in cash flow, this past shock is more likely to be the result of temporary non-fundamental fluctuations (Grenadier and Malenko 2010).

The investment signaling incentives of internal managers also affect investment timing. It is to fool the outside investors and take advantage of the actual investment timing to maximize the inside managers’ profits. Internal managers display four different kinds of behavior depending on the scenario. First, when inside managers care about both the long-term performance of the company as well as its short-term stock price, they tend to invest early in order to fool the market into overestimating their investment project’s NPV and raising their stock price. Second, when a manager is a venture capitalist with a short track record, he or she will struggle to take the company public early, so as to establish a reputation and raise more money to fund the business. Third, if a manager attempts to take some of the cash flow from investment as his or her private benefit, he or she will delay the investment to signal that the investment project’s NPV is lower than it really is. In this manner, a manager can divert some allocated investments from headquarters for his or her own personal consumption. Fourth, inside managers have all the information on their investment projects, so they will delay the decision to invest to fool their rival firms into underestimating their investment projects (Grenadier and Malenko 2011).

90.2.3 Relative Dependence on the External Capital Market

The relative dependence on the external market affects the capital budgeting strategy of a company's headquarters as well as its various divisions. When the external capital market has more abundant cash flow than the internal capital market, a company's divisions seek more financing from the external capital market. As a result, the company's headquarters will reduce its capital charge. The divisional managers will try to take advantage of this reduced capital charge by receiving capital allocation from headquarters. Accordingly, these managers will exaggerate the returns of their investment opportunities to headquarters to receive more capital. This creates distortions in investment information, leading to inefficient capital allocation.

In contrast, when divisional managers seek more financing from the internal capital market than from the external one, headquarters will raise the capital charge to extract surplus from the divisional managers. In response, these managers will under-report their investment returns to avoid high capital charges, which perverts the investment information, leading to inefficient capital allocation (Stoughton and Zechner 2007).

Specifically, for financial firms, a contingent convertible (CoCo) bond is a very recent example of an external capital market source for financing, especially for financial firms. A CoCo bond is a fixed-income security that converts into equity or writes-down its principal when the pre-determined lower capital ratio threshold is breached (De Spiegeleer et al. 2014). Therefore, it is a source of equity for financial firms to protect themselves from bankruptcy and satisfy the financial regulation requirements at the cost of their relatively high coupon payments to their investors.

90.2.4 Type of Firm

A firm's capital budgeting process depends on what type of firm it is, e.g., public/private, listed/unlisted, levered/unlevered. In countries with well-developed stock markets, the capital budgeting of public listed firms is more effective, since their investments are more sensitive to growth opportunities compared to the investments of public unlisted and private firms. In these markets, public listed firms can benefit from investments, which may not be possible to undertake if they were public unlisted or private firms (Mortal and Reisel 2013). The amount of a firm's risky debt also affects its internal capital budgeting. A levered firm invests earlier than an unlevered firm, because the option to wait becomes less valuable as a higher debt level leads to a higher default probability in the absence of wealth transfers among the claim holders (Lyandres and Zhdanov 2010).

90.2.5 Firm Boundary

A firm's internal capital budgeting can be affected by its internal and external boundaries. A firm's internal research and development (R&D) activities in particular face significant information asymmetry between its headquarters and its various

divisions. The managers involved in the R&D process have significant soft information, which can be difficult to communicate. Besides, they may conceal unfavorable information that could possibly emerge during the research stage, resulting in inefficient internal capital allocation (Scherer 1999; Seru 2014). This can happen if the costs of providing incentives inside the firm are greater than the benefits of innovative research. However, the problem can be alleviated if the firm shifts its internal R&D activity to the external boundaries of the firm (Seru 2014).

90.2.6 Type of Market

A firm's capital budgeting can be affected by its market type – competitive or concentrated. In a competitive market, a firm must follow the critical rule of survival, which is to invest as early as possible to avoid losing the investment opportunity to its competitors. It is optimal to invest when the value of the additional capacity is larger than the investment cost by an amount that corresponds to the value of the option to wait. However, in a competitive market, the value of the option to wait diminishes more than the difference between the value of the additional capacity and the investment cost, which discourages waiting for investments. In a concentrated market, on the other hand, a firm will have higher values both in case of the option to wait for investment and investment in additional capacity compared to a firm in a competitive market. This relatively encourages waiting for investment than in a competitive market. A firm in a concentrated market gains a higher value from the investment of additional capacity compared to the existing value of future cash flows from its installed capacity (Aguerrevere 2009).

90.2.7 Financial Shock

Internal capital budgeting interacts with financial shock. For instance, changes in stock price that reflect financial shock can signal changes in investment opportunities in a firm, which in turn affects its capital budgeting across its investment projects. These investments become more sensitive to financial shock when the firms are more levered, have less cash and cash flow and have lower dividends (Ovtchinnikov and McConnell 2009). Financial firms facing a financial shock or a banking crisis can see a negative impact on their internal capital budgeting, which is worse in developed countries. This is because financial firms in developed countries will move their intangible assets to firms in less developed countries with globalization activities and cross-border characteristics (Fernández et al. 2013). Conversely, internal capital budgeting can also help mitigate the negative effect of a financial shock. However, this process involves a significant amount of corporate socialism. Too little capital is allocated to stronger divisions and too much to weak divisions, in relation to their actual productivities (Matvos and Seru 2014).

90.2.8 Capital Budgeting Methodologies

Most companies rely on traditional standard discounted cash flow (DCF) calculations to make investment decisions. DCF is also a necessary input for real option valuation (McDonald 2006). The real options approach to capital budgeting involves actively managing projects to enhance the value of capital investments (Mittendorf 2004) and greatly simplifies difficult valuation problems (McDonald 2006). There have also been other capital budgeting methods reflecting agency problems (e.g., as discussed in Sect. 90.2.1), external financing (e.g., Almeida and Wolfenzon 2005), etc.

However, financial firms are highly leveraged since they issue equity infrequently but have continuous access to debt capital (Stoughton and Zechner 2007) compared to nonfinancial firms. Thus, financial firms require capital budgeting practices to be linked with risk management functions (Froot and Stein 1998). In addition, as their businesses are credit sensitive and largely depend on default risks, risk capital (i.e., equity capital) is crucial for them (Perold 2005) and should be allocated (Erel et al. 2015). There are several major risk capital allocation methods, such as the Euler allocation principle, the Lagrange method, capital-loss distance minimization, etc., all of which aim to maximize return-to-risks like RAROC, RORAC, and RARORAC.

The Euler allocation principle allocates capital according to the risk contributions of each business unit to the overall financial firm. The risk contributions are calculated using partial derivatives of the risk measure with respect to the capital of each business unit (Tasche 2008). This principle is mostly used in the context of RORAC maximization, as seen in Tasche (2008), Buch et al. (2011), and others. The Lagrange method for capital allocation aims to determine the optimal capital that should be allocated in order to maximize the overall NPV, the adjusted net present value (APV), the economic value added (EVA), etc. These are subject to several optimality conditions (e.g., marginal NPV equals marginal cost of risk capital and default risk, cost of risk capital offset by the benefit of reduction in default risk, etc.) and are sometimes linked with managers' utility maximization (Stoughton and Zechner 2007; Erel et al. 2015). The capital-loss distance minimization method allocates capital to each business unit such that the allocated capital and the loss are sufficiently close to each other (Dhaene et al. 2012). Baule (2014) develops a risk capital allocation process using an internal sequential auction, which reflects the managers' diverging preferences in terms of empire building while using the marginal risk contribution as a basis for the allocation decision.

90.3 Internal Capital Budgeting of Financial Firms

For firms in a complete market, capital budgeting disregards frictions such as taxes, bankruptcy costs, agency costs, and information asymmetry. Modigliani and Miller's (1958) theory proves that the firm value is unaffected by the type of its financing sources (i.e., equity or debt) in such a complete market. However, in an incomplete

market, capital budgeting accompanies those frictions, while the choice of financing source affects the firm value. In the case of financial firms, the risk of investments is particularly emphasized, which requires risk-adjusted capital budgeting approaches and financing. In an incomplete market, financial firms typically face three types of friction that are more risk-stressed than those described in traditional finance theories (Stoughton and Zechner 2007), namely:

1. Debt is favored in comparison to equity up to a certain limit based on the risk of the underlying asset.
2. Equity capital must be raised before the investment information becomes available.
3. Regulators associate their risk-taking ability with the equity capital.

Consequently, a large portion of financial firms' assets may be more difficult for outside investors to value with higher uncertainty (or risk) compared to nonfinancial firms due to its intermediary role in the financial markets (Houston et al. 1997). This can create an additional layer of agency problems with the need for contracts and institutions to "monitor the monitor" (Diamond 1984).

Risk capital, which is also referred to as economic capital, represents the smallest amount of equity capital required to cover potential losses (Buch et al. 2011; Merton and Perold 1993; Perold 2005). It is crucial for financial firms to back up their obligations to the liability holders, as well as reducing debt overhang, risk shifting, and bankruptcy problems. However, attempts to meet such obligations are costly and limited, since they impose high monitoring costs on shareholders, while the return is subject to corporate tax (Erel et al. 2015). Thus, financial firms must manage their capital structure so as to source risk capital in the most efficient manner by considering how much risk capital to maintain and how much contingent capital to arrange (Perold 2005) in order to manage the frictions in an incomplete market. This issue is particularly important because regulators now impose stricter capital requirements on financial firms, with risk capital being the principal focus of such requirements. In this sense, efficient risk capital management on the part of financial firms represents the core solution to the problem of capital budgeting. This research study investigates the issue of risk capital budgeting through internal and external financing in financial firms, with a particular focus on banks.

Optimal risk capital allocation from internal financing processes is one of the key approaches to this problem. Risk capital must be allocated for financial firms to evaluate performance, make investment decisions, price products and services, and set compensation (Erel et al. 2015). Return-to-risk optimization from risk capital allocation protects and/or enhances shareholder value (Zaik et al. 1996). It redistributes the total (frictional or opportunity) cost of holding capital across various business lines in order to transfer the cost back to depositors or policyholders in the form of charges. Additionally, the allocation of expenses across business lines is necessary for financial reporting purposes (Dhaene et al. 2012). Capital supportive programs of the government may enhance the resource allocation within the internal structure of banks. For instance, Capital Purchase Program (CPP), the first and most

prominent initiative under Troubled Asset Relief Program (TARP) in the USA, has proven to be highly valuable when the banking system is under stress since the program participating banks have transferred more capital to their subsidiaries than the nonparticipating banks (Mukherjee and Pana 2018).

Previous studies provide a number of theories concerning the risk capital allocation of financial firms in terms of performance measurement and return-to-risk optimization (Buch et al. 2011). More specifically, there exist several strands of literature in this area, including the mathematical finance, insurance-linked, and financial economics contexts (Buch et al. 2011). However, only a limited number of practical solutions accompanied by empirical guidance on optimal internal risk capital allocation can be found in the literature including Kang and Poshakwale (2019). The need for a practical solution becomes increasingly important as financial firms strive to maximize their profitability and shareholder value under conditions of stricter financial regulations and market frictions.

90.3.1 Performance Measures for Financial Firms

There are three major types of performance measurements for financial firms – risk-adjusted return on capital (RAROC), return on risk-adjusted capital (RORAC), and risk-adjusted return on risk-adjusted capital (RARORAC). These are different names to refer to adding interest rate to the economic capital or subtracting the product of the capital costs and the economic capital (Buch et al. 2011). These concepts can be confusing, as clear from the fact that even in case of the identical return-to-risk concept, Bielefeld and Maifarth (2005) referred to it as RORAC while Matten (2000) used the term RAROC (Lampenius 2012). Although this study is based on Buch et al.'s (2011) RORAC maximization model, it is also valid for the three types of return-to-risk measures mentioned in that study. The formulae for each of these three return-to-risk measures are as follows (Zaik et al. 1996; Saita 2007; Lampenius 2012; QFinance 2017):

$$\begin{aligned} \text{RAROC} &= \frac{\text{Risk} - \text{Adjusted Net Income}}{\text{Economic Capital}} \\ &= \frac{\text{Revenue} - \text{Expenses} - \text{Expected Loss} + \text{Net Interest Margin of Capital Change}}{\text{Economic Capital}} \end{aligned}$$

$$\text{RORAC} = \frac{\text{Expected Return}}{\text{Risk} - \text{Adjusted Economic Capital}} = \frac{\text{Net Income}}{\text{Allocated Economic Capital}}$$

$$\begin{aligned} \text{RARORAC} &= \frac{\text{Risk} - \text{Adjusted Expected Return}}{\text{Risk} - \text{Adjusted Economic Capital}} \\ &= \frac{\text{Economic Value Added (EVA)}}{\text{Allocated Economic Capital}} \end{aligned}$$

The RAROC measure was the first to be used in the late 1970s by a group at Bankers Trust (Zaik et al. 1996). It adjusts the risk for the income in the numerator.

Therefore, it not only considers direct revenues and expenses but also considers expected loss and net interest margin from the change in the capital (e.g., transfer prices from allocations, charges for internal services, and overhead and tax allocations) (Zaik et al. 1996). On the other hand, RORAC adjusts the risk of the capital in the denominator to emphasize the riskiness in the capital instead of adjusting the return in the numerator as in the case of RAROC. Moreover, RORAC is the most suitable return-to-risk measure for the Euler allocation principle, which calculates the credit risk as stated by the Basel committee (Tasche 2008). RARORAC adjusts the risk from both the return and capital in the numerator and denominator, respectively. RARORAC outperforms RORAC in terms of risk-adjusted performance measures (RAPMs) but only minutely (Lampenius 2012). However, RARORAC is far more complex in its computation than RORAC. Thus, of the three, RORAC is relatively the most practical and suitable return-to-risk performance measure for financial firms, which emphasizes the risk components in capital, reflects the financial regulation, and is relatively easier to calculate.

90.3.2 The Regulatory Capital Requirement: Basel

Regulatory capital is the minimum capital requirement for financial institutions as imposed by the regulator. The main emphasis is on the equity capital that is its key element (Basel Committee on Banking Supervision 1988). The Basel Committee on Banking Supervision outlines its composition and calculation, which evolves over time. The committee was established by the G10 countries in late 1974 in response to the collapse of the Bretton Woods system, which led to huge foreign currency losses in 1973. It sets minimum regulation and supervision standards for banks; shares supervisory issues, approaches, and techniques; identifies current or emerging global financial risks, etc. Its members have gone up to 28 in 2014 (Basel Committee on Banking Supervision 2015).

90.3.2.1 Basel I

The Latin American debt crisis in the early 1980s heightened the concerns of the Basel Committee regarding the deteriorating capital ratios of the main international banks with international risks. To strengthen the stability of the international banking system and to remove the source of competitive inequality from the differences in national capital requirements, the *Basel Capital Accord* (1988 Accord) was released in July 1988 (Basel Committee on Banking Supervision 2015). This accord, also known as Basel I, required banks to maintain a minimum capital ratio of the total capital (i.e., Tier 1 capital + Tier 2 capital) to risk-weighted assets of 8% by the end of 1992 (Basel Committee on Banking Supervision 2015). The definitions of Tier 1 and Tier 2 capital were nearly identical until the release of Basel II, and they further changed it in Basel III. Tier 1 capital is composed of paid-up share capital/common stock and disclosed reserves, while Tier 2 capital comprises undisclosed reserves, asset revaluation reserves, general provisions/general loan-loss reserves, hybrid (debt/equity) capital instruments, and subordinated debt (Basel Committee on

Banking Supervision 1988). Later, the Basel Committee amended Basel I by additionally regarding market risk, unlike the existing accord that mainly focused on credit risk. Accordingly, they issued the *Market Risk Amendment to the Capital Accord* (Basel Committee on Banking Supervision 2015), which allowed banks to use internal models to measure their market risk, and they introduced Tier 3 capital consisting of short-term subordinated debt to support market risk (Basel Committee on Banking Supervision 1996). The risk-weighted asset calculation also changed in Basel III. In Basel I, five different risk weights were imposed on different categories of assets, as shown below, to determine the total risk-weighted assets in the firm (Basel Committee on Banking Supervision 1988; De Spiegeleer et al. 2014).

- 0%: Cash and OECD government debt
- 10%: Loans extended to domestic public-sector entities
- 20%: Loans given to banks incorporated in an OECD country
- 50%: Loans fully secured by a residential property
- 100%: Loans to the private sector, non-OECD banks, real-estate investments, etc.

90.3.2.2 Basel II

The Basel Committee continued to improve its accord by developing more risk-sensitive capital requirements to reflect the underlying risks and effectively address the financial innovation that had taken place in recent years (Basel Committee on Banking Supervision 2015). After almost 6 years of preparation, the committee released the *Revised Capital Framework* in June 2004 known as Basel II. The key elements of Basel I were retained in Basel II, such as total capital (i.e., Tier 1 capital + Tier 2 capital) requirement ratio to the risk-weighted assets of 8%. However, the following three pillars comprised the main revised frameworks in Basel II compared to Basel I (Wernz 2014; Basel Committee on Banking Supervision 2015).

1. The minimum capital requirements were developed and expanded upon compared with the standard rules in Basel I
2. Supervisory review of capital adequacy and an internal assessment process in an institution
3. More emphasis on the effective use of financial reports on the risk and capital structure of an institution to encourage sound banking practices

Through these three pillars, the Basel Committee aimed to achieve three purposes. Through the first pillar, the committee showed that it considered operational risk together with credit and market risks to quantify risks more precisely for accurate minimum capital requirement calculations. Through the second pillar, the committee strove to have banks use adequate internal risk assessment measures that can cover pension risk or goodwill risk in addition to the risks covered in the first pillar. Through the third pillar, the committee stressed the importance of reporting the risk and capital structure of banks (Wernz 2014; Basel Committee on Banking Supervision 2015). Moreover, Basel II uses the internal ratings-based (IRB)

approach to calculate the risk-weighted asset through the following formula (Basel Committee on Banking Supervision 2006).

$$\text{Correlation (R)} = 0.12 \times \frac{1 - e^{(-50 \times \text{PD})}}{1 - e^{(-50)}} + 0.24 \times \left[\frac{1 - (1 - e^{(-50 \times \text{PD})})}{1 - e^{(-50)}} \right]$$

$$\text{Maturity adjustment (b)} = (0.11852 - 0.05478 \times \ln(\text{PD}))^2$$

Capital requirement (K)

$$\begin{aligned} &= \left[\text{LGD} \times \text{N} \left[(1 - R)^{-0.5} \times G(\text{PD}) + \left(\left(\frac{R}{(1 - R)} \right)^{0.5} \times G(0.999) \right) \right] - \text{PD} \times \text{LGD} \right] \\ &\times (1 - 1.5 \times b)^{-1} \times (1 + (M - 2.5) \times b) \end{aligned}$$

$$\text{Risk-weighted assets (RWA)} = K \times 12.5 \times \text{EAD}$$

where PD is probability of default, LGD is loss given default, EAD is exposure at default, M is maturity, N(x) is the cumulative distribution function of a random variable according to standard normal distribution, and G(x) is the inverse cumulative distribution function of a random variable according to standard normal distribution (Wernz 2014).

90.3.2.3 Basel III

The Basel Committee still needed to strengthen its framework, which it attempted to do in Basel II. The global financial crisis of 2008 revealed that the banking sector had been mispricing credit and liquidity risks and had excess credit growth, poor governance, poor risk management and inappropriate incentive structures (Basel Committee on Banking Supervision 2015). Accordingly, the committee set out *Basel III: International framework for liquidity risk measurement, standards and monitoring* and *Basel III: A global regulatory framework for more resilient banks and banking systems* in December 2010, which revised and strengthened the three pillars laid out in Basel II. It also contained several innovations (Basel Committee on Banking Supervision 2015), as follows:

1. Capital conversion buffer: An additional layer of common equity to help protect the minimum common equity requirement that limits payouts of earnings when breached.
2. Countercyclical capital buffer: It restricts the participation of banks in system-wide credit booms to reduce their losses in credit busts.
3. Leverage ratio: The minimum amount of loss-absorbing capital relative to all banks' assets and off-balance sheet exposures regardless of risk weighting.
4. Liquidity requirements: (1) The liquidity coverage ratio (LCR) requires sufficient cash to cover the 30-day period of stress; (2) the net stable funding ratio (NSFR) is a longer term liquidity ratio meant to address maturity mismatches.

5. Additional proposals for systemically important banks: Requirements for supplementary capital, augmented contingent capital, and strengthened cross-border supervision and resolution.

The capital definition changes in Basel III are as follows: Tier 1 capital comprises Common Equity Tier 1 capital and Additional Tier 1 capital. The Common Tier 1 capital consists of common shares, stock surplus, retained earnings, other accumulated comprehensive income, and other disclosed reserves (Basel Committee on Banking Supervision 2011). Additional Tier 1 capital is part of the Tier 1 capital not included in the Common Equity Tier 1 capital. The additional Tier 1 capital is perpetual in nature, has the possibility of a coupon deferral at the discretion of the issuer, has coupons that should be paid out of distributable profits, is subordinated to senior and subordinated debt, etc. (De Spiegeleer et al. 2014). However, Tier 3 capital has been eliminated from Basel III. The risk-weighted capital calculation in Basel III is almost similar to Basel II, except that Basel III uses the additional multiplier 1.25 to the correlation parameter for regulated financial institutions with assets greater than or equal to \$100 billion and unregulated financial institutions regardless of their size (Basel Committee on Banking Supervision 2011). Among all the accords, Basel III is the strictest financial regulation used these days, which makes it tougher for financial firms to be more speculative in raising profits.

90.3.3 Economic Capital

Financial firms can also estimate their risk with their own internal risk models and derive their minimum required equity capital, known both as “risk capital” and “economic capital.” The risk measures and/or confidence levels of risk capital are different from that of regulatory capital. Financial firms are increasingly using economic capital, with rapid advances in risk quantification methodologies, the rising complexity and sophistication of financial portfolios and supervisory expectations to develop internal processes to assess capital adequacy beyond the regulatory capital adequacy guidelines that may not fully reflect the underlying risks. Economic capital is highly dependent on several factors – risk measures, confidence level, time horizon, risk aggregation method, etc. (Basel Committee on Banking Supervision 2009). These have been explained in further detail below.

First, a financial firm can choose between various risk measures, such as standard deviation, value-at-risk (VaR), expected shortfall (ES), and spectral or distorted risk measures, which can affect its economic capital calculation. There are several criteria for evaluating these risk measures – intuitive, stable, easy to compute, easy to understand, coherent, simple, and meaningful risk decomposition (Basel Committee on Banking Supervision 2009). Of these risk measures, VaR and ES are the most widely used, while each of them has its own advantages and disadvantages. VaR is easier to understand than ES but does not satisfy the coherence criteria. ES is coherent but relatively less easy to interpret than VaR, and its link with desired target credit is not clear (Basel Committee on Banking

Supervision 2009). The Bank for International Settlement (BIS) proposed moving its standardized risk measure from VaR to ES in 2012 after identifying a number of deficiencies with VaR (Basel Committee on Banking Supervision 2013). The spectral or distorted risk measure is effective in assigning different weights to the quantiles of loss distribution, which makes it more powerful than other risk measures. However, it is highly dependent on the underlying loss distribution, and its computation method is complicated to use and understand (Basel Committee on Banking Supervision 2009, 2013).

Second, the economic capital calculation depends on the confidence level it uses. The confidence level is the amount of capital buffer for bankruptcy protection. Thus, it is highly related with the target credit rating. The capital buffer can erode when the available capital resources fail to exceed the economic capital. However, the link between the confidence level and target rating is difficult to establish as the relationship between the ratings and the probability of default (PD) can change due to several factors like the rating agency scope adopted, statistical noise, etc. Therefore, financial firms adopt different ranges of confidence levels, instead of just one, in order to link with target ratings for different purposes. For instance, they use high confidence levels when their main objective is to minimize the risk of bankruptcy, and they use low confidence levels when the goal is to increase profits (Basel Committee on Banking Supervision 2009).

Third, the economic capital is also affected by the time horizon it implements. The choice of horizon depends on several factors, such as asset liquidity, the need for risk management, the market position of the financial firm, etc. In general, the market risk is estimated using very short time horizons, such as days or weeks, while credit risk is measured using relatively long-time horizons like years. The time horizons of regulatory requirements – such as 1 year, 10 days, etc. – also affect the calculation of economic capital (Basel Committee on Banking Supervision 2009).

Fourth, the economic capital depends on the risk aggregation methodology it uses. Some typical risk aggregation methodologies are as follows:

- **Summation:** This method adds individual risk components. It assumes inter-risk correlations are one, and each risk component has an equal weight during summation. It also ignores the benefits of potential diversification.
- **Constant diversification:** This method is the same as the summation method, except that it assumes a fixed level of diversification benefits.
- **Variance-covariance:** This method allows for interactions across the risks. However, these interactions are assumed to be linear and fixed across time. The benefits of diversification depend on the pairwise correlation between the risks.
- **Copulas:** This method combines marginal distributions with the joint probability distributions of risks. It also allows for rich interactions between risks.
- **Full modeling/simulation:** This method simulates the impact of common risk drivers on all risk components through scenario analysis. The distribution of outcomes and economic capital risk measures are calculated based on this. It accounts for all risk interdependencies and effects for the financial firm.

The summation and constant diversification methods are easy to compute and communicate. However, they are relatively crude and not sophisticated enough to consider interactions among different risks. On the other hand, variance-covariance considers the interactions among individual risks. It is also easy and intuitive enough to communicate. Nonetheless, it can be difficult and costly to estimate and may lead to the underestimation of tail losses, since it does not consider the possible non-linearity of risk factors. In contrast, the copulas method is more flexible than variance-covariance since it takes into account the nonlinearity of risk factors, leading to better risk approximation. However, the copulas method requires high-quality inputs, requiring a complete set of individual risk components to produce highly sophisticated parameters. Moreover, it is difficult to calculate and communicate (Basel Committee on Banking Supervision 2009).

90.4 Comparison Between Financial and Nonfinancial Firms

Financial firms are not only highly leveraged and risk sensitive, but their equity capital amount is highly limited to cover the illiquid risks compared to nonfinancial firms. Therefore, they are subject to liquidity risks, which link their capital budgeting process with risk management functions. Financial firms manage their risks either by offsetting them through hedging transactions or by altering their investment policies to manage risks that are not feasible to hedge (Froot and Stein 1998). Their investments are financed largely through debt, while equity in the form of economic capital only supports the risks in the investments. The allocated economic capital shows each segment's contribution to the overall risk (Buch et al. 2011). Financial firms aim to attain the target credit quality measured as credit spread, debt rating, etc., through their optimal capital structure that maximizes their firm values. On the other hand, nonfinancial firms strive to attain an optimal capital structure to achieve their target debt ratio, rather than credit quality, to maximize their value (Erel et al. 2015).

Thus, capital budgeting for financial firms requires a rather different approach than that for nonfinancial firms (Buch et al. 2011). For instance, capital budgeting should aim at maximizing a financial firm's specific performance measures such as RAROC, RORAC, RARORAC, etc., which emphasize the risk component in the return and/or in the capital. These allocation methods for financial firms often accompany various risk measure models as well. These risk measures include VaR, ES, conditional tail expectation (CTE),¹ and so on. Besides, it is crucial for financial firms to consider the financial regulation, including regulatory capital requirement, which evolves over time. The risk-adjusted performance measures such as RORAC and RARORAC heavily regard the risk component in the capital and are helpful in reflecting the regulatory capital requirements. Many internal

¹The CTE measure describes the expected amount of risk that can be experienced, given that a potential risk exceeds a certain threshold value (Cai 2005).

capital budgeting issues (e.g., the agency problem, external capital market dependence, financial shock, capital budgeting methodologies, etc.) in the context of general firms are also related, albeit not entirely, to financial firms' internal capital budgeting. According to the type of firm (as discussed in Sect. 90.2.6), for instance, financial firms are highly leveraged, which may lead to greater incentives to invest earlier than nonfinancial firms. Financial firms are highly leveraged and may react more sensitively to financial shocks (as discussed in Sect. 90.2.7) than nonfinancial firms. Internal capital budgeting for general firms concerns efficient capital or resource allocation or management. However, financial firms are specifically concerned with efficient internal "risk" capital allocation/management as they are credit sensitive, highly leveraged, and possess relatively limited equity capital to cover their illiquid risks compared to nonfinancial firms. Therefore, financial firms employ "risk" capital budgeting to maximize their risk-adjusted performance measures, such as RAROC, RORAC, and RARORAC, which leads to the maximization of shareholder value (as discussed in Sects. 90.2.8 and 90.3.1). On the other hand, nonfinancial firms aim to make investment decisions mostly based on the traditional standard DCF measure (as discussed in Sect. 90.2.8).

90.5 Conclusion

Financial firms are highly leveraged, risk sensitive, and possess limited equity capital to cover their illiquid risks compared to nonfinancial firms. Thus, the internal capital budgeting process and its related issues for financial firms are somewhat different from those for nonfinancial firms. Issues related to internal capital budgeting for firms in general include the agency problem, optimal timing for investment, relative dependence on the external capital market, firm type, firm boundary, market type, financial shock, capital budgeting methodologies, and so on. Some of these issues – such as firm type and capital budgeting methodologies – are different for financial firms and nonfinancial firms. Risk-adjusted performance measures including RAROC, RORAC, and RARORAC, regulatory capital and economic capital are background characteristics that differentiate the internal capital budgeting process for financial firms from that for nonfinancial firms.

Therefore, internal capital budgeting for financial firms has several distinct characteristics compared with nonfinancial firms. Financial firms aim to maximize their risk-adjusted performance measures (e.g., RAROC, RORAC, and RARORAC) leading to the maximization of shareholder value, while in case of nonfinancial firms, the internal capital budgeting procedure is primarily affected by the traditional standard DCF method. In particular, RORAC and RARORAC, which emphasize the risk factors in the capital, are quite helpful in reflecting the regulatory capital requirements that financial firms need to meet. Besides, issues related to internal capital budgeting, such as type of firm, financial shock, and capital budgeting methodologies, are different for financial and nonfinancial firms.

Future extensions can be the empirical test of the quantified impact of internal capital budgeting issues on financial firms' performance and shareholder value. It will be interesting to investigate the directions (positive or negative) and magnitudes of these impacts. The challenge would lie in quantifying the nonfinancial effects through appropriate measures to derive practically meaningful results.

Job Security and CEO Compensation

91

James S. Ang and Wei Chen

Abstract

We analyze a sample of 2,914 hiring contracts and show how job security plays a role in pay negotiation. We find a significant impact of job security on CEO pay using both firm- and industry-level measures across US firms. In general, CEO candidates and the board members would trade pay for job security. We find this pay for job security also follows a hierarchy order; when a firm is unable to compensate job risk with a higher pay, the CEO will seek for alternative ways of compensation, including a severance agreement, a shorter grant vesting period, and an incentive plan metric that is easier to achieve. Moreover, job security has no value among risk-takers, and this value increases with CEO's risk aversion. By examining the impact of job security under different market condition, we find that this pay concession disappears when the CEO labor market is more favorable to the CEOs.

91.1 Introduction

Job security is important to both firms and the executives. Commitment to job security is an essential ingredient to motivate firm innovation (Manso 2011; Bena et al. 2020). Conversely, a less secured job could motivate managers to engage in accounting fraud, such as earning smoothing (Fudenberg and Tirole 1995; DeFond and Park 1997), to protect their positions. Since job insecurity implies uncertainty about future wealth, the consequences could extend beyond the executive's loss of current employment, including reduced future career options (Brickley et al. 1999) and the loss of equity-based compensation (Dahiya and Yermack 2008).

In this chapter, we examine the role of job security in initial pay negotiation between the new CEOs and their boards. More specifically, we examine whether job security has value to the CEO, which should be manifested in negotiating total pay package at hiring. If so, how much, in what way (compensation type), in what circumstance (firm's situations) and to whom (type of managers).

Prior literature studying the relation between job security and worker's income spans mostly in the labor economic literature. Campbell et al. (2007) study a sample of British adults and find that high fears of unemployment are found to be associated with lower levels of wage growth for men and no significant link with wage growth for women. Bertola (1990) finds that wages tend to be lower in high job security countries. Böckerman et al. (2011) find that high excessive worker turnover is positively related to individual wages. Firms can be reluctant to compensate job security risk. Lazear (1990) studies the European data and finds that severance pay requirements can even reduce employment. Dai et al. (2020) study the impacts of life-threatening events, such as terrorist attacks, on CEO compensation and finds that CEOs at terrorist attack-proximate firms prefer cash-based compensation increases over equity-based compensation. All studies suggest the strong evidence that there is a tradeoff between pay and job security. Although a substantial empirical literature explores the relationship between executive compensation and risk-taking (Coles et al. 2006; Kempf et al. 2009; Low 2009), the study of how job security is linked with CEO compensation has merely been discussed before.

The reasons that such area has received relatively little attention are in part because theoretical predictions concerning the effects of the threat are ambiguous, and empirical measurement of its effect is complicated by the endogeneity of CEO power on own pay, which is related to the firm's governance. Sitting CEOs gain power over the board, and could cause the board to initiate changes in firm's investment and financing policies to increase the CEOs' job security; this is related to the problem of entrenchment due to poor governance. Studies have shown that firm governance weakens as incumbent CEO's tenure increases since the board learns about the CEO's ability and the CEO gains bargaining power and negotiates for greater autonomy (Hermalin and Weisbach 2001). Therefore, these circumstances complicate attempts to study the value of job security to the CEOs. To avoid these complications, the prefer laboratory setting to study the value of job security should involve one in which job security is exogenous, i.e., outside the control of the CEO, and pay is negotiated in arm length. This setting occurs when a

new CEO engages in pay negotiation at hiring. The degree of job security in these firms exists before pay negotiation and is thus exogenous, i.e., whether the firms have a penchant to dismiss CEOs, or whether the industry or firm specific risk of failure is greater.

Peters and Wagner (2014) were the first ones to discuss such topic in the field of corporate finance, and empirically showed the link between CEO dismissal risk and CEO compensation. It is important to differentiate our paper to that of Peters and Wagners. We focus on CEO pay negotiations at hiring, such that CEOs can only use ex-ante events to estimate their job risk. On the other hand, Peters and Wagners study a sample that involves mostly sitting CEOs, and use ex-post events (eg. forced turnovers) to estimates one's dismissal risk. In our paper, we provide extensive measures for job security based on both industry-level and firm-level information prior to the hiring event to simulate how CEO candidates evaluate their job risks. Overall, our design is much closer to a real negotiation process such that one can only attempt to use ex-ante events to forecast future possibilities. Our paper also provides a more comprehensive analysis for CEO compensation including the magnitude of pay, structure of pay, severance agreement, rate of disbursement, and the difficulty of obtaining such payment. Moreover, we provide empirical evidence to show how CEO risk preference could play a role in pay contract negotiation. Using the CEO's type based on career advancement, employment status and expertise, we are able to categorize CEOs into different risk preference groups, and study how risk preference modulates the value of job security. In addition, we enrich the research by adding CEO job market condition and examine its impact on the value of job security.

We study 2,914 CEO's hiring contracts (including 1,349 severance agreements, and 1,143 grant vesting schedules) from Execucomp and Incentive Lab during 2000 to 2013. First, we find that job security has a price. CEOs and the board members would trade pay for job security. Second, we find that such compensation of risk follows a hierarchy order. When firms are unable to grant higher pay, CEOs would seek for alternatives to compensate their job risk; these include a severance agreement, a shorter grant vesting period, and an incentive plan metric that is easier achieve. Third, we find this pay concession disappears among risk-takers (i.e. ambitious CEOs or turnaround experts in financially distressed firms), and this price increases with CEO's risk aversion (i.e. external hires, outside industry hires and previously unemployed CEOs). Lastly, by examining the impact of job security under different labor market condition, we find that this premium diminishes under favorable CEO labor market condition.

Our research compliments that of Peters and Wagner (2014), and is the first empirical study to examine the impact of CEO's risk preference and CEO market condition on the value of job security. This chapter also contributes to the existing literature on determinants of CEO pay (Baber et al. 1996; Cadman et al. 2010, 2013; Olaniyi 2019; Göx and Hemmer 2020) and severance contract (Almazan and Suarez 2003; Rau and Xu 2013; Klein et al. 2021), and provides a new perspective on determinants of CEO pay packages and the optimal design of managerial incentive contracts at US firms.

The paper is organized as follows. In Sect. 91.2, we develop our hypotheses in further details. Section 91.3 describes our methodology and data. In section 91.4 we provide empirical analysis on relationship between job security and CEO compensation, and also on how CEO risk preference and labor market condition play a role in the compensation contract. Section 91.5 concludes.

91.2 Literature Background and Hypothesis Development

CEO faces very real risk of dismissal in a firm. If an organization experiences an extreme change in performance, observers tends to attribute such change to the organization leaders (Meindl et al. 1985). When the performance is improved, CEOs are praised with generous rewards (Wade et al. 2006). However, when firms fail, CEOs are often the ones to blame and are likely to be held accountable via dismissal (Zemba et al. 2006). CEOs could be at risk as soon as the start of their tenure. Studies have pointed out that CEO turnovers are more likely to occur in the first few years of their tenure (Sebora 1996; Allgood and Farrell 2000). Therefore, CEOs are expected to take into consideration the risk of job loss at hiring and to negotiate terms that can compensate this risk.

As mentioned earlier, both boards and CEOs value the importance of job security. Better job security can stimulate firm innovation (Manso 2011; Bena et al. 2020), and firms with less job security would lead CEOs to take counterproductive actions to hold on to their jobs, e.g., earning smoothing (Fudenberg and Tirole 1995; DeFond and Park 1997). From the CEO's stand point, dismissal from current employment might lead to reduced future career options (Brickley et al. 1999) and loss of equity-based compensation (Dahiya and Yermack 2008). The value of job security may, therefore, be priced in the managerial labor market. When job security is absent, CEOs may demand greater pay to compensate for the increasing risk of dismissal. On the other hand, the board of directors would try to negotiate a lesser pay package with these CEOs. The result of the pay negotiation is the prediction that there is a tradeoff between job security and pay.

H1: Job security has a price; CEO candidates and the board members would trade pay for job security; Or, more secured jobs pay less.

However, in certain cases when the firms do not have sufficient financial resources to grant greater total pay (i.e. financially distressed firms), CEOs would seek for a more foreseeable, stable, and shorter term pay structure as alternatives; that is higher percentage in cash pay, higher likelihood of signing a severance pay, shorter vesting period, and an incentive plan that is easier to achieve.

H1 Corollary: In case when firms are financially stressed, CEO candidates would demand a more secured pay structure to compensation for low job security.

Matching a person to the job based on ability and characteristics such as risk taking/ aversion is crucial for the success of many organizations and is often a device to retain employees. A substantial empirical literatures argue and find evidence consistent with the matching hypothesis, whereby boards of directors seek to

match the “right” executives to their firm’s unique characteristics (Finkelstein and Hambrick 1997; Gibbons and Murphy 1992). The implication is that good matches are more productive than bad matches. These executives may also self-select into their desired firms. In terms of their compensation package, Lazear (1998) and Abdel-khalik (2003) find that CEOs self-select into compensation schemes that are consistent with their risk preferences. It is important to note that the extent the CEO is concerned with job security may also lead to self-selection into job matches. Firms with a need for either a stable management team or commit to a business strategy may choose to hire a CEO who values job security. On the other hand, Risk-averse (risk-seeking) CEOs may self-select to serve in a company that provides high (low) job security.

Consistent with risk averse employees’ preference for job security, previous literatures find a positive relationship between incentives pay and job risk (Demsetz and Lehn 1985; Core et al. 1999; Oyer 2004; Kini et al. 2020). They show that employees require to be compensated for employment in riskier jobs. Less secured jobs could truncate lifetime incomes if ousted CEO faced diminished prospects for a similar CEO job, or a top managerial position. Dismissals often leave these CEOs the stigma of a “damaged goods.” Ward et al. (1995) study the subsequent career outcomes for CEOs who are fired during 1988 to 1992 and find that 39 of the 60 former CEOs have not resumed an executive career after being dismissed.

More secured CEO jobs provide longer duration and more certain lifetime incomes, which are the employment conditions that the more risk-averse CEOs prefer. Everything else equals, they would demand greater pay in case they should be offered a high job risk position. Less risk-averse CEOs, on the other hand, are more willing to take these higher risk jobs and thus, more likely to be hired into such jobs as they demand less premium to compensate for the risk of job loss.

H2: Job sorting: Price of job security increases with CEO’s risk aversion. Conversely, less risk averse CEOs demand lower job security related pay.

In a more extreme case, when the CEOs are risk seeking, job security should lose its value.

H2 Corollary: Job Security Has No Value Among the Risk-Seeking CEOs

CEO candidates’ availability of job alternatives could dramatically influence CEO’s concern for job security in a particular position. More and better job alternatives reduce their perceived dependence on the boards (Kelley et al. 1967; Bacharach and Lawler 1981; Mannix et al. 1989; Pinkley et al. 1994). When the availability of alternatives is limited, the difficulty of finding another position in case of dismissal is greater. To a CEO job candidate, the availability of job alternative depends both on the number of available CEO job vacancies and the number of similar CEO candidates looking for similar jobs, we examine the effect of supply and demand in the CEO job market. If number of job openings is limited relative to the number of qualified executives for the CEO jobs, i.e., job market is unfavorable to CEO job seekers, hiring firms can afford to offer less generous terms and job candidates are more eager to accept. Accordingly, boards with more secured jobs are more likely to demand CEO candidates to make concession in pay in exchange for greater job

security. Similarly, CEOs in this market condition would not be able to demand a higher premium to compensate for riskier jobs.

H3: Price of job security increases (decreases) when the labor market condition is favorable (unfavorable) to CEO job seekers.

91.3 Methodology and Data

Our sample consists of 2,914 CEO hiring events in the 2000–2013 period drawn from the Execucomp¹; 2,895 of which include the dollar amount of total annual pay, and 1,349 of which include a severance agreement.² To reduce a tenure-related bias in observed pay, we limit our sample to new hires because sitting CEO could gain power over the board during their tenure (Hermalin and Weishbach 2001), and use their control of information and board appointment to entrench themselves, resulting in having greater influence on their own pay and job security. To concentrate on pay of new hires, we can avoid this endogenous influence on pay. Moreover, we use Incentive Lab database to incorporate 1,143 detailed incentive plans at hiring, including the metrics and vesting schedules of the incentive grants. The accounting data are from the Compustat database.

The empirical analyses are carried out in three stages. The first stage verifies the validity of our choice of job security variables. Since we focus only on hiring contracts, the CEO candidates can only use past information of firm to evaluate the security of their potential jobs. Therefore, the proxy for job security should be available from the firm or industry before the arrival of the new CEO. Moreover, for a job security proxy to be valid, it should be highly correlated with the new hired CEO's tenure and the chance of dismissal. The second stage explores how job security plays a role in pay negotiation. More precisely, we investigate whether the new hires can, in turn, use lack of job security to negotiate higher pay with the boards. In the cases when the firms do not have sufficient financial resources to provide greater pay, CEOs could seek for an alternate pay structure to compensate for lower job security; that is, in terms of more cash pay, more likelihood of signing a severance agreement, shorter vesting period and an incentive plan that is easier to achieve. In the third stage, we incorporate CEO risk preference and CEO labor market condition into the study, and discuss how they would modulate the value of job security.

91.3.1 Job Security Measures

We categorize our measures into firm-level and industry-level. The first firm-level measure we use is the average job tenure of the firm's previous CEOs before the appointment of the new CEO. A job with long expected tenure would be a strong

¹To avoid complications, we exclude firms with two CEOs at the same time.

²Execucomp database includes severance information starting from 2006.

indicator of high degree of job security. We argue that this measure captures the overall firm-level risk of job security, and could expect to be highly correlated with the future tenure of the incoming CEO. The job tenure information is gathered from Execucomp. We calculate the average job tenure of a firm by summing up the total years of CEO tenures and then divide by the number of CEOs.

$$\text{Firm_}JS_{1,i,j} = \sum_{l=1}^N \frac{\text{Tenure}_l}{N_{i,j}} \quad (1)$$

where $\text{Firm_}JS_{1,i,j}$ is the level of job security measure by the average past CEO tenure of Firm j in year i ; Tenure_l is CEO l 's tenure; and N is firm's total number of past CEOs.

One might argue that job tenure can be time specific since information about tenure are less during the earlier years in the database. This problem is alleviated because our sample focus on later years alone, which starts at 2000 whereas the starting year for Execucomp is 1993. The fact that newly listed firms have less tenure information can also indicate greater uncertainty. This set up is also in line with our job security definition.

The second firm-level variable is based on outgoing CEO's reason for departure. If the outgoing CEO leaves the firm near the customary retiring age, the chance of him successfully ending his CEO career would be high, and thus generate a positive signal of a secured job to the next CEO. We set $\text{Firm_}JS_{2,i,j}$ equal to 1 when the outgoing CEO left the firm at an age of 60 or greater, and 0 otherwise.

The third firm-level variable we use is an indicator for financially distressed firms. Studies have shown that the likelihood of dismissal is much greater among the distressed firms (Gilson 1989; Engel et al. 2003; Desai et al. 2006). These firms are identified based on Altman's (1968) Z-score. Altman estimates the financial health of a firm using an overall index Z , where

$$Z = 0.012X_1 + 0.014X_2 + 0.033X_3 + 0.006X_4 + 0.999X_5 \quad (2)$$

X_1 is the working capital to total assets ratio, X_2 is the retained earnings to total assets ratio, X_3 is the earnings before interest and tax to total assets, X_4 is the market value of equity to total liabilities ratio, and X_5 is the sales to total assets ratio. For firms achieving an Altman's Z-score less than 2.7 are categorized as financially distressed firms, and set $\text{Firm_}JS_{3,i,j}$ equal to 1.

For industry-level job security, we construct measures based on industry market performance, cash flows and credit ratings. Studies have shown that firm's stock market performance are highly correlated with the likelihood of CEO dismissal (Kaplan and Minton 2012; Jenter and Kanaan 2021). We construct our first industry-level measure accordingly by capturing the stock market risk. Which is defined as the ratio of industry annual stock return average to their standard deviation

$$\text{Ind_}JS_{1,i,k} = \sum_{s=1}^M \frac{\text{stock return}_{s,i,k}}{M_{i,k}} / \sigma(\text{stock_return}_k) \quad (3)$$

where $Ind_JS_{1,i,j}$ is the industry-level job security measure by stock market risk in year i and in industry k ; $stock_return$ is firm's annual stock return; M is total number of firms in the industry. The measure is negatively correlated with the industry risk of stock market and therefore positively correlated industry's job security.

The second measure we follow Nguyen (2007)'s methodology, and use the ratio of the industry's average cash flows to their standard deviation to capture cash flow risk.

$$Ind_JS_{2,i,k} = \sum_{s=1}^M \frac{NCF_{s,i,k}}{M_{i,k}} / \sigma(NCF_k) \quad (4)$$

Where NCF is firm's net operating cash flow. The measure is negatively correlated with the industry risk of cash flow and therefore positively correlated industry's job security.

For our third measure, we use S&P long-term issuer credit ratings from Compustat. Compustat maps the official rating categories into integer values from 2 (AAA) to 23 (CC). We further scale these numbers such that a unit increase in our variable corresponds to the difference between an AAA and a BBB rating (the scaling factor is 1/9). Finally, we compute the industry-level job security by computing the average industry credit ratings. The higher $Ind_JS_{3,i,j}$ is the riskier industry, and thus lower industry job security.

$$Ind_JS_{3,i,k} = \sum_{s=1}^M \frac{\text{Credit rating}_{s,i,k}}{M_{i,k}} \quad (5)$$

91.3.2 Compensation Measures

We use the total annual compensation ($tdc1$ scaled to the \$ millions) in Execucomp to measure the total pay described on the hiring contract. This variable consists of the following components: base salary, annual bonus, stock awards, option awards, long term incentive plan, other benefits, and other components.

We use the ratio of annual cash pay to total annual compensation to measure cash payout. Cash pay is calculated as the sum of total annual cash awards plus base salary. In addition to these pay components, we also study the payout when the executive leaves employment at the firm. This is called the severance package which is instituted to help protect the newly unemployed. In general, there are two types of severance agreement. The first type is the severance agreement upon involuntary termination which describes the payment for the named executive officer who are involuntarily terminated but not for cause, e.g., reason other than deliberate and serious disloyal or dishonest conduct. The second type of severance protects the CEOs in case of change-in-control. This agreement describes the payments that are triggered by the occurrence of an acquisition. Severance is a measurement for CEO's protection against dismissal. Therefore, we would expect CEOs to be more likely to demand for a severance agreement when the firm is unable to grant a higher total pay

for job risk. In Execucomp, severance data are available for the years after and including 2006. We define a dummy variable, *severance*, equal to 1 for CEOs who sign severance agreements (i.e., the dollar amount of severance data is non-zero and non-missing).

Firms often break their incentive awards into several vesting periods with amount and schedule based on either year of employment or firm performance. These mechanisms are used to motivate CEO for better performance. However, when the CEO is dismissed, it would also lead to the forfeiture of these unvested compensation. Therefore, a shorter vesting period would provide a greater expected payoff (or greater certainty equivalent) to the employees since it consists of payments that are either guaranteed or foreseeable in the near future. We take advantage of detailed grant vesting schedules provided by the Incentive Lab database, and calculated the weighted average vesting period using a modified method of Gopalan et al. (2014).

$$\text{Average_vesting_period} = \frac{\sum_{i=1}^{n_c} \text{Cash}_i \times t_i + \sum_{j=1}^{n_s} \text{Restricted_stock}_j \times t_j + \sum_{k=1}^{n_o} \text{Option}_k \times t_k}{\sum_{i=1}^{n_c} \text{Cash}_i + \sum_{j=1}^{n_s} \text{Restricted_stock}_j + \sum_{k=1}^{n_o} \text{Option}_k} \quad (6)$$

Where the subscript i denotes a cash grant, the subscript j denotes a restricted stock grant, and subscript k denotes an option grant. Cash is the dollar value of cash grant i with corresponding vesting period t_i . Restricted_stock $_i$ is the dollar value of restricted stock grant i with corresponding vesting period t_i in months. Option $_k$ is the Black-Scholes value of option grant k with the corresponding vesting period t_k in months. In our equation we do not include salary and bonus as the one in Gopalan et al. (2014) because we solely study the vesting schedule of the grants.

Lastly, we measure the ease of incentive plan by considering metrics of the plan. In general, incentive plans are paid out based on either time or performance. A time-based incentive plan is designed to encourage CEOs to work longer for the firm, whereas a performance-based incentive plan is designed to motivate CEOs to achieve certain goal performance. When the high job risk is present, an early dismissal would certainly lead to the forfeiture of unvested time-based compensation. However, under performance-based incentive plan, there is still a chance for CEO to receive the compensation (in the worst case scenario, CEO can manipulate accounting performance). Therefore, time-based incentive plan should be avoided. We calculate time-based portion of the incentive grants by dividing total amount of time-based incentive plan granted by total amount of incentive plan granted.

91.3.3 Risk Preference Measures

Special circumstances may cause the relationship between job security and CEO pay to deviate from the standard prediction above. In the third stage, we point out these

special circumstance. We use information of new hires' previous employment, career advancement, and financial data from Execucomp and Compustat to construct our risk preference measures.

When CEOs possess certain expertise that the firms require, they would have less desire for job security for two reasons. First, the firm would value the expertise of the CEO and should, therefore, be more tolerate of the CEO occasion below par performance which in turn decreases the likelihood of early dismissal. Second, this type of CEOs will likely to be more self-assured that their specialties would cause an impact on the firm, and thus they are more confident of the possible outcomes; this over-confidence which leads them to give less weight to job security. A good example would be a turnaround expert in a financially distressed firm. When a firm desperately needs to change its financial situation, its board will likely to hire a turnaround expert (Ellis 2012). The boards will be more lenient on the CEO who the possesses such turnaround specialty by providing enough time for him to improve the firm. Meanwhile, due to the previous successful experience, these CEO are confident of the possible impact he could bring, and thus would underweight the value of job security.

The turnaround experts in our sample are defined as the executives who has participated in turning a financially distressed firm into a healthy firm. In other words, these executives have increased a firm's Z-score from lower than 2.7 to greater than 3. The dummy variable, $D(Expert)$, equals to 1 if such CEO is a turnaround expert, and 0 otherwise.

We identify ambitious CEO candidates as our second measure of risk preference. These are defined as the ones who are promoted or hired from a rank lower than the third position (we rank executive by their total compensation). This type of candidates has less concerns for job security than the need to excel (or ambitious). At the same time, because the increase in pay is much higher than their original compensation at a lower position, which would could compensate for less job security.

For the third measure, we identify those CEOs who are extremely risk-averse. Campbell et al. (2007) find that workers' fears of unemployment are increased by their previous unemployment experience. Since having successive dismissals on their resume could adversely reduce their prospect to finding the next job, we expect that CEO candidates who were unemployed for a considerable period of time, before taking on a job, would place greater value on job security. We calculate the gap in years between the current and previous employment from Execucomp, and set the $D(Unemployed)$ variable to 1 if the CEO was out of job for more than 2 consecutive years.

Lastly, we create two specific risk preference variables for external hires. Information asymmetry plays a big part in CEO compensation negotiation. Stakeholders who control information can release only enough to manipulate the outcome that they desire (Pfeffer and Lammerding 1981). In general, CEO candidates can be sourced from inside or outside the firm. Internal candidates have more firm-specific human capital than external candidates (Harris and Helfat 1997), and have the access to the first-hand information about the firm, thus they have the upper hand in evaluating firm's current situation comparing to the external candidates. Therefore,

Table 1 CEO Risk Preference Groups

Risk-seeking	Risk-neutral/Unknown	Risk-averse
Ambitious CEO	Non-ambitious	
Turnaround expert	Non-turnaround expert	
	Employed	Unemployed
	Internally hired	Externally hired
	Hired from within industry	Hired from outside industry

it would cause the external hires to value the publicly available firm-level information even more. Similarly, CEOs who are hired outside of the industry would value publicly available industry-level information more than their counterparts.

Following Parrino (1997), we define an external hire to be an executive who has been appeared for the first time with the firm. All others are classified as external hires. The dummy variable $D(External)$ equals to 1 if such new CEO is an external hire and 0 otherwise. We also use Execucomp to verify CEO’s previous employment. If the CEO was hired from outside industry, we set $D(Outside_Ind)$ to 1 and 0 otherwise.

As shown in Table 1 We separate our CEOs into three categories based on their risk preference, risk-seeking, risk-neutral/unknown and risk-averse.

91.3.4 CEO Labor Market Condition Measures

For CEO labor market condition, we calculate the demand/supply ratio of the entire CEO labor market and the market within the same industry during each year. The demand is calculated as total number of CEO turnovers (new CEO openings) plus total number of incumbent CEOs who are older than 60 in a given year. The supply is calculated as the total number of dismissed CEOs who are 55 or under in the previous year plus the total number of executive who are 55 or under in number 2 and 3 position in a given year.

Table 2 summarizes our key variables (see Appendix A for variable definitions). On average, the total annual pay on hiring year is about \$5.28 million. Of which, 37.3% consists of cash pay. Since the availability of severance data on Execucomp from 2006, 83.3% of the new hires sign a severance agreement. Using the Incentive Lab sample, we find that the weighted average grant vesting period is around 38.51 months. For all the CEOs in our sample, 32.9% are ambitious, 4.5% were unemployed before the appointment, 78% are internally promoted CEOs, and 13.4% are turnaround experts.³ The average age at hiring is 52.64. One other thing to notice

³These categories are not mutually exclusive.

Table 2 Summary Statistics. The sample consists of all CEO who are hired or promoted during 2000–2013 in Execucomp firms. The data for severance agreement are available from 2006–2013 only. The information on vesting period are taken from Incentive Labs. All variables except dummies are winsorized at the 1st and 99th percentiles

	Obs	Mean	Std. Dev.	Min	Max
<i>Compensation</i>					
Total pay (\$million)	2895	5.283	6.562	0.135	38.247
Cash/Total pay	2891	0.373	0.279	0.000	1.000
Severance	1620	0.833	0.373	0.000	1.000
Average vesting period	1116	38.513	14.098	0.170	88.730
Time based grant ratio	1143	0.726	0.321	0.000	1.000
<i>Job security</i>					
Firm_JS ₁	2895	8.709	6.306	1.000	36.000

Firm_JS ₃	2380	0.441	0.497	0.000	1.000
Ind_JS ₁	2528	0.095	0.583	−2.222	2.440
Ind_JS ₂	2815	0.185	0.346	−0.065	2.163
Ind_JS ₃	1581	1.399	0.194	0.937	1.993
<i>CEO Characteristics</i>					
Ambitious	2914	0.329	0.470	0.000	1.000
Unemployed	2536	0.045	0.206	0.000	1.000
Outsider	2914	0.220	0.414	0.000	1.000
Insider	2914	0.780	0.414	0.000	1.000
Expert	2914	0.134	0.341	0.000	1.000
CEO age	2891	52.644	7.008	30.000	80.000
Outside Industry	2536	0.040	0.197	0.000	1.000
<i>Market condition</i>					
Demand/supply	2914	0.363	0.481	0.000	1.000
Industry demand/supply	2880	0.339	0.473	0.000	1.000
<i>Firm Characteristics</i>					
lnSize	2832	7.681	1.868	3.308	12.532
Sales growth	2818	0.049	0.239	−0.587	1.243
ROA	2829	0.001	0.162	−0.859	0.305
Leverage	2817	0.237	0.210	0.000	0.991
M/B	2769	2.524	3.237	−9.614	20.332
R&D	2822	0.042	0.090	0.000	0.558
Stock volatility	2661	0.031	0.018	0.009	0.102
Industry-adj stock return	2542	−0.101	0.442	−1.231	1.445
Firm age	2612	24.947	19.26	0.038	88.06

is that 44.7% (*Firm_JS₃*) of the firms are financially distressed. Along with the close-to-zero average ROA and negative stock performance in our sample, our results are consistent with prior literature that a CEO turnover occurs when firm performance is poor (Meindl et al. 1985; Zemba et al. 2006).

91.4 Empirical Analysis

91.4.1 Verification of Job Security Measures

In this section, we verify the validity of the two types of job security measures we discussed in the previous section.

Figure 1a and b depict the relationship between our choice of job security measures and future CEO tenures. We separate our sample into high and low job security groups based on the median of each continuous job security variable. For dummy variable

Fig. 1 (a) Average Tenure of Newly Hired CEOs Based on Firm-level Job Security Measures. The sample consists of all CEO who are hired or promoted during 2000–2013 in an Execucomp firm. We separate the level of job security into two groups based on the median of each firm-level job security measure. (b) Average Tenure of Newly Hired CEOs Based on Industry-level Job Security Measures

Firm_JS₃, we categorize as high job security when it equals to 0, and low job security if it equals to 1. We observe difference between the two groups. The new hires in high security jobs have longer tenure than the ones in low security jobs, and the results are significant at 5% level at least across all six measures.

A valid job security measure should also capture CEO's early dismissal risk. Figure 2a and b depicts the relationship between our choice of job security measures and the chance of dismissal during the first 3 years of tenure. The chance of dismissal is calculated as the total number of dismissed CEOs during the first 3 years of tenure divided by the total number of new CEOs at year 0. Again, we find that CEOs are at greater risk of dismissal in low security jobs than its counter-group across all six measures. Thus, these results verify our choice of job secure measures.

91.4.2 Job Security and CEO Compensation

In this section, we examine the relationship between CEO compensation and the two main types of job security measures discussed in the previous section: industry-level measure and firm-level measure. Due the large amount of missing corporate governance data, we consider regression specifications in which control variables are added sequentially. The baseline specification includes only firm characteristics and CEO characteristics, and the second specification includes corporate governance controls is reported in our robustness test section.

In Table 3, we investigate the impact of industry-level job security in column 1 to 3. First, our results indicate that industry-level job security is highly correlated with CEO total pay. Consistent with Hypothesis 1, CEOs are compensated for higher industry job risk; or more secured job pay less. We calibrate the economic significance of these findings. On average, each unit increase in the inverse coefficient of variation (or one-unit decrease in risk) in industry-average stock return and cash flow would lead would lead to a \$984 thousand and \$914 thousand decrease in total pay respectively for newly hired CEOs. Each unit increase in industry-average credit rating (or from an AAA to a BBB, or an BBB to CCC, etc...), new hires' total pay would increase by \$5 million.

In the latter half of Table 3, we investigate the impact of firm-level job security. In column 3 and 4, our results indicate that firm-level job security is highly correlated with CEO total pay. Again, consistent with Hypothesis 1, CEOs are compensated for higher firm-level job risk. On average, each year decrease in average past CEO tenure would lead to a \$24 thousand increase in total pay for newly hired CEOs. New hires' total pay would decrease by \$405 thousand if their predecessors have successfully retired.

In Column 6, we find that firm-level job security measured by financially condition produces a seemingly contrary result; more secured jobs pay more. This situation is further analyzed in the next section.

Fig. 2 (a) Rate of Dismissal within the First 3 Years Based on Firm-level Job Security Measures. The sample consists of all CEO who are hired or promoted during 2000–2013 in an Execucomp firm. We separate the level of job security into two groups based on the median of each industry-level job security measure. The chance of dismissal is calculated as number dismissed CEOs during the first 3 years of tenure divided by the total number of CEOs. (b) The sample consists of all CEO who are hired or promoted during 2000–2013 in an Execucomp firm. We separate the level of job security into two groups based on the median of each firm-level job security measure. The chance of dismissal is calculated as number dismissed CEOs during the first 3 years of tenure divided by the total number of CEOs

Table 3 Regression Analysis for Job Security and CEO Pay. Column 1 to 3 report the OLS regression of industry-level job security measure on CEO total pay. *Ind_JS₁* and *Ind_JS₂* are the inverse coefficient of variation in industry stock returns and cash flow, which both are positively correlated with industry job security. *Ind_JS₃* is the industry average credit rating (inversely correlated with industry job security). Column 3 to 6 report the OLS regression of firm-level job security measure on the CEO total pay. Both *Firm_JS₁* and *Firm_JS₂* are positively correlated with firm job security; *Firm_JS₃* is the average tenure of past CEOs and *Firm_JS₂* is an indicator whether the predecessor successfully retired. *Firm_JS₃* is an indicators equal to 1 if the firm is financially distressed. All other independent variables are defined in [Appendix A](#). Robust standard errors are reported in parentheses

91.4.3 Job Security and CEO Compensation in Firms with Financial Constraints

The above analyses cover the general cases. However, in a special case when the firms do not have sufficient financial resources to grant greater total pay, we would expect CEOs to seek for alternatives to compensate for low job security.

In Panel A of Table 4, we conduct a univariate analysis for total pay scaled by firm size based on different firm-level job security measures. Indeed, we find that new hires in financially distressed firms receive a lower total pay. This shows distressed firms are unable to grant CEOs with the same pay level as the normal firms. Therefore, CEOs in this type of firms would seek alternative ways to compensate the job risk. And this is exactly what we find in the latter Panels of Table 5. In Panel B, we find that CEOs in financially distressed firms demand 2.395% higher in

Table 4 Univariate Analysis for Financially Distressed Firms. We separate our sample into high and low job security firms based on the median of each firm-level job security measure. The total annual pay, cash pay portion, average vesting period and time-based portion of the grant are compared between two groups

Panel A: Annual Pay (scaled by size)

cash pay than those in normal firms. We also include alternative job security measures and show that there is no significant difference in the general case. We make use of the Incentive Lab database, and compare the vesting periods and the metrics of incentive plans between high and low job security groups in Panel C. Again, we confirm that CEOs in distressed firm demand a shorter vesting period. In Panel D we find that CEOs in distressed firm tend to choose a metric that is easier to achieve. Using alternative measures, we do not find a similar result. All these results indicate that compensation for job risk follows a hierarchy; CEO will ask for alternate forms of compensation when the firm cannot grant higher pay.

In Table 5, we conduct a more rigorous analysis using regression, and again confirm our findings in the univariate analysis. In terms of economic significance, when the firm cannot grant a higher pay, CEOs on average demand 3.1% higher in cash pay, 3.4% increase in the likelihood of signing a severance agreement, and shortened average vesting period by 1.765 months in less secured jobs. In column 4, we do not find a significant impact on the choice of metrics of incentive plans. We suspect that is due to the differences in CEO risk preference, which will be discussed in more details in the next section.

91.4.4 Job Security under Different Risk Preferences

We would expect the above findings to hold under normal conditions. However, special circumstances may cause the payment scheme to deviate from the standard prediction above. In this section we study the impact of job security under different CEO risk preference. Table 6, we separate our sample based on how CEOs were promoted to current position. We classify those ambitious CEO are those who were promoted from a lower rank to be labelled as ambitious (or risk-seeking). Corroborate with our prediction in Hypothesis 2, job security has a value only among the non-ambitious CEO and has no impact on the CEO's total pay among ambitious ones. From Table 5 in the previous section, we suspect that CEO's risk preference causes the insignificant correlation between job security and the choice of incentive plan metrics. The findings in column 5 and 6 of Table 6 confirm this suspicion. We find CEOs, in financially distressed firms, choose a metric that is easier to achieve to compensation the job risk only if they are non-ambitious. Again, these findings support Hypothesis 2 such that job security has no value among the risk seeking CEOs.

Next, we examine whether external hires would value job security differently from the internal hires. We first study the firm-level measures in Column 1 and 2. The interaction term of external hire indicator and job security measures demonstrate that external hires value the firm-level security more than the internal hires. On average, external hires require a \$97 thousand higher premium for each year decrease in average past CEO tenure than their counterparts. At the industry-level, we compare the difference between CEOs who are hired from outside industry and within industry in Column 3 and 4. The signs of interaction terms of outside-industry hire indicator and job security measures are same as we expected, and are significant

Table 6 Regression Analysis for CEOs with different Risk Preference. Column 1 to 4 report the OLS regression of firm-level job security on CEO total pay among ambitious and non-ambitious CEOs respectively. Ambitious CEOs are defined as the ones who were promoted or hired from a rank lower than the 3rd position. Column 5 and 6 report the Tobit regression of job security on time based grant ratio (left censored at 0 and right censored at 1). The independent variables are defined in [Appendix A](#). Robust standard errors are reported in parentheses

at 5% level in Column 4 and 5. These findings confirm that CEOs hired from outside industry value industry-level job security more than those who are hired within. In terms of economic significance, CEOs hired from outside-industry would demand a \$6.39 million higher premium for each unit decrease in the inverse coefficient of variation (or one-unit increase in risk) in industry-average cash flow than their counterparts; for each unit decrease in industry-average credit rating (or from an AAA to a BBB, or an BBB to CCC, etc. . .), outside-industry hires would demand a \$14.40 million higher premium than inside industry hires (\$1.66 million higher premium from an AAA to a AA or AA to A, etc...).

We expect that CEO candidate who were unemployed for a long period of time, before taking on the job, should especially value job security. Consistent with our prediction, the interaction term of job security and unemployment indicator is strongly correlated with total pay in Column 1 of Table 8. On average, CEOs who were unemployed previously require a \$197 thousand higher premium for each year decrease in average past CEO tenure than their counterparts. We also develop a case specifically for financial distressed firms in column 3. The interaction term of turnaround expert indicator and job security measure is negatively correlated with the likelihood of signing a severance agreement. As an economic interpretation, turnaround experts in financially distressed firms are 10.6% less likely to sign a severance agreement as a compensation for job risk than their counterparts.

Table 8 Regression Analysis for Turnover Experts. Column 1 and 2 reports the results of OLS regression. The dependent variables in Column 1 and 2 are CEO total pay. *D(Unemployed)* is an indicator that equals to 1 if the CEO was previously unemployed. The dependent variable in Column 3 is an indicator whether the CEO signs a severance agreement. Logit regression model is used in this column and the marginal effects of the coefficients are reported. The independent variables are defined in [Appendix A](#). Overall, the regression results corroborate the prediction stated in Hypothesis 2. We find that job security has no value among CEOs who are risk-seeking (i.e. ambitious or turnaround experts in financially distressed firms). However, when CEOs are not risk-seeking, job security will have an impact on their compensation, and this impact will increase as CEOs become risk-adverse (i.e. external hires, outside-industry hires, or previous unemployed CEOs).

91.4.5 Job Security under Different Labor Market Conditions

We now investigate the link between job security and CEO pay under different labor market conditions.

Hypothesis 3 predicts that the price of job security increases with CEO's risk aversion; conversely, less risk averse CEOs demand lower job security related pay. To test this prediction, we separate our sample into two groups by industry labor market conditions. We categorize industry-years with above average demand/supply ratio as favorable labor market condition, and, vice versa, categorize industry-years with below average demand/supply ratio as poor labor market condition.

As shown in Table 9, job security under favorable labor market condition has no significant impact on CEO pay. This is because it is relatively easier for CEO candidate to find jobs under such market condition, and therefore the need of job security diminishes. On the other hand, job security has significant impact on CEO pay under poor market condition across all three job security measures. Overall, the regression results corroborate the prediction stated in Hypothesis 3. On average, under poor labor market condition, CEOs are compensated with \$39 thousand for each year decrease in average CEO tenure; \$479 thousand for CEOs with a predecessor who was not successfully retired; and 2.4% increase in the likelihood of demanding the easier incentive metric when the firm is unable to provide a greater pay.

Table 9 Regression Analysis for Firm-level Job Security under Different Labor Market Conditions. Column 1 to 4 report the OLS regression of CEO total pay across the three firm-level job security measures under different CEO labor market condition. We use Tobit regression for Time based grant/Total grant in Column 5 and 6 (left censored at 0 and right censored at 1). We separate our sample into two labor market condition groups based on the median of the CEO industry-year demand/supply ratio. The independent variables are defined in [Appendix A](#). Robust standard errors are reported in parentheses

We also examine the impacts of industry-level job security measure under different labor market condition categorized by the median of year average demand/supply ratio. We find that job security has a significant impact across all industry-level measures under poor labor market condition. Although some of the results also show that job security has a value even under well market condition, one of the measures, *Ind_JS₁*, becomes statistical insignificant. This is an evidence that job security's impact somewhat decreases under well market condition.

91.4.6 Robustness Test

We do not include corporate governance controls in our main analysis since it would dramatically decrease our sample size. However, the correlation between corporate governance and CEO compensation has been proven by many scholars (Core et al. 1999; Dicks 2012). In [Appendix B](#), we add corporate governance index (G-index), board independence (percentage of independent directors) and board size into our main models. At the same time, instead of measuring the total annual pay by the millions, we take the total pay reported on Execucomp (*tdc1*) by the natural log. Overall, the results remain in line with our main analysis.

We have proved that when firms are unable to grant the CEOs with greater pay, CEOs would seek for higher cash pay portion to compensate their job risks. However, this pay alternative might simply be the compensation scheme at financially distressed firms instead of firm's concession for job risk. For example, the high cash pay ratio can be merely caused by low valuation of firm stocks.

We give two explanations for this concern. First, low valuation of firm stock should not change CEO's cash pay ratio. CEOs are able to use prior firm performance to evaluate the firm and demand a favorable pay structure accordingly. When firm's stock price is low, CEO can, in return, demand more shares to compensate for such low valuation, and thus the cash pay ratio should remain the same. Second, if job security truly has a value in financially distressed firms, this value should increase as the job risk increases. We conduct a regression analysis by adding the interaction term of job security measure and financially distressed indicator (*Firm JS₃*). We construct a dummy variable equal to 1 when the predecessor of the CEO did not successfully retire, and thus indicating a risky job position. In [Appendix C](#), the results show that the interaction term is significantly positive, and therefore confirm that a more conservative pay structure in distressed firms is indeed caused by the decrease in job security.

91.5 Conclusion

We examine how job security has a price during CEO pay negotiation at hiring. We find significant impact of job security using different measures across firms. In general, CEO candidates and the board members would trade pay for job security; that is in terms of higher total pay. We further find this compensation for risk follow a

hierarchy order; when firms are unable to provide a higher pay, the CEOs will seek for alternative ways to compensate their job risk, including a severance agreement, a shorter grant vesting period, and an incentive plan metric that is easier to achieve. Moreover, job security has no value among risk-takers (i.e., ambitious CEOs or turnaround experts in financially distressed firms), and this price increases with CEO's risk aversion (i.e., external hires, outside industry hires, and previously unemployed CEOs). By examining the impact of job security under different market condition, we find that this premium disappears under favorable CEO labor market. Overall, our results are in line with the findings in labor economic literatures that workers are compensated in low job security positions. Our research compliments that of Peters and Wagner (2014), and is the first empirical study to examine the impact of CEO's risk preference and CEO market condition on the value of job security. We hope to add a new perspective to the determinants of CEO compensation and on the optimal design of managerial incentive contracts.

Appendix A: Variable Description

Variable Name	Description
Compensation	
Total pay (\$million)	Total annual compensation including salary, bonus and the grant date fair values of stock and option grants, long-term incentive payouts, and other compensation (tdc1 in Execucomp)
Total pay (scaled by size)	Total annual pay scaled by firm size
Cash/Total pay	Total cash components (salary + annual cash bonus) as a percentage of the total annual pay
Severance	Equals to 1 if the CEO signs a severance agreement
Avg. vesting period	The weighted average vesting period of grants
Time based/Total grant	Time based incentive grants over total grant
Job security	
Firm_JS ₁	Firm average CEO tenure before the new appointment
Firm_JS ₂	Equals to 1 if the outgoing CEO left the firm at a retiring age, and 0 otherwise
Firm_JS ₃	Equals to 1 for financially distressed firms, and 0 otherwise
Ind_JS ₁	The inverse coefficient of variation in industry stock returns
Ind_JS ₂	The inverse coefficient of variation in industry cash flow
Ind_JS ₃	The industry average credit rating
CEO Characteristics	
Ambitious	Equals to 1 if the CEO was from a rank lower than #3
D(Unemployeed)	Equals to 1 if the CEO was unemployed for 2 or more years
D(Insider)	Equals to 1 if the CEO was an internal hire
D(External)	Equals to 1 if the CEO was an external hire
D(Outside industry)	Equals to 1 if the CEO was an outside industry hire
D(Expert)	Equals to 1 if the CEO is a workout expert

(continued)

Variable Name	Description
D(Unsuccessful outgoing CEO)	Equals to 1 if the predecessor was not successfully retired
Market condition	
Demand/supply	The total CEO job demand divide by the total CEO supplies in a given year
Industry demand/supply	The total CEO job demand divide by the total CEO supplies within the industry in a given year
Controls	
lnSize	Natural logarithm of total asset
Sales growth	Logarithm of the ratio between sales and lagged sales
ROA	Operating income divided by total assets
Leverage	The sum of long-term debt and debt in current liabilities divided by total assets
M/B	Market value of total assets over book value of total assets
R&D	Research and development expense divided by total assets
Stock volatility	The standard deviation of daily stock returns in each year
Industry-adj. stock return	Annual stock return minus its industry mean.
G-index	Gompers, Ishii, and Metrick (2003) governance Index
Board independence	Percentage of independent directors on board
Board size	Number of board members

Appendix B: Robustness Tests for the General Case

Column 1 to 5 report the results of OLS regression. The dependent variable is the neutral log of the total pay reported in the Execucomp database. Robust standard errors are reported in parentheses. We add corporate governance index (G-index), board independence (percentage of independent directors) and board size into our main models as control variables.

Tail-Risk Protection: Machine Learning Meets Modern Econometrics

92

Bruno Spilak and Wolfgang Karl Härdle

Abstract

Tail risk protection is in the focus of the financial industry and requires solid mathematical and statistical tools, especially when a trading strategy is derived. Recent hype driven by machine learning (ML) mechanisms has raised the necessity to display and understand the functionality of ML tools. In this chapter, we present a dynamic tail risk protection strategy that targets a maximum predefined level of risk measured by Value-At-Risk while controlling for participation in bull market regimes. We propose different weak classifiers, parametric and nonparametric, that estimate the exceedance probability of the risk level from which we derive trading signals in order to hedge tail events. We then compare the different approaches both with statistical and trading strategy performance, finally we propose an ensemble classifier that produces a meta tail risk protection strategy improving both generalization and trading performance.

92.1 Introduction

“Black swan events” are occurring from time to time. After 2008, investors in the DAX had to wait 5 years before recovering their loss. The Nikkei stock index still has not yet recovered, even 25 years after the bubble burst. The cryptocurrency market has plunged drastically at the end of 2017. What choices are left to investors in these situations?

Indeed, it is one of the main challenges of quantitative finance to build models and develop tools able to protect investments from such extreme events (Bollerslev and Todorov 2011). The first risk management strategy addressing the latter is diversification but Longin and Solnik (2001) show that when financial markets exhibit huge downturn periods, correlation significantly increases, hence are counteracting the effect of portfolio diversification. Another strategy for tail risk protection is option based, where the risk manager is long in put options. Yet, loss aversion leads to high prices of put options (Kozhan et al. 2013; Packham et al. 2017). A solution to escape this dilemma is to build a strategy with dynamic asset allocation. The risk manager creates an asymmetric risk profile with participation in upside market and protection against severe loss. This trading strategy is often called tail risk protection strategy by practitioners and is much more cost efficient and flexible than the options strategy (Franke et al. 2019). In order to pursue such a strategy, one needs to predict distributional properties of the portfolio. This, of course, is obviously impossible since not only distributions but also their parameters change in time. This motivates our entry where we hint on comparing Econometrics tools, Machine learning (ML), and modern Local Parametric Approach (LPA). We present a dynamic tail risk protection strategy that targets a maximum predefined level of risk measured by Value-At-Risk while controlling for participation in bull market regimes. We propose different weak classifiers, parametric, based on GARCH tool, and nonparametric using ML, that estimate the exceedance probability of the risk level from which we derive trading signals in order to hedge tail events.

The GARCH tool with normally distributed innovations allows us to catch volatility clusters and yields good volatility forecasts. The application of Extreme

Value Theory (EVT) to GARCH residuals provides insight into the tail probabilities, that is, the likeliness of an extreme loss. Nevertheless, econometric models rely on strong assumptions and cannot deal with structural breaks that happen in financial time series.

ML has been successful in many applications during the last years thanks to its generalization power on large datasets, but, in quantitative finance, in particular for financial returns forecasting, ML did not prove its superiority in comparison with its application to text analysis or image recognition, where Deep Learning (DL) tools became state-of-the-art. Moreover, the black box effect of DL makes the industry reluctant to invest in such models. In theory, DL can extract information from nonlinear relations in high dimensional space, so for quantitative finance practitioners, it should be natural to use the machine learning tool box. Nevertheless, DL models suffer from overfitting and can be very difficult to train. If they offer similar prediction accuracy than econometrics, it might be preferable to use the latter with regards to its interpretability, lower complexity, and cheaper computational costs.

The cryptocurrency market has experienced an exponential growth during 2017, where BTC peaked at \$19783.06 on December 17, 2017, and dropped below \$14,000 24 h later, losing one third of its value. One year later, on December 7, 2018, BTC price briefly dipped below \$3300, a 76% drop from the previous year and a 15-month low. At the time of writing, the cryptocurrency market is experiencing a new large uptrend as swathes of institutional investors are gaining new interest because of the launch of new futures contracts on both regulated and unregulated cryptocurrency exchanges. Central banks also reacted to private initiatives of launching digital currencies, such as Facebook's Libra, as they may have the potential to dilute the main power of central banks – to control the supply of money to the economy. With high volatility and new interest in the cryptocurrency market, the BTC ecosystem is a perfect environment to show the effectiveness of tail risk strategy. Indeed, its high volatility promises high gains in upward movement of the price. Our goal is then to protect investors from large downturns of the market through an accurate prediction of tail risk.

Since Basel committee on Banking Supervision Amendment to incorporate market risk (1996), regulators imposed the use of certain metrics to measure the risk of investments, such as Value- At-Risk (VaR) and Expected-Shortfall (ES). In order to meet both investors' and regulators' will, we build a tail risk protection strategy that controls the VaR of our portfolio by ensuring that it is below a certain level, denoted as target VaR.

As high volatility segments often precede market swings, the GARCH model is a natural tool for tail risk protection, since GARCH catches these volatility clusters. Nevertheless, a volatility-based risk management strategy forces us to divest in such period, reducing alpha possibilities in case of positive movement. Since financial returns have heavy tails, the EVTGARCH McNeil and Frey (2000) allow us to improve our forecast of the tail event direction. Indeed, seeking alpha, excess return over a benchmark, has become more challenging for banks and institutional investors which follow strong regulations based on VaR estimates. We address this problem here by focusing on dynamic risk management based on econometrics,

explaining stylized facts of financial time series with parametric approaches, and non- or local parametric methods, in particular the LPA from Spokoiny (2009), Multilayer Perceptron (MLP), and Long Short-Term Memory (LSTM) neural networks, which catches nonlinear features with memory.

Our contribution is a rigorous comparison of GARCH- and ML-based tools in the context of extreme loss prediction based on their forecast in a classification scheme. On top, we show how to use standard Ensemble method as a meta classifier that produces a hybrid tail risk protection strategy, improving both generalization and trading performance by taking advantage of each approach. Finally, we evaluate our strategy with a realistic backtest including trading fees, by comparing it with classical buy-and-hold benchmark and other recent machine learning oriented tail risk protection strategies, such as the constant target VaR from Rickenberg (2019) and the Varspread strategy from Packham et al. (2017).

The results showed here will certainly motivate practitioners to apply ML techniques in order to improve GARCH performance. We provide comparison metrics such as forecast error, classification metrics, and backtest results of our tail risk strategies on the cryptocurrency market with BTC investment. We also provide robustness checks through cross-validation.

This chapter is structured as follows. First we review the current literature of our subject, then we explain the trading strategy we aim to build. In the third and fourth part, we explain the theoretical models used to build our strategy. In the final section, we present our results.

92.2 Background and Literature Review

92.2.1 Volatility as a Risk Measure?

A good risk measure must be tailored to the investor's preferences which are often unknown in practice. Starting from preferences, practitioners often make assumptions in order to build an "optimal risk measure," corresponding to an imagined investor's goal. A large part of the financial literature studies volatility as a risk measure, since it is nicely tied to Gaussian and LS techniques. For example, the VIX, referred to as the "investor fear gauge," is often taken as a sentiment indicator since volatility reflects investors' aversion to risk. The mean-variance portfolio, developed by Markowitz, is built under such assumptions where the weights of the risky assets included in the portfolio are derived from their volatility. Nevertheless, financial returns often have fat-tails and are not normally distributed, which Markowitz theory does not account for. Finally, volatility, being symmetric, is not realistic as a risk measure, since it does not take into consideration investors' loss aversion, weighting equally volatility associated with gains and losses. Most investors are more concerned about downside risk, or losses, rather than volatility (Bollerslev et al. 2015). In this chapter, our goal is to build a trading strategy avoiding large losses or tail risk which is better suited for loss averse investors.

Packham et al. (2017) showed that a trading strategy accounting for tail risk can outperform simple buy-and-hold and traditional portfolio protection strategies. By using models such as GARCH with normally distributed innovations and GARCH with innovations following a Generalized Pareto Distribution (GPD), they built a new criterion for riskiness defined as the evolution of the estimated Value-At-Risk (VaR) spread between the two models. Thus, in period of increasing tail risk, this spread is significantly different from 0 which allows the trader to take adequate decisions. We denote this strategy as the Varspread strategy. Rickenberg (2019) compares different risk measure such as volatility, VaR, and Conditional-Value-at-Risk (CVaR), also named Expected Shortfall (ES), in order to build dynamic trading strategies and find that downside risk measures outperform volatility in terms of a higher Sharpe Ratio, better drawdown protection, and higher utility gains for mean-variance and loss-averse investors. Happersberger et al. (2019) also focus on ES and VaR forecasts in order to manage dynamic tail risk protection strategies.

All the papers mentioned above and in general the literature of tail risk protection focus on predicting risk measures in a regression manner and study the total distribution of the returns where the goal is to minimize Mean Squared Error (MSE) type measures of fit. Our argument is that it is not necessary to predict the total distribution of the return, whether it is crucial to correctly forecast the direction of the tail, in particular since in our case big profits or losses are at stake (Jordà and Taylor 2011).

92.2.2 Investors' Preferences

Rickenberg (2019) developed a tail risk protection strategy, denoted target VaR strategy, where the trading signals are calibrated so the VaR of the strategy is constant over time for a predefined significance level α . The weights of the risky asset in the simple portfolio consisting of two assets, one risky and one risky-less asset, is a function of a constant level of risk defined as a VaR level denoted, target VaR, depending on investors' risk aversion measured by α . The weights are calibrated so the VaR of portfolio is constant and equals to the target VaR. The target VaR strategy has the main advantage to be better interpretable for investors who can prescribe their acceptable loss limit to the trader. Nevertheless, it is assumed that investors' preferences are static since the target VaR is fixed and does not depend on t . Such strategy is based on the standard financial theory assumption that investors are rational and have invariant risk preferences.

However, with the development of Behavioral Finance, numerous studies draw attention on the fact that investors are often irrational and their preferences change with different situations. The early paper of Kahneman and Tversky (1979) shows that investors are more risk averse with gains, but less with losses. More recently, Wen et al. (2014) study the characteristics of investors' risk preferences with different states of gains and losses and show that investors' risk preferences are time-varying with them. Indeed, the degree of risk aversion rises with the increasing gains and that of risk seeking improves with the increasing losses.

Taking into consideration investors' time-varying preferences, a constant target VaR strategy is inadequate. Indeed, we should decrease our target VaR in period of gains and increase it in periods of losses to allow more conservative trades in period of gains and more aggressive ones in case of losses.

92.2.3 Dynamic Tail Risk Protection Strategy

Our goal is to build a dynamic tail risk protection with an adaptive predefined level or risk, adapting to the benchmark's performance which influences investors' preferences (Wen et al. 2014). At constant significance level α , when the benchmark is experiencing a period of good performance where the gains are increasing, its VaR is decreasing; thus, the investors give more attention to smaller losses and tend to be more risk averse. As follows, the trader should adapt its strategy and aim for a smaller target VaR. In the inverse situation, during a period of losses, the tail risk of the benchmark is increasing and the investor only pays attention to large losses, tending to seek more risk. For example, one could use a threshold as a function of volatility in order to build a dynamic threshold labeling function as in de Prado (2018), chapter 3.3. In the next section, we will explain how to build such strategy.

92.3 Trading Strategy

92.3.1 Tail Risk as a Risk Measure

Let us give the following **tail risk definition**. Throughout this chapter, we consider a risky asset, for example, one stock, with price process p_t , where $t \in [0, \dots, T]$ with T the final period time step. As usual, we define the one period log-return, where one period is here 1 h, as $r_t = \log \frac{p_t}{p_{t-1}}$ and the loss series $-r_t$. As in Packham et al. (2017), we define the Value-At-Risk for a risk level α , denoted VaR_t^α , as the α -quantile of the distribution of the loss $-r_t$:

$$\text{VaR}_t^\alpha = \inf \{l \in \mathbb{R} : \mathbb{P}(-r_t > l) \leq 1 - \alpha\} = \inf \{l \in \mathbb{R} : \mathbb{P}(-r_t \leq l) \geq \alpha\}$$

If r_t follows an absolutely continuous loss distribution, then the Value-At-Risk can be defined as an unlikely and severe loss which satisfies:

$$\mathbb{P}(-r_t \leq \text{VaR}_t^\alpha) = 1 - \alpha$$

where α is small corresponding to investors' risk aversion. In practice, the risk level often takes the value of 0.01, 0.025, or 0.05. The Value-At-Risk characterizes the far right tail of the distribution of the loss; thus, we use it as a measure of tail risk. For example, a $\text{VaR} = u_t^\alpha = 0.05$ for $\alpha = 0.01$ means that returns below -5% only happen 1% of the time. Moreover, for any threshold u , $\mathbb{P}(-r_t \geq u)$ is called the exceedance probability over u .

92.3.2 Tail Risk Protection Strategy

Now, let us consider a simple buy/sell trading strategy where the trader decides at time t either to enter the market with a full position (he invests the totality of his available capital at time t into BTC) or to stay out of the market (he sells all available BTC or does not invest capital at time t in order to have all his capital in a risk free asset) based on the information available at time t denoted $\mathcal{F}_t$. The trader's decision can be represented as a binary variable, or trading signal, $s_t \in \{0, 1\}$ where 1 corresponds to the decision to stay out of the market and 0 to the decision to fully invest the capital at time t . The return of such strategy is defined for all $t \in [1, \dots, T]$ as $R_t = (1 - s_t - 1)r_t$ and the excess return $R_t - r_t$.

Target VaR The goal of tail risk protection is to maximize the expected economic utility of a risk averse investor which can be represented by the risk-adjusted return of the strategy, where risk is characterized by the tail behavior of the portfolio. In other words, our goal is to lower the probability of tail risk, that is, at constant level T , to have a lower portfolio VaR than the buy-and-hold benchmark strategy which buys the asset at the beginning of the period and sell it at time T , the end of the period of investment. In parallel, we have two choices to maximize the return, either we can maximize the expected return, following the portfolio selection criterion from Markowitz (1952), or we can maximize the total return at T , as suggested by Kelly (1956). Since in our setting, we are optimizing the strategy for multiple periods (Hakansson 1971) we choose the latter. We can write the following optimization program:

$$\begin{aligned} \max \quad & \sum_{t=1}^T (R_t - r_t) \\ \text{s.t.} \quad & \text{VaR}_t^\alpha \leq \text{TVaR}_t^\alpha \end{aligned} \quad (1)$$

where VaR^α is the portfolio VaR and TVaR_t^α is the **target VaR for level α** given by the investor.

We have the following equivalence, $\forall t \in [1, \dots, T]$:

$$\begin{aligned} \text{VaR}_t^\alpha &\leq \text{TVaR}_t^\alpha \\ \text{P}(-R_t \leq \text{TVaR}_t^\alpha) &\geq 1 - \alpha \end{aligned} \quad (2)$$

Thus, one relaxes the constant constraint from Rickenberg (2019) and aims at constructing a trading mechanism with signal $s = \{s_1, \dots, s_T\}$ that has a maximum TVaR^α . From now on, we think of fixed α and we will write TVaR_t^α as TVaR_t for the benchmark Value-At-Risk and VaR_t^α as VaR_t for the portfolio.

How to define the signals s_t For all $t \in [0, T-1]$, we define:

$$s_t = \mathbf{I}_{-r_{t+1} \geq \text{TVaR}_{t+1}} \quad (3)$$

and by construction $R_t = (1 - \mathbf{I}_{-r_t \geq \text{TVaR}_t})r_t$. Since TVaR_t is strictly positive for financial assets loss series, we have $\text{P}(-R_t \leq \text{TVaR}_t) = 1$, thus (2) is verified.

Since we do not know the true distribution of r_t and, obviously, at time t , we do not observe r_{t+1} , we do not know s_t , and we must build estimates based on the observation available in order to make a trading decision. We estimate the following conditional probability, $P(-r_{t+1} \geq \text{TVaR}_{t+1} | \mathcal{F}_t)$, which is the exceedance probability over the threshold TVaR_{t+1} , and decide whether the trader must close his position $s_t = 1$ or stay in the market $s_t = 0$.

Tail Risk Target TVaR^α The tail risk target, TVaR^α , is defined by the investors' preferences. Here, our goal is not to study investors' preferences, but to show how to build trading signals based on estimates of the exceedance probability over a given risk level. This problem has been well studied in the literature, for various applications, such as seismic risk assessment (Honegger and Wijewickreme 2013), risk assessment for decision making with application to terrorism (Kunreuther 2002), or again floods, earthquakes, drought, and hurricanes risk management (Lambert et al. 1994; Mason et al. 2007). For trading strategies, Christoffersen and Diebold (2006) and Linton and Whang (2007) considered exceedances above 0, whereas Chung and Hong (2007) focused on nonzero thresholds. In particular, Taylor and Yu (2016) studied thresholds that are not close to 0, as this is of greater relevance for risk management. This is also our interest but we consider extreme thresholds which are time varying and can be used as tail risk measure.

For illustration, we focus in this chapter on different tail risk targets derived from the data itself. That is we use sample quantiles for different level α computed on the historical losses in a rolling window manner for different window size. In other words, to describe the investors' preferences for the next trading period $t + 1$, we use the historical VaR of the loss series as tail risk measure defined for $w \in [1, T]$ as:

$$\forall t \in [w, T], \forall i \in [t - w + 1, t], \text{TVaR}_{t+1} = \text{hist-VaR}_t^{\alpha, w} = \inf \{l \in \mathbb{R} : P(-r_i > l) \leq 1 - \alpha\} \quad (4)$$

The main advantage of this risk target is its computational simplicity allowing us to easily build training labels for our classifiers that we will develop in the next sections. On top, it is adaptable to investors' preferences, since using a small rolling window would suit an investor with varying preferences where the risk target quickly adapts itself to changes in the true return distribution, while large rolling windows give more stable risk target, corresponding to an investor with static preferences. In this chapter, we will use three window sizes: 24 (1 day), 2880 (4 months), and 4320 (6 months), since we are using hourly data, which are plotted on Fig. 1 for $\alpha = 0.01$. We give more details about the dataset in the next section. Our choice is motivated by the goal to study how the tools used here react to different levels of noise in the target variable.

As we can see in Fig. 1, the $\text{TVaR}_t^{0.01, 24}$ is much more conservative than the $\text{TVaR}_t^{0.01, w}$ with larger w , with much more losses exceeding the risk target. Indeed, we have, respectively, 0.045, 0.012, and 0.011 exceedance for the $\text{TVaR}_t^{0.01, w}$ with w is 24, 2880, and 4320, where the exceedance is defined as $N_e = \frac{1}{T} \sum_{t=1}^T -r_t \geq \text{TVaR}_t^\alpha$, that is the proportion of data exceeding the threshold. A strategy with

Fig. 1 Hourly btc losses and $TVaR_t^{0.01,w}$ for different window size, $w = 24$ (1 day), $w = 2880$ (4 months), $w = 4320$ (6 months)

$TVaR_t^{0.01,24}$ as tail risk target should be much more conservative and hedges much more losses than the two other risk targets.

Trader's Decision Finally, how to decide whether we should hedge our position for the next trading period? We could build an estimation of the return at the next period, r_{t+1} , in a regression manner, nevertheless, we are only interested in the distribution of the tail. Thus, in this chapter, we directly approximate the conditional probability classes of the variable s_t , that is p_t , defined $\forall t \in [0, \dots, T-1]$ as:

$$p_t = P(s_t = 1 | \mathcal{F}_t) = P(-r_{t+1} \geq TVaR_{t+1}^\alpha | \mathcal{F}_t) \quad (5)$$

From p_t , we can make the trading decision $\hat{s}_t$ defined for a threshold $u \in \mathbb{R}$:

$$\hat{s}_t = \begin{cases} 1, & \text{if } p_t \geq u \\ 0, & \text{otherwise} \end{cases} \quad (6)$$

We can now write the realized return of our strategy, for all $t \in [1, T]$:

$$R_t = (1 - \hat{s}_{t-1})r_t \quad (7)$$

92.4 Machine Learning Trader

Let $X_t \in \mathbb{R}^p$ be some input feature vector of dimension p which summarize $\mathcal{F}_t$. The aim is to approximate the true unknown conditional probability $P(s_t | X_t)$ with a learning algorithm $\mathcal{M}$ for different risk targets. We consider four different α : 1%,

2.5%, 5%, and 10%, and three rolling windows to compute TVAR: 24, 2880, and 4320. In the next two sections, we present different models $\mathcal{M}$ we use as estimator for each risk target. We first present the dataset we use and then we explain the different models considered.

92.4.1 Data

We apply the proposed strategy on BTC. We collected 36,193 close prices from Poloniex exchange, using its API, from 2016-01-01 to 2020-02-16 on an hourly basis. We look at intraday frequency, since it is not rare to observe severe loss at such frequency, due to a relatively higher volatility in the cryptocurrency market compared to traditional assets.

We split the dataset into two sets, train, from 2016-01-01 to 2019-01-01 00:00:00, and test sets, from 2019-01-01 01:00:00 to 2020-02-16 22:00:00. We keep a relatively large test set in order to produce a final robust estimation of the out-of-sample trading strategy performance with a large backtesting period of 9486 observations.

92.4.2 Neural Networks

We first use two different neural network architectures for the trading signals prediction, the multilayer perceptron (MLP) and the long short-term memory neural network (LSTM) architecture from Hochreiter and Schmidhuber (1997). Neural networks are nonparametric, which allows us to avoid making strong assumptions on the data that are not met in reality and that is often the case for financial time series, for example, with the normality assumption of financial returns. On top, neural networks are universal approximators (Leshno et al. 1993) which means that, in theory, neural networks can arbitrarily closely approximate the true process of r_t . In particular, LSTM neural networks are state-of-the-art for many applications such as speech recognition, text extraction, translation, or handwriting recognition, since plain recurrent neural networks are not suited to nonstationary time series modeling. In finance, deep learning has been used in various researches, in particular by Franke (1999) and Zhang et al. (2020) for portfolio management or by Kim and Won (2018) for volatility forecasting with LSTM in comparison with GARCH. Nevertheless, one has yet to prove the superiority of neural networks compared to simpler parametric models in their application.

92.4.2.1 Trader's Function Mapping

Output In order to train the neural networks, we need to build the training input-output pairs. We could directly use the trading signal s_t from (3) as output labels, nevertheless, since $\text{TVaR}_t^{\alpha,w}$ belongs to the tail of the loss series, s_t suffers from severe class imbalance since $\frac{\sum_{t=w+1}^T \mathbf{1}_{-r_t > \text{TVaR}_t^{\alpha,w}}}{T} \ll 0.5$, which is difficult to handle for machine learning models (Krawczyk 2016). On top, financial returns follow an

asymmetric distribution and suffers from the leverage effect (Black 1976; Christie 1982), commonly defined as volatility rising more rapidly when returns are negative than positive. To address that problem, we introduce a new category for r_t , when r_t belongs to the right tail of the distribution, which allows us to control the misclassification cost of the final model. Indeed, let us introduce the following output variable defined as:

$$Y_t = \begin{cases} 1, & \text{if } -r_t < \text{TVaR}_t^{1-\alpha, w} \\ 2, & \text{if } -r_t > \text{TVaR}_t^{\alpha, w} \\ 0, & \text{otherwise} \end{cases} \quad (8)$$

We can define the predicted strategy signals as a function of the predicted output variable $\hat{Y}$ as follows:

$$\hat{s}_t = \begin{cases} 1, & \text{if } \hat{Y}_t = 2 \\ 0, & \text{otherwise} \end{cases} \quad (9)$$

and we easily derive the unconditional misclassification costs matrix in terms of excess returns.

Outcome	Prediction		
	0	1	2
0	0	0	$\bar{r}_0 \bar{p}_0$
1	0	0	$\bar{r}_1 \bar{p}_1$
2	0	0	$\bar{r}_2 \bar{p}_2$

where $\bar{r}_i$ is the expected return on class i estimated with $\frac{1}{\sum_{t=w+1}^T \mathbf{1}_{Y_t=i}} \sum_{t=w+1}^T r_t \mathbf{1}_{Y_t=i}$

and $\bar{p}_i$ is the weight of class i defined as $\frac{\sum_{t=w+1}^T \mathbf{1}_{Y_t=i}}{T-w}$ which is the empirical estimate of the unconditional probability $P(Y_t = i)$.

As expected, when using the risk target defined in (4), we can see in Table 1 that one has negative costs for the correct classification of class 2 since $\bar{r}_2 \leq 0$ and by definition, the conditional cost for predicting class 2 instead of 1 is much higher than the one for predicting class 2 instead of 0, since in the former, we miss the opportunity to invest during an extremely positive return period. Thus, we clearly see that the classifier must correctly predict the sign of the tail events in order to maximize the strategy return. In order to do so, we use a 3 neurons output layer with softmax activation function corresponding to the output variable Y_t defined in (8).

Input Layer As we are interested in understanding whether neural networks can, by themselves, learn valuable features to produce trading signals and feature selection is not our interest in this work, we use simple transformations of the returns, which can be seen as momentum features.

Table 1 Class 2 misclassification costs for different TVaR^{α,w}

α	w (hours)	Prediction		
		0	1	2
0.01	24	0.01	0.15	−0.15
	2880	0.01	0.14	−0.14
	4320	0.01	0.13	−0.14
0.025	24	0.01	0.15	−0.15
	2880	0.01	0.14	−0.14
	4320	0.01	0.13	−0.14
0.05	24	0.01	0.15	−0.15
	2880	0.01	0.14	−0.14
	4320	0.01	0.13	−0.14
0.1	24	0.01	0.15	−0.15
	2880	0.01	0.14	−0.14
	4320	0.01	0.13	−0.14

In particular, since price time series are not stationary, we use multiple returns instead, $X_t^p = r_{t-p}$ for different periods p , where $r_{t-p} = p/p_{t-1-p} - 1$ and $p \in \{0, 1, 2, 4, 6, 13\}$. We also use the normalized difference between the returns and the two class thresholds which should help identifying a risk-buildup situation, when the returns either explodes toward the upper class threshold $\text{TVaR}_t^{1-\alpha,w}$ or severely drops toward the lower threshold $\text{TVaR}_t^{\alpha,w}$, which are defined respectively as $U_t^{\alpha,w} = \frac{r_t - \text{TVaR}_t^{\alpha,w}}{\text{TVaR}_t^{\alpha,w}}$ and $D_t^{\alpha,w} = \frac{r_t - \text{TVaR}_t^{1-\alpha,w}}{\text{TVaR}_t^{1-\alpha,w}}$.

For the MLP, we then use the vector $X_t \in \mathbb{R}^8 = (X_t^0, X_t^1, X_t^2, X_t^4, X_t^6, X_t^{13}, D_t^{\alpha,w}, U_t^{\alpha,w})$ as input for each risk target. For the LSTM model, since it is a recurrent neural network, we take advantage of its ability to directly modelize sequential data and we use the same features as above on a certain historical window of length 24, using one historical day to make a prediction for the next hour. Thus, the features become: $X_t^p = (r_{t-p-23}, \dots, r_{t-p})$ for $p \in \{0, 1, 2, 4, 6, 13\}$ and $U_t^{\alpha,w} = \left(\frac{r_{t-23} - \text{TVaR}_t^{\alpha,w}}{\text{TVaR}_t^{\alpha,w}}, \dots, \frac{r_t - \text{TVaR}_t^{\alpha,w}}{\text{TVaR}_t^{\alpha,w}} \right)$ and $D_t^{\alpha,w} = \left(\frac{r_{t-23} - \text{TVaR}_t^{1-\alpha,w}}{\text{TVaR}_t^{1-\alpha,w}}, \dots, \frac{r_t - \text{TVaR}_t^{1-\alpha,w}}{\text{TVaR}_t^{1-\alpha,w}} \right)$. We use the same input vector as for the MLP, but now X_t is in $\mathbb{R}^{24, 8}$. We explain the hidden layer architecture in the next section.

Finally, we train our classifier, using Keras python library, on the training data $D = \{(X_w + 1, Y_w + 1), \dots, (X_T, Y_T)\}$ with Adam algorithm, which is a stochastic gradient descent method based on adaptive estimation of first-order and second-order moments of the gradient (Kingma and Ba 2015) and 128 batch size.

92.4.3 Model Selection

92.4.3.1 Hidden Layers Architecture

On the train set, we performed 10 folds cross-validation for time series, described in Fig. 3, with one fold corresponding to 1 month, in order to test different hidden layers architectures for the MLP model. In this work, we keep the hidden layers relatively simple in order to show how a single architecture can effectively extract features for different risk target output. Based on the cross-validation performance evaluated with AUC score (area under the ROC curve), we choose the model with highest AUC score between class 1 and 2, while still controlling for robustness. That is we select the model with highest median AUC score between class 1 and class 2. After a small tuning, we keep three hidden layers and three fully connected layers with 16, 4, and 2 neurons, respectively, as in Fig. 2.

As regularization technique, we use the state-of-the-art Dropout layer after the first and the second hidden layers with a dropout rate of 0.2, in order to prevent overfitting (Srivastava et al. 2014).

Fig. 2 Final MLP architecture

Fig. 3 Time series cross-validation with four folds

As for the LSTM architectures, we simply change the first two fully connected layers to LSTM units in order to test whether LSTM can directly improve the performance of the MLP models. We use the hyperbolic tangent as activation function for the hidden layers.

92.4.3.2 Strategy Parameters and Final Decision

Any classifier $\mathcal{M}$ trained on the dataset D gives for output the probability class p_t . Thus, the trading strategy based on $\mathcal{M}$ has one parameter, the probability threshold u from which we can make a trading decision with respect to (6). The optimal parameter must solve the investor’s goal define in (1) with respect to their risk target. We can now reformulate the optimization problem as it follows (Fig. 3):

$$\begin{aligned} \max_{u,w} \quad & \sum_{t=w+1}^T (R_t - r_t) = \sum_{t=w+1}^T \{(1 - \hat{s}_t)r_t\} \\ \text{s.t.} \quad & \text{VaR}_t^\alpha \leq \text{TVaR}_t^\alpha \end{aligned} \tag{10}$$

Probability Threshold u Denote $\mathcal{U}_\alpha$ the set of u which are tail loss optimal, that is the set of u respecting the constraint formulated in (2). Let us define our strategy with the trading signals $\{\hat{s}_{tw+1}, \dots, \hat{s}_{tT}\}$ and corresponding return $S_{w,\alpha} = \{R_{w+1}, \dots, R_T\}$ for a predefined risk target with level α . We wish to define:

$$\mathcal{U}_\alpha = \{u \in \mathbb{R}, \text{ P}(R_t \leq \text{TVaR}_t^\alpha) \geq 1 - \alpha\}$$

Let us introduce the conditional probability classes for an arbitrary threshold $u \in \mathbb{R}$:

		Prediction	
		0/Hold	1/Sell
Outcome	0/Hold	$\text{TNR}(u) = \text{P}(\hat{s}_t = 0 s_t = 0)$	$\text{FPR}(u) = \text{P}(\hat{s}_t = 1 s_t = 0)$
	1/Sell	$\text{FNR}(u) = \text{P}(\hat{s}_t = 0 s_t = 1)$	$\text{TPR}(u) = \text{P}(\hat{s}_t = 1 s_t = 1)$

where $\text{TNr}(u)$, $\text{FPR}(u)$, $\text{FNR}(u)$, and $\text{TPR}(u)$ stand for *True Negative*, *False Positive*, *False Negative*, and *True Positive Rates* for the threshold u , respectively. In statistical tests, $\text{FPR}(u)$ and $\text{FNR}(u)$ are often called type I and type II errors, respectively. The optimal threshold is given by the optimal trade-off between FPR and FNR , but in order to respect the risk target, one cannot choose any trade-off, since, as one can easily see, $\text{FNR}(u)$ corresponds to the exceedance probability of the portfolio over the risk limit. In practice, as it is pointed out in Packham et al. (2017), such a strategy cannot avoid tail events that occurs “totally out of the blue” (type II error in our formulation). Also, given the empirical stylized fact that return data feature little or no autocorrelation implies that such a strategy may signal a sell order, when ex-post holding the position would have been optimal (type I error).

We can easily see that any threshold $u^* \in \mathcal{U}_\alpha = \left\{ u \in \mathbb{R}, \text{TPR}(u) \geq \frac{\text{P}(-r_t > \text{TVaR}_t^\alpha) - \alpha}{\text{P}(-r_t > \text{TVaR}_t^\alpha)} \right\}$ is tail loss optimal.

Proof We need to compute the following probability for all $u \in \mathbb{R}$ and $t \in [w, T]$:

$$\text{P}(R_t \leq \text{TVaR}_t^\alpha) = 1 - \text{P}(R_t > \text{TVaR}_t^\alpha)$$

We have:

$$\begin{aligned} \text{P}(R_t > \text{TVaR}_t^\alpha) &= \text{P}(R_t > \text{TVaR}_t^\alpha \cap s_t = 1) + \text{P}(R_t > \text{TVaR}_t^\alpha \cap s_t = 0) \\ &= \text{P}(R_t > \text{TVaR}_t^\alpha \mid s_t = 1) \text{P}(s_t = 1) + \underbrace{\text{P}(R_t > \text{TVaR}_t^\alpha \mid s_t = 0) \text{P}(s_t = 0)}_{=0} \\ &= \text{P}(R_t > \text{TVaR}_t^\alpha \mid s_t = 1) \underbrace{\text{P}(s_t = 1)}_{= \text{P}(-r_t > \text{TVaR}_t^\alpha)} \end{aligned} \quad (11)$$

and:

$$\begin{aligned} \text{P}(R_t > \text{TVaR}_t^\alpha \mid s_t = 1) &= \text{P}(R_t > \text{TVaR}_t^\alpha \cap \hat{s}_t = 0 \mid s_t = 1) \\ &\quad + \text{P}(R_t > \text{TVaR}_t^\alpha \cap \hat{s}_t = 1 \mid s_t = 1) \quad \text{P}(\hat{s}_t = 0 \mid s_t = 1) \\ &= \underbrace{\text{P}(R_t > \text{TVaR}_t^\alpha \mid \hat{s}_t = 0 \cap s_t = 1)}_{=0} \quad \text{P}(\hat{s}_t = 0 \mid s_t = 1) \\ &\quad + \underbrace{\text{P}(R_t > \text{TVaR}_t^\alpha \mid \hat{s}_t = 1 \cap s_t = 1)}_{=0} \text{P}(\hat{s}_t = 1 \mid s_t = 1) \\ &= \text{P}(\hat{s}_t = 0 \mid s_t = 1) = \text{FNR}(u) = 1 - \text{TPR}(u) \end{aligned} \quad (12)$$

By plugging (12) in (11), we have:

$$\text{P}(R_t > \text{TVaR}_t^\alpha) = \{1 - \text{TPR}(u)\} \text{P}(-r_t > \text{TVaR}_t^\alpha)$$

Hence:

$$\begin{aligned} P(R_t \leq \text{TVaR}_t^\alpha) &= 1 - \{1 - \text{TPR}(u)\}P(-r_t > \text{TVaR}_t^\alpha) \\ &= 1 - P(-r_t > \text{TVaR}_t^\alpha) + P(-r_t > \text{TVaR}_t^\alpha)\text{TPR}(u) \end{aligned}$$

In order to achieve the goal of our tail risk protection strategy, we must have:

$$\begin{aligned} P(R_t \leq \text{VaR}_t^{\alpha, \text{target}}) &\geq 1 - \alpha \\ 1 - P(-r_t > \text{TVaR}_t^\alpha) + P(-r_t > \text{TVaR}_t^\alpha)\text{TPR}(u) &\geq 1 - \alpha \\ \text{TPR}(u) &\geq \frac{P(-r_t > \text{TVaR}_t^\alpha) - \alpha}{P(-r_t > \text{TVaR}_t^\alpha)} \end{aligned} \quad (13)$$

Thus, any threshold u^* with satisfies (13) is tail loss optimal, since it will ensure a maximum target VaR by controlling the type II error.

Finally, to decide for the final probability class threshold u^* , we simply choose the threshold that maximize the cumulative excess return on the train set and apply it on the corresponding test set.

For illustration, in Fig. 4, we plotted the shape of the constraint on TPR with respect to the risk limit of the investor for different risk level α . As we can see, as the target risk for a level α diverges from the α -quantile of the true distribution of the returns, the constraint on the classifier performance strengthens.

As described in Sect. 92.3, the risk targets are defined by Eq. (4). In Table 2, we show the different constraints from Eq. (2) on the classifier in order to achieve the goal of the tail loss strategy based on the hourly returns of btc on the train set.

As we can see, using a small rolling window to compute the risk target is more conservative; thus, the classifier must have a large TPR in order to ensure a maximum risk target of the final strategy.

92.5 Auto-Regressive Models

Since neural networks are complex nonlinear multifactor models, it is justified to ask if a simple parametric model calibrated on the same training set can catch tail-events as good ML methods or better. In order to compare both approaches, we used three different parametric and a LPA technique from Spokoyny (009a), that we present in this section.

92.5.1 ARMA-GARCH Type Models

92.5.1.1 ARMA-GARCH

As a benchmark, we first used an ARMA-GARCH model for BTC loss series. Indeed, GARCH, developed by Bollerslev (1986), catches well volatility clusters,

Fig. 4 Expected exceedance and corresponding minimum TPR for significance levels 0.01, 0.025, 0.05, 0.1

Table 2 Expected exceedance and corresponding minimum TPR for different VaR estimators with parameters (α, w), $w = 2880$ and $w = 4320$ correspond to 4 months and 6 months respectively

α	w (hours)	Exceedance	min TPR (%)
0.01	24	4.5	78
	2880	1.2	18
	4320	1.1	11
0.025	24	5.5	55
	2880	2.7	7
	4320	2.6	5
0.05	24	8.0	38
	2880	5.2	4
	4320	5.1	3
0.1	24	12.5	20
	2880	9.7	0
	4320	9.4	0

which often appears in returns time series and ARMA model allows for a time-varying mean of the returns. The ARMA(P, Q)-GARCH(q, p) model is defined as:

$$r_t = a_1 r_{t-1} + a_2 r_{t-2} + \dots + a_P r_{t-P} \\ + \varepsilon_t + b_1 \varepsilon_{t-1} + b_2 \varepsilon_{t-2} + \dots + b_Q \varepsilon_{t-Q}$$

with

$$\varepsilon_t = Z_t \sigma_t \\ Z_t \sim N(0,1) \\ \sigma_t^2 = \omega + \sum_{i=1}^p \beta_i \sigma_{t-i}^2 + \sum_{j=1}^q \alpha_j \varepsilon_{t-j}^2$$

where $\omega > 0$, $\alpha_i \geq 0$, $\beta_i \geq 0$ and $\sum_{i=1}^p \beta_i + \sum_{j=1}^q \alpha_j < 1$.

92.5.1.2 ARMA-EVTGARCH

Assuming normally distributed innovations, Z , is often not justified and, since in our case we are interested in modeling extreme events, we also fitted an ARMA-GARCH model with a Generalised Pareto distribution (GPD) for the innovations of the GARCH process. This approach has been studied numerous time in the literature, in particular in Packham et al. (2017) or Taylor and Yu (2016) for risk management in trading. We refer to that model as ARMA-EVTGARCH.

The distribution function of the GPD is given by:

$$G_{\xi, \beta}(x) = \begin{cases} 1 - (1 + \xi x / \beta)^{-1/\xi}, & \xi \neq 0 \\ 1 - \exp^{-x/\beta}, & \xi = 0 \end{cases}.$$

where $\beta > 0$, $x \geq 0$ when $x \geq 0$ and $0 < x \leq -\beta/\xi$ when $\xi < 0$.

The GPD describes the tail of the data since only the extremes outcomes are included in the estimation with the method of threshold exceedances as we explain in the next paragraph.

92.5.1.3 Model Selection, Calibration, and Exceedance Probability

To find the proper lag orders, P and Q , for the mean, and p and q , for the volatility processes, we use the classical Box-Jenkins method and AIC criterion, see Chen et al. (2018) for a detailed explanation. We perform the model selection on the last 2280 observations (4 months) of the train set. The final model selected is an ARMA(3, 1)-GARCH(1, 2); we use the same orders ARMA-EVTGARCH.

We calibrate the parameters of ARMA-GARCH and ARMA-EVTGARCH simultaneously via quasi-maximum likelihood estimation (QMLE) (McNeil and Frey 2000) using a rolling window of fixed length of 4 months (2880 observations). The size of the rolling window is relatively large for GARCH modeling, nevertheless, in this chapter, we are using intraday data which justifies that choice. As a comparison Taylor and Yu (2016) used a rolling window of 2500 observations. The

Fig. 5 QQ plots of GARCH residuals. Left: normal distribution; right: GPD distribution (samples beyond upper 5% threshold, g)

calibration of the GPD is based on the upper 5% of the residuals of the ARMA-GARCH; we denote the upper 5% threshold as g . For illustration, residual QQ-plots based on hourly BTC loss data are given in Fig. 5.

The estimated probability class of for the category 2 of Y_t , that is, $P(-r_t > \text{TVaR}_t^\alpha)$, is then given by $p_t = 1 - F((\text{TVaR}_t^\alpha - \hat{\mu}_{t+1})/\hat{\sigma}_{t+1})$ where $\hat{\mu}_{t+1}$ and $\hat{\sigma}_{t+1}$ are the models' mean and volatility forecasts and F is the normal distribution function for the ARMA-GARCH and GPD for the ARMA-EVTGARCH model. For computing p_t of ARMA-EVTGARCH, the GPD is defined only for $x \geq g$, so if $(\text{TVaR}_t^\alpha - \hat{\mu}_{t+1})/\hat{\sigma}_{t+1} < g$, F is the normal distribution, since it is not necessary to use a GPD distribution for observations that do not belong to the tail. We recalibrate the parameters of the models every hour for each new observation in the test set.

92.5.2 CARL-vol Model

The benefit of ARMA-GARCH type models is their effectiveness at catching stylized facts of financial time series and their simplicity, nonetheless, they do not directly model the exceedance probability p_t , but the total distribution of the return r_t . In order to use the advantages of GARCH models and to directly modelize the exceedance probability, we also fit a CARL-vol model from Taylor and Yu (2016) which specifies p_t for a constant threshold $Q \in \mathbb{R}$ as:

$$p_t = \frac{0.5}{1 + \exp(-x_t)} + 0.5\mathbf{I}(Q > 0)$$

where $x_t = \phi_0 + \phi_1\sigma_t$ and we assume a GARCH(1, 1) for the return, that is, $\sigma_t^2 = \omega + \beta_1\sigma_{t-1}^2 + \alpha_1(r_{t-1} - \mu)^2$. ϕ_i , α_i , β_i , and μ are constant parameters.

We calibrate the parameters of CARL-vol with Maximum Likelihood Estimation using a Bernoulli distribution with density specified as $f(r_t) = p_t^{\mathbf{1}_{(y_t \leq Q)}} (1 - p_t)^{1 - \mathbf{1}_{(y_t \leq Q)}}$. For the model calibration, we use the same rolling window as for the GARCH-based models of the previous section, where Q is set to TVaRt of the last observation of the rolling window. Since CARL-vol assumes a fixed threshold Q and that, in our case, it is time-varying, we also recalibrate the model every hour, estimating new parameters for each observation in an online manner.

92.5.3 Local Parametric Approach (LPA)

For the calibration of the three previous models, we use a fixed rolling window, assuming time homogeneity on that interval, in the sense that the process r_t follows the same structural equation at each time point defined by ARMA-GARCH, ARMA-EVTGARCH, and CARL-vol models. This approach, of course, does not take into consideration structural breaks (Bouri et al. 2019). Ignoring breaks will increase the bias (Hillebrand 2005). Though, in order to relax time homogeneity, we can either use a nonparametric model which allows for time-varying parameters, as we do with the neural network models presented in chapter 92.4, or we can use a Local Parametric Approach (LPA) thanks to the Local Change Point detection method suggested by Spokoiny (1998) and developed by Härdle et al. (2003), Mercurio and Spokoiny (2004) and Spokoiny (2009) in the context of volatility modeling.

As in Cizek et al. (2009), we assume GARCH(1, 1), characterized by parameters θ , is a good candidate for the process r_t on a local scale. For estimating θ , we apply the QMLE approach using a Gaussian distribution for the innovations. The LPA allows us to find the largest interval of homogeneity, $\mathcal{I}(t)$, that is, the longest interval $\mathcal{I}$ with the right-end point t , where data do not contradict the assumption that θ is constant. To find the change points, we use the test procedure proposed by Klochkov et al. (2019) that uses the multiplier bootstrap method from Spokoiny and Zhilova (2015) to find the critical values for the likelihood ratio test, generating 100 bootstrap weights sequences for the test. The computational cost is high and our test set is quite large; thus, in practice, we choose a fixed decreasing size of 5 observations for the successive intervals tested and we only performed the LPA detection every 5 observations in the test set. This does not come without cost and automatically increases the bias of $\hat{\theta}$, nevertheless, it decreases the bias in comparison of a fixed window size approach, as for the GARCH-based models of the previous sections. We denote the model calibrated with LPA method as LCP-GARCH.

92.6 Applications

92.6.1 Meta Strategy: Stacking

In the previous section, we presented six different classifiers to build trading signals for tail events hedging. Since the GARCH-based approach is essentially linear, but MLP and LSTM are nonlinear classifiers, we expect them to extract different

features from the data. A direct question is then to know which model to use in which situation. To address that problem, we propose to combine all models output from the test set into a meta model with a stacking classifier. Stacking is an ensemble learning technique where the predictions of multiple classifiers (referred as level-0 classifiers) are used as new features to train a meta-classifier (level-1 classifier).

The meta-classifier is trained on the predictions made by level-0 classifiers on the out-of-sample data. That is, data which has not been used to train the level-0-classifiers is fed to them in order to get the predictions $p_t = (p_t^j)$, where $1 \leq j \leq 6$ corresponds to the level-0 models and t belongs to the test set indices. We then use the predictions to build input features and the corresponding labels Y_t to build the training input-output pairs for the meta classifier.

Our meta-classifier should be explainable in order to directly interpret which level-one classifier contributes the most to the final meta-prediction. For its simplicity and interpretability, we use logistic regression. We have for all $t \in [T - n - 1, T]$ where n is the test set size:

$$s_t = \sum_{j=1}^6 \beta^j P_t^j$$

where $P_t^j = \log \frac{p_t^j}{1-p_t^j}$ and p_t^j is the output of each one-level classifier that is the estimated probability of class 2 of Y_t . Moreover, since we need to interpret the coefficients β^j , we rescale p_t^j to $[0, 1]$ range.

When using stacking technique, the issue is the multicollinearity of the prediction of the level 1 classifiers. In particular, we can expect ARMA-GARCH and ARMA-EVTGARCH models to present multicollinearity in their output. To address that problem, we use L2 regularization to improve robustness, performing a Ridge type logistic regression (Hoerl and Kennard 1970), where the final estimator for the model coefficients is the solution of:

$$\min_{\beta_1, \dots, \beta_6} \sum_{i=T-n-1}^T \left(s_t - \sum_{j=1}^6 \beta^j p_t^j \right)^2 + \lambda \sum_{j=1}^6 \beta^j{}^2$$

where $\lambda \in \mathbb{R}^+$ is the regularization hyper-parameter. In practice, we must finetune this parameter by performing, for example, cross-validation. In our setup, we did not tune it since cross-validation would be too computationally intensive and fixed it to $\lambda = 1$. We will denote that model as Ensemble.

In the next sections, we present our results. They correspond to out-of-sample performance of the different models on the test set from 2019-01-01 to 2020-02-16. The neural network models are retrained every 824 observations corresponding to the size of the validation folds in order to reflect the validation performance, whereas the ARMA-GARCH, ARMA-EVTGARCH, CARL-vol, and Ensemble are recalibrated every new observation and LPA-GARCH every five observations as stated in the previous section.

Every hour, each model generates the trading decision $\hat{s}_t$ based on the data available until t , then it is applied to the return, r_{t+1} , on the next period $[t, t + 1]$. The current set-up does not account for market frictions, such as bid-ask spreads, and other associated costs, but we included the trading fees from Binance exchange, which are, at most, 0.1% on each trade. Nonetheless, the cost associated to the fees should be very low since we only trade when a tail event is predicted.

92.6.2 Benchmarks

There are a few well-documented tail risk protection strategies in the literature, such as the constant proportion portfolio insurance (CPPI) strategy (Black and Jones 1987), the Dynamic Proportion Portfolio Insurance (DPPI) or Time-varying Proportion Portfolio Insurance (TPPI) strategy (Hamidi et al. 2009; Happersberger et al. 2019), or the protective put strategy using options. In this chapter, we compared our results with more recent and machine learning oriented work, in particular the Varspread and target VaR strategies. Finally, the last benchmark used is the simple buy-and-hold strategy, where an investor buys BTC at 2019-01-01 00:00:00 and sells it at the end of the test set at 2020-02-16 22:00:00.s.

92.6.3 Out-of-Sample Performance

92.6.3.1 Model Risk Evaluation

In order to assess the performance of each strategy, we first look at the model risk which comes from the statistical performance of the classifier. A familiar metric is the Area Under the ROC Curve (AUC), nevertheless, the classical AUC, while taking into consideration class imbalance, does not include the cost associated with each class. For our trading application, as we stated in Sect. 92.4.2, we have strong cost imbalance between the outcomes. Thus, for our evaluation, we use the risk-adjusted or cost-adjusted AUC by Jordà and Taylor (2011).

The ROC curve is defined for all threshold u as:

$$\begin{aligned} \text{ROC} : [0, 1] &\rightarrow [0, 1] \\ \text{FPR}(u) &\mapsto \text{TPR}(u) \end{aligned}$$

We incorporate the average costs associated with false positives ($c_F = \bar{r}_0 p_0 + \bar{r}_1 p_1$) and true positives ($c_T = -\bar{r}_2 p_2$) in order to get the risk-adjusted curve, denoted AROC and rescaled to $[0, 1]$, defined for all threshold u as:

$$\begin{aligned} \text{AROC} : [0, 1] &\rightarrow [0, 1] \\ c_F \text{FPR}(u) &\mapsto c_T \text{TPR}(u) \end{aligned}$$

The risk-adjusted AUC, denoted AAUC is then $\text{AAUC} = \int_0^1 \text{AROC}(u) du$.

Table 3 Risk-adjusted AUC on the test set

α (%)	w (hours)	MLP	LSTM	ARMA-GARCH	ARMA-EVTGARCH	LPA-GARCH	CARL-vol	Ensemble
1.0	24	69	69	73	73	71	71	73
	2880	62	67	69	72	72	69	74
	4320	70	69	70	72	72	74	74
2.5	24	66	69	70	70	69	69	71
	2880	72	71	74	74	76	72	77
	4320	71	73	74	74	75	73	77
5.0	24	65	65	66	66	65	66	67
	2880	71	70	74	74	75	73	76
	4320	70	71	74	73	75	73	76
10	24	63	63	63	63	60	62	64
	2880	67	66	70	70	71	71	72
	4320	66	68	69	70	70	71	71

In Table 3 we show the risk-adjusted AUC score on the whole test period. We can see that the MLP and LSTM models have similar performance; we can make the same observation for the ARMA-GARCH, ARMA-EVTGARCH, and LPA-GARCH approach model. Nonetheless, we observe that LPA-GARCH performs better than ARMA-GARCH and ARMA-EVTGARCH for stable risk target where $w = 2880$ or $w = 4320$. This indicates that using a model with less complexity fitted on a time-homogeneous window generalized better than more complex models fitted on large window. Finally, all parametric or local parametric models perform better than the neural network-based models in terms of risk-adjusted classification, which is a major drawback to the deep learning approach in our setting.

In Table 4 we present the cross-validation performance on the test set. Indeed recall, that the results from the MLP and the LSTM models are obtained by retraining the models every 824 observations in the same approach as depicted in Fig. 3. For comparison, we also evaluate the other classifiers with the same sampling method.

We can clearly see that ARMA-GARCH and ARMA-EVTARCH outperforms MLP and LSTM classifiers for small significance level and varying risk target ($\alpha = 0.01$ or $w = 0.025$ and $w = 24$) both on average and in terms of robustness. This shows that, in our setup, GARCH-based models still outperforms nonparametric models at catching volatility clusters. On the other hand, for larger significance level and stable risk target ($\alpha = 0.05$ or $\alpha = 0.1$ and $w = 2280$ or $w = 4320$), the nonparametric approaches do at least as good as the simple GARCH-based models on average and in terms of robustness which indicates a higher generalization power.

From the two tables above, we can also conclude that we benefit from combining those classifiers into a stacking classifier, since the AAUC of the Ensemble classifier is always higher or equal to the maximum AAUC of the weak classifiers on the whole test period. Moreover, in terms of cross-validation performance, the Ensemble

Table 4 Average risk-adjusted AUC and (variance risk-adjusted AUC) over the testing periods

α (%)	w (hours)	MLP	LSTM	ARMA-GARCH	ARMA-EVTGARCH	LPC-GARCH	CARL-vol	Ensemble

10	24	64 (0.2)	64 (0.2)	64 (0.1)	64 (0.1)	61 (0.1)	63 (0.2)	65 (0.2)
	2880	61 (0.7)	63 (0.8)	61 (0.8)	61 (0.8)	61 (0.7)	60 (0.7)	62 (0.8)
	4320	62 (0.7)	64 (0.7)	61 (0.7)	61 (0.7)	61 (0.8)	60 (0.6)	62 (0.9)

classifier always outperforms the average performance, except for the strategy with TVAR^{0.01,4320} risk target. In particular, for larger risk level ($\alpha = 0.025$, $\alpha = 0.5$ and $\alpha = 0.1$) and small window ($w = 24$), the Ensemble classifier outperforms the best performing weak classifier. This result is a clear indicator that each classifier can extract information which is uncorrelated with some of the other classifiers for highly adaptive risk target. This is a sign that each classifier might be more adapted to specific market regimes, but that the Ensemble model is more general.

Overall, from those metrics, we can say that the nonparametric models present more risk than the parametric ones or the Ensemble classifier. Now, in the next section, we will relate the model risk to the economic risk via backtest performance of the associated trading strategies.

92.6.3.2 Backtest Performance

Risk Profile First, we must verify that the strategy associated with each classifier is verifying the target risk constraint. For this we compare, in Table 5, the exceedance of each strategy with the risk level α , if the exceedance is larger than α , then the strategy does not respect the investor’s risk preferences.

All classifiers achieve the risk targets, but both benchmark target VaR strategies, where VaR is estimated with ARMA-GARCH and ARMA-EVTGARCH, do not respect the constraint for TVaR^{1%,24}. The Varspread strategy is not a target VaR strategy, but we also look at its exceedance and we see that it also fails for the same risk target, TVaR^{2.5%,24} and TVaR_{5%,24}, indicating difficulties for those strategies to adapt to varying risk preferences.

Now, in Table 6, we compare the average return of the strategies associated with each classifier and the benchmarks on the whole test period. Achieving a larger average return, while having lower exceedances indicates a better risk-profile for a tail risk averse investor. First, the Ensemble strategy always has a larger average

Table 5 Exceedances of tail risk protection strategies in %

return than the average performance of the weak strategies, that is, the strategies associated with the weak classifiers, except for the $\text{TVaR}^{1\%,2880}$ risk target, and has larger average return than the maximum of the weak strategies for the $\text{TVaR}^{1\%,24}$ and $\text{TVaR}^{1\%,4320}$. In general, the Ensemble strategy also outperforms the benchmark strategies, except for the target VaR strategies with $\text{TVaR}^{1\%,2880}$, $\text{TVaR}^{2.5\%,24}$, $\text{TVaR}^{5\%,24}$, and $\text{TVaR}^{10\%,24}$. Only these strategies are better suited than our offered Ensemble strategy for their respective investor’s profile, as they offer larger average return, while respecting the corresponding risk target. This result shows that traders can benefit from combining classical econometrics and machine learning oriented approaches in order to offer better tail risk protection strategies to their investors.

Historical Performance In Fig. 6, we show the historical performance on the test period and on Fig. 7, the excess return over the BTC Buy&Hold benchmark in strong uptrend period. We can clearly see how Varspread strategy is too conservative in

Fig. 6 Ensemble strategy returns on test period for $\text{TVaR}^{\alpha,w}$ with $\alpha \in \{1\%, 2.5\%, 5\%, 10\%\}$ from top to bottom and $w \in \{24, 2880, 4320\}$ from left to right with BTC Buy&Hold, Varspread, target VaR norm, and target VaR evt benchmarks

period of uptrend which severely affects its total return. While the Ensemble strategy significantly outperforms the other actively managed tail risk protection strategies in terms of total return for $\text{TVAR}^{1\%,24}$, $\text{TVAR}^{1\%,4320}$, $\text{TVAR}^{2.5\%,2880}$, $\text{TVAR}^{2.5\%,4320}$, $\text{TVAR}^{5\%,2880}$, and $\text{TVAR}^{5\%,4320}$. For the other risk targets, the historical performance is similar. In the meantime, only two strategies outperform the simple Buy&Hold strategy on the whole test period, for $\text{TVAR}^{2.5\%,4320}$ and $\text{TVAR}^{5\%,4320}$ risk targets, managed by our proposed Ensemble model. This shows that for BTC asset, it is very hard to find the right trade-off between investment during strong uptrend and deinvestment in period of downtrend and that strategies based on simpler models, as Varspread or target VaR strategies, cannot beat the Buy&Hold benchmark in terms of total return, as they overshoots risk in strong uptrend periods.

Indeed, as you can see in Fig. 7, in strong uptrend period, all strategies underperform the Buy&Hold benchmark except for the Ensemble strategy with $\text{TVAR}^{1\%,4320}$ risk target.

Fig. 7 Ensemble strategy excess returns on uptrend period for $\text{TVAR}^{\alpha,w}$ with $\alpha \in \{1\%, 2.5\%, 5\%, 10\%\}$ from top to bottom and $w \in \{24, 2880, 4320\}$ from left to right with Varspread, target VaR norm and target VaR evt benchmarks

Fig. 8 Ensemble strategy excess returns on downtrend period for $\text{TVAR}^{\alpha,w}$ with $\alpha \in \{1\%, 2.5\%, 5\%, 10\%\}$ from top to bottom and $w \in \{24, 2880, 4320\}$ from left to right with Varspread, target VaR norm, and target VaR evt benchmarks

Nevertheless, as we can see in Fig. 8, that, in period of downtrend from 2019-06-26 to 2019-11-25 where BTC suffered a 60% drawdown, the Varspread strategy is very efficient at catching tail events achieving 50%, 48%, 64%, and 64% excess return for $\alpha \in \{1\%, 2.5\%, 5\%, 10\%\}$, respectively, even generating a positive total return of 4% for $\alpha \in \{5\%, 10\%\}$.

Switching Strategy In order to benefit from the effective tail risk protection from the Varspread strategy in bear market and the well calibrated risk protection of the Ensemble strategy in bull market, we build a final switching strategy which either invest in the Varspread strategy or in the Ensemble strategy depending on the market regime. In order to decide when to switch strategy, we build a simple estimator of the trend by using a simple moving average of BTC price, defined for $n \in \mathbb{N}$ as $\text{MA}_{t-1,n} = \frac{1}{n} \sum_{i=1}^n P_{t-i}$. We define the following trend indicator δ_t as in Rickenberg (2019):

Fig. 9 Historical performance on the test period of Ensemble, Varspread, Switch, and Buy&Hold strategies

$$\delta_t = \begin{cases} 0, & \text{if } P_{t-1} \leq \text{MA}_{t-1,n} \\ 1, & \text{if } P_{t-1} > \text{MA}_{t-1,n} \end{cases}$$

Then we define the weights for each strategy as $w_t^{Ens} = \delta_t$ and $w_t^{Varspread} = 1 - \delta_t$. The historical performance of the final meta-strategy, denoted Switch strategy, is presented in Fig. 9.

In Table 7, we present different backtest statistics for the benchmark, Ensemble, and final Switch strategies. First, we see that the Switch strategy has the highest total return on the testing period for relatively high risk target, but also for $\text{TVAR}^{1\%,2880}$ and $\text{TVAR}^{2.5\%,2880}$. Moreover, we can see that the Switch strategy provides an enhanced risk-return profile indicated by larger Sharpe ratio for all risk targets, than the average between the Varspread and the Ensemble strategies. For example, with $\text{TVaR}^{5\%,2880}$, the Switch strategy increased the Sharpe Ratio by 62% and 219% for the Ensemble and Varspread strategies, respectively. On top, the switch strategy

Table 7 Backtest performance of switch strategies: Total return (%), Sharpe ratio, Sortino ratio, Max Drawdown (MDD), Valut-at-Risk, and Volatility of different strategies on the test period. The total return, Sharpe, and Sortino ratio are annualized. Legend: winner/loser

has the best risk-return profile for all risk targets, clearly outperforming the Buy&Hold and other benchmarks, except TVAR^{2.5%,24} where the Varspread strategy has the largest Sharpe ratio. This indicates that the switch strategy is also better suited for Markowitz type optimization where the objective is the mean-variance performance. For the Ensemble strategy itself, the results are mixed with respect to mean-variance performance, since it has a relatively high volatility for all risk targets. Indeed, finding the right trade-off between participation in bull market regimes and hedging tail events comes with a cost in terms of volatility. Since in our case, we know that the Switch and Ensemble strategies are respecting the tail risk constraint, we are interested in the Sortino ratio, which penalizes only volatility

associated with negative returns and is defined as $S = \frac{R}{\sigma^-}$, where R is the expected return and σ^- is the portfolio downside standard deviation. We can see that the Switch strategy clearly outperforms other benchmarks, except for conservative strategies with $\text{TVAR}^{1\%,24}$, $\text{TVAR}^{1\%,2880}$, $\text{TVAR}^{2.5\%,24}$, and $\text{TVAR}^{5\%,24}$.

92.7 Conclusion

We build a dynamic trading strategy in which the goal is to protect against severe losses by targeting a maximum Value-At-Risk defined for any significance level. For this, we model distributional properties of BTC returns in time with nonparametric models such as MLP and LSTM neural networks and compare their performance to local-parametric GARCH, parametric GARCH fitted with various distribution for the innovation, and CARL-Vol models. In our approach, we directly take into account varying investor's risk preferences and optimize the strategy accordingly, allowing us to compare the models for multiple risk targets.

First, we can conclude that for relatively stable risk preferences, parametric and local parametric approaches have a better generalization than nonparametric methods, but for unstable preferences they work better, taking into account time varying risk targets and adapting to sudden changes in the market. On top, we show that, for BTC returns, a general model performing well enough in all market regimes is too hard to find. A tail loss protection strategy based on a single model, while often outperforming a simple Buy&Hold strategy, is still not optimal, either overshooting the risk target in periods of losses or being too conservative in bull market regimes. That is why, we show the benefits of combining multiple models in an Ensemble classifier, which improves generalization with a higher prediction accuracy and economic gains with an enhanced risk-return profile. Indeed, the Ensemble-based strategy combines advantages of classical GARCH tools, which catches better volatility clusters than more complex MLP or LSTM, and deep learning tools which can adapt to time-varying properties of the data distribution. Further, we show that tail loss protection strategy also suits Markowitz type investors when we combine conservative strategies, such as Varspread, and more aggressive ones, such as Ensemble strategy, into a switching strategy.

For the purpose of tail loss protection, our proposed Ensemble strategy can be improved. Here, we measure risk with Value-At-Risk, nonetheless, other risk metrics can be considered for optimization, in particular Expected Shortfall or Maximum Drawdown. On top, it would be interesting to open the Ensemble learning tool box and to study how the different classifiers interacts which other in time, to better understand when their corresponding tail loss protection strategy might be suited for the respective market regime.

Yiannis Karavias

Abstract

The purpose of this chapter is to review recently developed methods for analyzing structural breaks in panel data. Structural breaks are caused by events that change the parameters of economic and financial models, such as the 2007–2008 financial crisis and the COVID-19 crisis. If not correctly accounted for they lead to an invalid inference. It is not always clear if a significant event has affected a particular economic model or relationship, or the date on which the relationship suffered the change. Answers to these questions can only be given through formal econometric analysis. This chapter reviews methods for both detecting and dating structural breaks. Furthermore, the usefulness of structural break method is demonstrated in examining trade credit determinants in a panel of small and medium European enterprises. A structural break was detected and dated in the year 2010. Before the break, firm profitability, sales growth, and bank loans all contributed to an increase in trade credit. After the break, the bank loans' effect was significantly reduced, providing evidence that the trade credit's redistribution channel collapsed after the 2007–2008 financial crisis.

93.1 Introduction

Structural changes or “breaks” are recurring phenomena in economic and financial systems. They are unanticipated shocks that can cause significant changes in the established relationships between key variables. This has the potential to cause expectations and forecasts formed from econometric models to go significantly astray. For example, investment decisions made before the 2007–2008 financial crisis or the 2020 COVID-19 crisis were based on very different expectations and forecasts to those obtained after these crises.

While structural changes are sometimes clearly observed, at other times, they can occur more subtly and can only be detected later by formal econometric methods. Their recurring nature makes their study and identification a timely issue. Current practice detects breaks by analyzing time series data. Still, detection is much more precise when it is done on information-rich panel data. A review of structural break applications in financial time series can be found in Andreou and Ghysels (2009).

Panel data are complex data sets, which are being used to study interconnected assets, firms, and markets at a local, national, and international level. They provide a unique capacity for modeling the mosaic of heterogeneous and interlinked economies, as they contain information not available in a single time series. Some examples of their application in financial economics include bank profitability, see, for example, Delis and Karavias (2015), the determinants of board structure, see, for example, Wintoki et al. (2012), multi-factor CAPM, see, for example, Makwasha et al. (2019), firm performance, see, for example, Asimakopoulous et al. (2020), firm employment, see, for example, Da Silva Fernandes et al. (2019), forecasting, see, for example, Liu et al. (2020), and return predictability see, for example, Westerlund et al. (2017).

The objectives of structural change analysis are to find answers to questions such as “Was there a structural change?” and if so, “When did the change happen?”. Answering these questions may help identify those events which have caused the structural change and inform future expectations and investment decisions. Where a break is detected, [estimating the date of the break](#) facilitates tracing the cause of change, making similar structural breaks easier to predict in the future. Connecting a structural break to an event can happen by matching the break’s estimated date to that event. Furthermore, knowledge of the existence of two distinct sample periods, pre-break and post-break, will allow the correct measurement of economic outcomes in each period. Finally, when models are subject to structural change, better forecasts can be obtained by putting increased weight on observations after the break, see, for example, Pesaran and Timmermann (2004).

The first aim of this chapter is to review methods for the analysis of structural breaks in panel data. Such techniques were first developed about a decade ago. Bai (2010) was the first paper to derive an estimator for the date of the break in a panel data model with individual intercepts but no other regressors. The first test for structural change in panel data was developed by De Wachter and Tzavalis (2012),

for dynamic panel data models with exogenous or predetermined regressors. Ever since, the literature has gained traction with many new methods being proposed, see, for example, Kim (2014), Baltagi et al. (2016), Hidalgo and Schafgans (2017), and Karavias et al. (2021). Structural breaks have also been considered in panel data unit root and cointegration tests, see, for example, Westerlund (2006), Bai and Carrion-i-Silvestre (2009), Hadri et al. (2012), Banerjee and Carrion-i-Silvestre (2015), and Karavias and Tzavalis (2014, 2017, 2019). The literature review in this chapter will focus on methods for detecting and dating structural breaks and not on panel data unit root and cointegration tests with breaks, although some of these methods will be used in the application part.

The second aim of the chapter is to demonstrate the usefulness of the structural break analysis. This is done by examining trade credit provision. Meltzer (1960) was the first paper to examine the determinants of trade credit. Ever since, this literature has flourished, with the most recent contributions being Box et al. (2018) and Coricelli and Frigerio (2019). Trade credit is the most important source of short-term firm finance with implications at both the microeconomic level, see, for example, Asimakopoulos et al. (2020) on the impact of trade credit on firm performance, or at the macro level see, for example, Meltzer (1960) for the impact of trade credit on monetary policy and Fisman and Love (2003) for the impact of trade credit on economic growth.

Using a large sample of Small and Medium Enterprises (SME's) over the period 2004–2015, this chapter examines how trade credit is determined by sales growth, firm profits, and bank loans. The initial regression, which does not account for structural breaks, strikingly finds that bank loans are insignificant to the amount of trade credit provided, and therefore, that there is no redistribution of bank funds to firms that have no direct access to bank lending. Testing for structural change, however, reveals that a break existed in 2010. The detection of the break and the estimation of its date is done using the methodology of Karavias et al. (2021). The latter is the first paper to establish the complete asymptotic theory for testing and dating structural breaks in panel data.

Once this break is incorporated in the trade credit regression, the new results show that bank lending had a positive and statistically significant effect on trade credit before 2010, but this effect becomes zero after the break. This finding provides evidence of the redistribution channel of trade credit before 2010; see, for example, Fisman and Love (2003). It further shows that the Great Recession reached European SME's in 2010 and stopped the redistribution of bank lending. Finally, the relationship between firm profits and trade credit remains constant in time and is unaffected by structural breaks. The same applies to trade credit generated by increased sales.

The chapter is organized as follows. Section 93.2 introduces structural breaks in panel data models. Section 93.3 reviews the literature on hypothesis tests for the existence of structural change. Section 93.4 reviews the literature on dating structural breaks. Section 93.5 analyses structural breaks in the provision of trade credit. Finally, Sect. 93.6 concludes.

93.2 Structural Breaks in Panel Data: The Model

Consider the general panel data model with N units and T periods, that is $i = 1, \dots, N$, and $t = 1, \dots, T$, where a break has occurred at time k :

$$y_{i,t} = \begin{cases} \beta_i' x_{i,t} + e_{i,t}, & \text{for } t \in \{1, \dots, k\} \\ \beta_i' x_{i,t} + \delta_i' z_{i,t} + e_{i,t}, & \text{for } t \in \{k+1, \dots, T\}, \end{cases}$$

The above model may be written more compactly as:

$$y_{i,t} = \beta_i' x_{i,t} + \delta_i' z_{i,t}(k) + e_{i,t}, \quad (1)$$

where $x_{i,t}$ is a $p \times 1$ vector of regressors, $z_{i,t}(k)$ is a $q \times 1$ vector, $e_{i,t}$ is the error term and $y_{i,t}$ is the scalar dependent variable. The coefficients β_i and δ_i are $p \times 1$ and $q \times 1$ vectors, respectively. The regressor $z_{i,t}(k)$ is defined as:

$$z_{i,t}(k) = R' x_{i,t} I(t > k), \quad (2)$$

where R is a $p \times q$ matrix with full column rank q , $I(\cdot)$ is the indicator function, and k is the date of the break. The matrix R selects the subset of q regressors in $x_{i,t}$ which experience a change in coefficient at time k . If $p > q$, then $R = (0_r \times (p - q), I_q)'$, while if $p = q$ then $R = I_p$ and all the coefficients change at the time of the break. I_q and I_p are q and p dimensional identity matrices, respectively. For $p = q$ the model is called a “pure structural change model,” while for $q < p$ the model is called a “partial structural change model.”

The aim in the analysis of structural change is two-fold: (a) test for the existence of a structural break, and (b) estimate the date of the break and construct a confidence interval which contains the true break date with probability $(1 - \alpha)\%$, where α is the significance level.

The above model allows for a common break which happens at the same time k for all units. The common break assumption is acceptable in most settings and largely depends on the frequency of the data. It is generally easier to justify in low-frequency data. For example, changes in economic policy will appear in a specific year in annual balance sheet data, even though each firm may have responded on a different day or month to the change in policy. A common break can also be justified as the mean of random breaks, see, for example, Bai (2010).

Testing for structural change is equivalent to testing the null hypothesis that $H_0 : \delta_i = 0$, for all i , against one of two different alternative hypotheses. The first alternative hypothesis is for the scenario where the researcher wishes to test the null against the alternative hypothesis that the break occurred at a selected date. This alternative can be written as $H_1(k_0) : \delta_i \neq 0$ for some $i \in \{1, \dots, N\}$. In this case, the true break date k_0 is assumed known by the researcher. If the investigator is mistaken on this choice, the resulting structural change test will not behave properly; specifically, it will not have size $\alpha\%$. Consider Brexit, for example. Did its effect materialize a day after the 2016 referendum, possibly through changes in economic

agents' expectations? Did the effect emerge when the UK left the EU? Will it materialize after the transition period is over? This example shows that even if the researcher has an idea of the break's date, the date may not be correct. For these reasons, we would like to have a way of doing the above hypothesis test without assuming a known break date. The second and more empirically relevant hypothesis is that the break may have occurred at an unknown date. This alternative can be stated as $\cup_{k \in K} H_1(k) : \delta_i \neq 0$ for some $i \in \{1, \dots, N\}$, where K is the set of all possible break dates.

If the date of the break is unknown and the test rejects the null hypothesis, then it becomes of interest to estimate the date of the break k_0 and construct a confidence interval which contains the true break date with probability, say 95%, depending on our significance level. For this, we need an estimator $\hat{k}$ and its limiting distribution. Unfortunately, inference in both cases is non-standard as neither the test for structural change against the alternative of unknown break date or the break date estimator have the typical limiting distributions, for example, standard normal or χ^2 , and therefore these must be either tabulated if they are free of nuisance parameters or bootstrapped if they are not. The following sections demonstrate how this can happen.

93.3 Structural Breaks in Panel Data: The Errors

The specification of the error term completes the model (1), where $e_{i,t}$, which is defined as:

$$e_{i,t} = \gamma_i' f_t + \varepsilon_{i,t}, \quad (3)$$

where γ_i is an $m \times 1$ vector of individual-specific factor loadings and f_t is an $m \times 1$ vector of common factors. If $m = 1$ and $f_t = 1$ for all t and the model is homogeneous, that is, $\beta_i = \beta$ and $\delta_i = \delta$ for all i , we have the typical panel data model with individual effects which may be fixed or random. The γ_i This case is called unobserved individual heterogeneity and captures systematic differences in the units, which do not change over time. For example, if the units are countries, individual heterogeneity captures the effects of geography, culture, and state efficiency. If the units are firms, then heterogeneity captures technological differences, years of education, and managers' ability, among others. The unobserved heterogeneity is usually correlated with the regressors because the regressors depend on the characteristics mentioned above, see, for example, Baltagi (2008) for further details.

If $m = 2$, $\gamma_i = (\xi_i, 1)'$ and $f_t = (1, \psi_t)'$ where ξ_i and ψ_t are scalars, then $\gamma_i' f_t = \xi_i + \psi_t$, which is the two-way error component model with individual heterogeneity and time effects, see, for example, Baltagi (2008). Time effects capture aggregate time-series effects such as the oil price, economic growth, and financial volatility. These are common shocks at time t , which affect all units simultaneously. The error model with $m = 2$ is the simplest model of cross-section dependence between the units in the panel. Cross-section dependence is a critical issue in financial and economic data,

see, for example, Sarafidis and Wansbeek (2012). If $\gamma_i' f_t = \xi_i + \psi_t$ then, consistent parameter estimation requires that these effects are removed before estimation. The removal can be done easily due to the simple structure of the error components by subtracting the cross-sectional averages for ψ_t and the within-groups mean for ξ_i .

More general panel specifications consider the “interactive effects” model with m factors: $\gamma_i' f_t$. In this model, the γ_i loadings capture the heterogeneous responses of individual units to the common shocks captured by the factors f_t . The interactive effects panel data models are widely applicable. Consider, for example, the Fama and French (1992) model. The dependent variable $y_{i,t}$ is the excess return of asset i at period t , and $x_{i,t}$ is a set of observable factors such as dividend yields or balance sheet data on the five factors of Fama and French (2015). The factors f_t in the error term are unobservable factors left out of the model specification, see, for example, Cochrane (2011). Another example comes from the firm performance literature, where $y_{i,t}$ is a measure of firm performance such as the return on assets, $x_{i,t}$ captures observable firm characteristics such as liquidity, debt, and sales, and the unobserved factors f_t capture the effects of changes in technology, which are heterogeneous for each firm according to the factor loadings γ_i .

It is reasonable to assume that these factors are correlated with the regressors through the equation:

$$x_{i,t} = \Gamma_i' f_t + v_{i,t}, \quad (4)$$

where Γ_i is an $m \times p$ matrix of factor loadings and $v_{i,t}$ is a $p \times 1$ vector of idiosyncratic errors. The correlation between $x_{i,t}$ with $e_{i,t}$ through the interactive effects $\gamma_i' f_t$ makes $x_{i,t}$ endogenous, consistent estimators must be used. The two more popular are the concentrated least squares estimator of Bai (2009) and the Common-Correlated Effects (CCE) estimator of Pesaran (2006).

93.4 Testing for Structural Change

Testing for structural change when the date of the break is known, that is, testing H_0 against $H_1(k_0)$ can be done easily through a Wald or F test as in Chow (1960). In the following, we shall denote such a test statistic as $W(k_0)$. The limiting distribution of $W(k_0)$ is a χ_q^2 distribution with q degrees of freedom, for which critical values are readily available.

Testing H_0 against $\cup_{k \in K} H_1(k)$ can not be done using the typical Wald tests because the break's date is a parameter that appears only under the alternative. This problem was studied by Davies (1977, 1987) who proposed using the following test statistic:

$$SW = \sup_{k \in K} W(k),$$

derived from the union-intersection principle, see, for example, Casella and Berger (2001, p. 380). The idea behind this statistic is that if $W(k)$, for each $k \in K$, is greater

than an appropriate critical value, then we can reject the null hypothesis. In other words, if the supremum of the $W(k)$ is greater than a critical value, the test is rejected. Andrews (1993) derived the asymptotic distribution of SW for single time series models and tabulated its critical values. The researcher determines the set of permissible break dates K . Some trimming is necessary for the first and last time periods, so that there are enough data to identify the pre- and post-break regimes. Andrews (1993) suggests that $K = 0.15T, 0.85T$, where $\lfloor \cdot \rfloor$ is the greatest integer function.

An alternative method for deriving structural change tests is using the cumulative sum of squares test (CUSUM) in Brown et al. (1975). However, this test, and its variants, have several pronounced weaknesses. They suffer from trivial power against some types of alternatives, see, for example, Kramer et al. (1988), they have nonmonotonic power functions, see, for example, Andreou and Ghysels (2009), and ultimately, they have worse power and size performance when compared to SW , see, for example, Andrews (1993).

De Wachter and Tzavalis (2012) were the first to consider testing structural changes in panel data. They maintain a homogeneous panel model with lagged dependent and exogenous variables as regressors and individual fixed effects. Their $W(k)$ statistic is based on $\hat{\beta}$ and $\hat{\delta}$ estimators, which is estimated by the generalized method of moments as in Arellano and Bond (1991). Zhu et al. (2020) extend this test to allow for errors as in (3). Both these tests have excellent size and power properties when $N \rightarrow \infty$ and T are fixed. However, the limiting distribution must be simulated every time, which hinders their application. Another issue arises when T is moderate, in which case the small sample behavior deteriorates as they have to estimate many parameters. CUSUM tests are considered by Antoch et al. (2019) and Hidalgo and Schafgans (2017), under more restrictive error assumptions. Antoch et al. (2019) assume that the interactive effects are asymptotically negligible, while Hidalgo and Schafgans (2017) considered a weaker form of cross-section dependence than the one which appears in (3). Both tests need simulated critical values for each application. Karavias et al. (2021) consider testing for breaks in the model (1), (2), (3), and (4) with $\beta_i = \beta$ and $\delta_i = \delta$ using the SW statistic based on a new variant of the pooled CCE estimator of Pesaran (2006). They show that the limiting distribution of SW , in that case, coincides with that of Andrews (1993). Therefore, the same critical values can be used for hypothesis testing. Additionally, it was found that the test has excellent size and power properties, even for small T . This test will be used in Sect. 93.5, in the empirical part of this chapter.

93.5 Estimating the Date of the Break

Given the existence of a structural break, the next step is to estimate the break's date and construct a valid confidence interval. The estimator of choice in the literature is:

$$\hat{k} = \underset{k \in K^*}{\operatorname{argmin}} SSR(k),$$

which is the breakpoint which minimizes the sum of squared residuals. The method of calculating this estimator is as follows. Step 1: Select the first possible break date

$k \in K^*$, say k^1 . Then, considering k^1 given, estimate the model and get the $SSR(k^1)$. Step 2: repeat this process for all $k \in K^*$. Step 3: find the minimum of all $SSR(k)$; then $\hat{k}$ is the estimate which corresponds to this minimum. Notice that $K^* = [q, T - q - 1]$, is different from K .

The break date estimator exhibits an irregular behavior regarding its rate of convergence and its asymptotic distribution. This behavior has an impact on its asymptotic distribution. Bai (2010) considered the heterogeneous location model where $x_{i,t} = 1$, with independent errors, and derived the break date estimator's consistency and asymptotic distribution. Kim (2011, 2014) considered the model with intercept and linear trend $x_{i,t} = (1, t)'$ but also errors as in (3). Similarly, he derived consistency, rate of convergence, and asymptotic distribution. Kim (2011, 2014) shows that the convergence rate depends on the interplay between the error structure and the factor removal method.

Baltagi et al. (2017) consider a homogeneous version of (1) with independent errors that may be stationary or not and exogenous regressors that may be stationary or not. They prove the consistency and derive the rate of convergence and the asymptotic distribution of $\hat{k}$. The main finding is that if $N \rightarrow \infty$ and $T/N \rightarrow \infty$ then $\hat{k}$ is consistent regardless of the stationarity properties of $e_{i,t}$ and $x_{i,t}$. When both the regressor and the errors are nonstationary, then the rate of convergence is very fast, of the order $O((NT)^{-1})$. Further consistency results are provided by Boldea et al. (2020) which for the first time consider the fixed T case in a homogeneous model with independent errors. They show that $\hat{k}$ based on residuals of the ordinary least squares estimator, the estimator, which does not remove the individual effects in the error term, is consistent.

For the full model (1), (2), (3), and (4) with exogenous regressors and common factors in the errors, Baltagi et al. (2016) prove the consistency of $\hat{k}$ when the model is estimated by the CCE estimator of Pesaran (2006). Baltagi et al. (2019) extend this consistency result to endogenous regressors. Li et al. (2016) consider the homogeneous version of the above, where $\beta_i = \beta$ and $\delta_i = \delta$ for all i , and prove the consistency of $\hat{k}$, but use principal components to estimate the common factors, instead of CCE. Karavias et al. (2021) also consider the homogeneous version of (1), and they prove the consistency of $\hat{k}$ and derive its rate of convergence and its limiting distribution. They find that the convergence rate depends on the relationship between the number of regressors p and factors m . If $m < p$ and N is larger than T , then the speed of convergence to the true k_0 increases. Furthermore, they show that consistency and the limiting distribution hold when both T is fixed or asymptotic, and derive valid confidence intervals for $\hat{k}$ in both cases. All these papers consider common breaks for all units. Okui and Wang (2020) have considered estimation in panel data where breaks are common within a group, and there are several groups of units in the panel.

93.6 Structural Breaks in Trade Credit Provision

As it was argued in the introduction, financial relationships are subject to structural breaks frequently enough, so that it is suggested that testing for breaks should be reported together with descriptive statistics in any research paper. If a break is

detected, this will impact the rest of the econometric analysis. Karavias et al. (2021), that is, examine the impact of COVID-19 on stock returns using weekly data on sixty-one countries. They find that COVID-19-related variables such as cases, deaths, and government restrictions hurt stock returns during the first three months of the pandemic. A structural break happens, and the adverse effects disappear; the stock market is no longer affected by the COVID-19-related variables. The break is estimated to take place in the first week of April 2020. The result is attributed to the massive quantitative easing programs put forth by central banks across the world in the last days of March 2020.

In this chapter, we wish to examine if there is a structural break in the fundamental relationship between trade credit provision and its determinants, particularly a change related to the 2007–2008 financial crisis. Trade credit is a type of short-term loan that supplier firms provide to customer firms at the same time as goods. Suppose customers cannot pay for the goods upon delivery. In that case, they enter a contract with the supplier to delay payment for a while, with interest. Such agreements are usually standardized. An example is a contract named “2-10 net 30,” which means that if the customer pays in the next ten days after the delivery of goods, they will get a 2% discount. Still, after the first ten days, they lose the discount and have to pay the full amount within 30 days of delivery. The 2% discount can be seen as a loan with an interest rate of 2% for 20 days. If this is annualized, then the one-year interest rate is 44%. Because trade credit is so expensive, many theories are trying to explain why it exists. Petersen and Rajan (1997) provide an excellent review of the topic.

Two theories which are of particular interest are the financial motivation theory of Emery (1984) and the redistribution view of trade credit of Meltzer (1960). The financial motivation theory posits that suppliers have more information and power over customer firms and, therefore, can offer credit at better rates than banking institutions. Customer firms prefer this expensive credit over the even more costly credit of financial institutions. The redistribution view of trade credit argues that firms with access to cheap bank finance will use this financial motive to redistribute bank credit to the less privileged firms.

The theories mentioned in the previous paragraph can be tested using the following panel data regression model:

$$TC_{i,t} = \beta_1 S_{i,t} + \beta_2 L_{i,t} + \beta_3 R_{i,t} + \beta_4 B_{i,t} + \beta_5 SG_{i,t} + e_{i,t}, \quad (5)$$

where $TC_{i,t}$ is the trade credit extended by firm i at time t , $S_{i,t}$ is the size of the firm, $L_{i,t}$ is firm liquidity, $R_{i,t}$ are firm profits, $B_{i,t}$ is bank loans received by the firm, and $SG_{i,t}$ is sales growth since the previous period. This is a standard regression in the literature, see, for example, Meltzer (1960), Nadiri (1969), Petersen and Rajan (1997), and Box et al. (2018). The parameters of interest are the coefficients of profits, sales growth, and bank loans. Positive profit and sales growth coefficients mean that an increase in these variables generates trade credit directly; therefore, suppliers provide trade credit because they have a financial motive. On the other hand, a positive coefficient of bank loans means that suppliers redistribute bank loans to their customers in trade credit.

It is assumed that the errors $e_{i,t}$ include common factors as in (3), capturing firm characteristics, industry, and country effects, as well as the impact of other unobserved factors such as consumer confidence, interest rate conditions, economic growth, and oil price fluctuations.

The data includes observations on 2526 European SMEs over the period 2004–2015. The data came originally from Amadeus (Analyse Major Database from European Sources) database, distributed by Bureau Van Dijk (BvDEP). A description of the data collection and cleaning can be found in Asimakopoulou et al. (2020). The variable $TC_{i,t}$ is equal to the accounts receivables over total assets. Size $S_{i,t}$ is set equal to the logarithm of total firm assets, $L_{i,t}$ is defined as cash and cash equivalents over total assets, $R_{i,t}$ is equal to the returns on assets before taxes, $B_{i,t}$ is defined as bank loans over total assets, and finally, $SG_{i,t}$ is sales growth of the firm from period $t - 1$ to period t .

Table 1 provides descriptive statistics for the variables above. The average trade credit in the sample is 33% of the total assets, signaling the item's significance in the firm balance sheets. Figure 1 presents the trade credit provided by the average firm by year. A significant drop can be seen for the year 2009. Afterward, it seems that trade credit fluctuates along this new level. Given that the data include a small set of time series observations, two fixed-T panel unit root tests are employed, the Harris and Tzavalis (1999) test and the Karavias and Tzavalis (2019) test. The results appear in the HT and KT19 columns. The specifications allow for intercepts only and KT19 allows for a structural break in the series' mean under the alternative. The results are in favor of stationarity for all series.

The first column of Table 2 presents the regression results (5), where no structural breaks have been considered. The estimation method used is that of Pesaran (2006), with no observed common factors. Furthermore, the matrix of cross-section averages contains only the averages for the variables $S_{i,t}$, $L_{i,t}$, $R_{i,t}$, $B_{i,t}$, and $SG_{i,t}$, and not the averages of $TC_{i,t}$ as in Pesaran (2006), as in Karavias et al. (2021). Profits, bank loans, and sales growth all have the expected positive signs. From the three, bank loans are statistically insignificant, meaning no loan redistribution is taking place. The other two are statistically significant. Size is negative but insignificant. Liquidity has a negative and statistically significant effect, a result in line with the literature, see, for example, Meltzer (1960), and Coricelli and Frigerio (2019).

It is time now to examine the above relationship for structural breaks. A modeling issue which arises is how to choose which variables are subject to a structural break. There is no compelling argument on why size and firm liquidity should have different effects based on the potential impact of the financial crisis, so they are assumed unchanged. This is also corroborated by unreported robustness checks. Concerning the remaining three variables, for robustness, the following three regressions are examined:

$$TC_{i,t} = \beta_1 S_{i,t} + \beta_2 L_{i,t} + \beta_3 R_{i,t} + \beta_4 B_{i,t} + \beta_5 SG_{i,t} + \delta_1 SG_{i,t} I(t > k) + e_{i,t}, \quad (6)$$

Table 1 Descriptive statistics

Variable	Obs.	Mean	SD	Min	Max	HT		KT19		Break
						AR(1)	P-value	AR(1)	P-value	
Trade credit	30,312	0.334	0.153	0	0.909	0.522	0	0.954	0	4
Size	30,312	8.167	1.141	5.336	11.35	0.753	0	1.004	1	
Liquidity	30,312	0.149	0.131	0	0.635	0.487	0	0.939	0	8
Profitability	30,312	0.075	0.075	-0.229	0.369	0.364	0	0.803	0	8
Bank loans	30,312	0.07	0.085	0	0.578	0.386	0	0.862	0	8
Sales growth	30,312	0.035	0.179	-2.667	3.109	-0.178	0	-0.057	0	8

Notes: This table reports selected descriptive statistics for a panel of 2526 firms observed over 2004–2015. For each variable, the mean, standard deviation (SD), minimum (Min), and maximum (Max) statistics are reported. The HT test refers to the Harris and Tzavalis (1999) homogeneous-coefficient panel unit root test. The reported first-order autoregression (AR(1)) coefficient is bias-adjusted, and its associated p-value is also reported. The KT19 test refers to the Karavias and Tzavalis (2019) fixed-T test that allows for serial correlation and a common break under the alternative; we assume uncorrelated errors

Fig. 1 Average trade credit over time

$$TC_{i,t} = \beta_1 S_{i,t} + \beta_2 L_{i,t} + \beta_3 R_{i,t} + \beta_4 B_{i,t} + \beta_5 SG_{i,t} + \delta_1 SG_{i,t}I(t > k) + \delta_2 B_{i,t}I(t > k) + e_{i,t}, \quad (7)$$

$$TC_{i,t} = \beta_1 S_{i,t} + \beta_2 L_{i,t} + \beta_3 R_{i,t} + \beta_4 B_{i,t} + \beta_5 SG_{i,t} + \delta_1 SG_{i,t}I(t > k) + \delta_2 B_{i,t}I(t > k) + \delta_3 R_{i,t}I(t > k) + e_{i,t}, \quad (8)$$

which correspond to model (1) with $p = 5$ and $q = 1, 2$ and 3 , respectively.

Columns (2), (3), and (4) of Table 2 present the above regression results. Column (2) considers regression (6). The *SW* test of Karavias et al. (2021) rejects the null hypothesis of no structural change at the 10% significance level. The $\hat{k}$ estimator of the same paper estimates the date of the break in 2010 with a 95% confidence interval being (2009, 2011). This seems to be reasonable as there was a delay in the propagation of the global financial crisis in Europe. The coefficient of sales growth before the crisis is positive and statistically significant, but after the crisis, it is reduced by δ_1 . The coefficient after the crisis is equal to $\hat{\beta}_5 + \hat{\delta}_1 = 0.055 - 0.01 = 0.045$, which is still positive. Notice that δ_1 is barely not significant at the 10% level. This result supports the financial motive for firms.

Column (3) considers the same regression, but now the bank loans variable changes coefficient as well. The *SW* test now strongly rejects the null of no structural

Table 2 Main regression results

Years	12	12	12	12
Interactive effects	Yes	Yes	Yes	Yes

Notes: This table is based on regressions containing a panel of 2526 firms, where the dependent variable is $TC_{i,t}$, and control variables are $S_{i,t}$, $L_{i,t}$, $R_{i,t}$, $B_{i,t}$, and $SG_{i,t}$. *SW* is the Sup-Wald test for the existence of a structural break. Finally, *, **, and *** denote statistical significance at the 10%, 5%, and 1% levels, respectively

breaks, and the break date is the same as before. Before the break, bank loans had a positive and statistically significant effect on trade credit at the 1% level. This is the first evidence in favor of the redistribution channel of trade credit. After the break, the bank loan coefficient becomes $\hat{\beta}_4 + \hat{\delta}_2 = 0.049 - 0.047 = 0.02$, which is very close to zero. Notice that $\hat{\delta}_2$ is statistically different from zero and the test for $H_0 : \beta_4 = -\delta_2$ has a p-value equal to 1. All this is evidence that after 2010, the redistribution of bank loans stopped. The conclusion here is that, if structural breaks were not considered, there would be no evidence of the redistribution channel of trade credit. Still, the structural breaks analysis shows that this channel is potent up until 2010. The coefficients of sales growth are similar to column (3). Column (4) of the table confirms these results and also shows that the break does not impact the effect of profitability on trade credit because, although the coefficient $\hat{\delta}_3$ is negative, it is small and insignificant. Overall, the structural break analysis allows us to conclude that the financial motivation theory holds and the redistribution theory of trade credit holds until 2010 but not later.

93.7 Conclusions

This chapter's first contribution is a review of the panel data structural breaks detection and estimation literature. This literature has considered a diverse set of panel data models and has found significant, qualitatively new results. Despite the tremendous progress achieved in the past decade, there are still many questions open for research in nonstationary panels, panels with group structure, and models with multiple structural breaks.

The second contribution of the paper is the analysis of the determinants of trade credit. Meltzer (1960) argues that banks reduce lending in times of contractionary monetary policy; therefore, bank loans are available only to the largest and more trustworthy firms. In turn, these firms will redistribute the available credit in the form of trade credit to their customers. Meltzer (1960) argues that this process reduces the adverse impact of money tightening on small firms. In this chapter, using data on a large sample of European firms for the period 2004–2015, we find evidence that this theory is valid up to a point. A structural break was detected and dated in 2010. Before 2010, the relationship between bank loans and trade credit was positive, which means that some of the bank funds were being redistributed in the form of trade credit. However, after 2010, this phenomenon stopped.

To summarize, structural change has long been recognized as one of the greatest threats to inference. The longer the time dimension of the panel, the higher the probability that a break has happened. A suggestion would be that tests for structural breaks are routinely reported with other descriptive statistics in papers with panel data regressions.

More on Equilibrium Credit Rationing and Interest Rates: A Theory with New Evidence

94

Ying Wu

Abstract

In contrast to conventional understanding, an integrated theory of equilibrium credit rationing that allows restrictions on loan size as well as loan denials reveals a *positive* relationship between credit availability and interest rates when rationing by loan size (Gray, J. A. and Y. Wu, *Journal of Macroeconomics* 17: 405–420, 1995). This chapter uses the US bank lending practices from 1997 to 2010 as a quasi-natural experiment to test the interest rate hypothesis under loan-size rationing. Based on the vector error correction analysis of commercial and industrial loans made by the US domestic banks to large and middle-market firms, there is a cointegrating relation that sufficient tightness of credit market conditions (either an average loan size less than \$888,880 or a net percentage of banks tightening loan standards greater than -11%) rescues a positive relationship between loan sizes and loan rates. The net percentage of tightening banks plays a pivotal role in interacting with the size of loans and the demand for loans to maintain such a long-run equilibrium relationship.

94.1 Introduction

Credit rationing, under which borrowers fail to get their desired funds even if they willingly pay higher interest rates, can exist as an equilibrium phenomenon in a completely free market in which there are no institutional and legal restrictions on interest rate adjustment. Asymmetric information is at the heart of equilibrium credit rationing. The well-known classical paper on equilibrium credit rationing by Stiglitz and Weiss (1981) posits information asymmetry in the form of *ex ante* private information about the riskiness of a firm's investment projects. Although the firm knows its own risk type, the intermediary that extends loans has no knowledge of the firm's risk type prior to making loans. Williamson (1987), on the other hand, analyzes the *ex post* private information about the firm's realized return on investment in a credit rationing model. The financial intermediary has to pay a monitoring cost to observe the outcome of projects that the firm can observe costlessly. In both of these studies, equilibrium credit rationing takes the form of restricting the number of loans whereby some borrowers get loans and others do not and thus rationing through restriction on loan size is not investigated at all. Consequently, changes in loan supply may be accompanied by no change at all in interest rates. While such a prediction of invariance of interest rates with respect to credit availability makes macroeconomists particularly intrigued, it is also interesting because it may suggest a new pattern of monetary policy transmission mechanism in terms of credit channel and interest rate behavior.

Besides the type of credit rationing by the number of loans studied by Stiglitz and Weiss, the credit-rationing literature has been exploring the other non-price types of credit rationing, which expands the scope of rationing and enriches the insights of the issue (see Kjenstad and Su 2015; Su and Zhang 2017). Nevertheless, while there are some studies that permit credit rationing by loan size, they either ignore the interest rate-credit relationship or take for granted that interest rates are negatively related to credit supply. Following the precursors to the equilibrium credit rationing literature,¹ Jaffee and Russell (1976) concentrates on credit rationing by size under *ex ante* asymmetric information but leaves the interest rate behavior under the rationing aside. Keeton (1979) studies credit rationing by both number and size of loans but it is not done in a consolidated setting: the possibility of rationing by loan number relies on either an interest rate ceiling or moral hazard in the lending process, neither of which is present in the model in which rationing by loan size occurs. Hence, it is impossible to evaluate the relative desirability of the two types of rationing. In Schreft and Villamil (1992), one of few efforts in exploring equilibrium credit rationing by loan size and interest rate behavior under the rationing, credit rationing occurs as a result of both the lender's market power (imperfect interest-rate discrimination) and imperfect information regarding the borrowers' characteristics, rather than depending on default risk and loan administration costs. Consequently,

¹Hodgman (1960), Freimer and Gordon (1962), Miller (1962), and Jaffee and Modigliani (1969), for examples.

instead of reflecting an endogenous effect on interest rates of changes in credit supply, the inverse relationship between loan sizes offered and interest rate charged plays a role only as a lender's strategy inducing borrowers to reveal their preferences for loan contract terms.

How do interest rates respond to tighter availability of loanable funds if credit rationing restricts the size rather than the number of loans? What new evidence concerning the relationship between credit supply and interest rates is available since the late 1990s after the two decades of intensive theoretical development of equilibrium credit rationing? For the first question, Gray and Wu (1995) provides a proof that tighter credit can cause interest rates to fall. In this chapter, I will first sketch an integrated theoretical framework to highlight the earlier findings for the first research question, and then I will turn to a vector-error correction model to address the second question above by analyzing the recent evidence of US banking practices and associated interest rate behavior with respect to credit supply.

94.2 A Theoretical Framework²

94.2.1 Model

Instead of appealing to any institutional or legal restrictions on interest rate adjustment or imperfect competition system, my study of loan-size rationing considers a competitive economy with a large number of identical households (ultimate savers/lenders), banks (intermediaries), and firms (ultimate investors/borrowers). In such a free-market economy flawed only by the *ex post* asymmetric information about borrowers' investment return, I focus on a representative member of each type of economic agents.³

Suppose that $\theta f(H)$ is the Cobb-Douglas production function with a uniformly distributed random term θ on the interval $[0, \bar{\theta}]$, H is the amount of the capital input employed by the firm and funded by bank loans. With ω denoting the capital rental rate and R the loan rate, the firm's profit can be expressed as $\theta f(H) - (1 + R)\omega H$. Although the debt contract specifies a fixed, non-contingent loan repayment at the end of the production period that the intermediary must collect from the firm, the firm may default if the value of production fails to cover the specified payment due to the adverse realization of random productivity parameter θ . The minimum value of the productivity factor θ required for the profit-maximizing firm's solvency, i.e., the threshold value of loan default θ^* , increases in both the loan rate and the amount of loans:

²The theoretical framework in this section is based on portions of Gray and Wu (1995) and Wu (2017).

³This setting naturally excludes the possibility for lenders to exercise price discrimination against borrowers, which helps, though, generate loan-size rationing in Schreft and Villamil (1992).

$$\theta^* = \frac{(1+R)\omega H}{f(H)}, \quad 0 < \theta^* < \bar{\theta} \quad (1)$$

Thus, the firm must choose H to maximize its expected profit

$$\int_{\theta^*}^{\bar{\theta}} \frac{[\theta f(H) - (1+R)\omega H]}{\bar{\theta}} d\theta \quad (2)$$

The firm's inverse input demand function for capital goods is derived from Eq. (2) as⁴

$$F(H) \equiv \frac{(\bar{\theta}/2)f'(H)}{[1 - (\varepsilon(H)/2)]} = 1 + R \quad (3)$$

where $0 < \varepsilon(H) < 1$ is the elasticity of output with respect to capital input. It can be shown that $F(H)$ is a decreasing function of loan size, H . If the intermediary honors the firm's inverse input demand so that the contract pair of loan size and loan rate exactly traces $F(H)$, then the $F(H)$ further generates the corresponding expected return to the intermediary, $\pi^F(H)$, which possesses a unique maximum.

On the other hand, the household endowed with a fixed amount of the capital good chooses to deposit more with the intermediary if the gross deposit rate, $1 + r$, gets higher⁵:

$$h = h(1 + r), \quad h' > 0 \quad (4)$$

In channeling purchasing power between households and firms, the intermediary chooses the loan rate to maximize its expected return on each "real" dollar loaned to the firm:

$$\max_{1+R} \left\{ \int_{\theta^*}^{\bar{\theta}} \frac{[(1+R)\omega H]}{\bar{\theta}} d\theta + \int_0^{\theta^*} \frac{[\theta f(H) - \gamma]}{\bar{\theta}} d\theta \right\} \frac{1}{\omega H} \quad (5)$$

where γ is the monitoring cost for the intermediary when the firm defaults. An increase in the loan rate affects the intermediary's expected return in two opposing ways. It raises the return by raising the loan payment when the firm is solvent but lowers the return by raising the probability of loan default. It is the second effect that produces the possibility of credit rationing.

⁴For simplicity, the rental price of capital, ω , is normalized at unity.

⁵Although the return the intermediary receives on a particular loan is random, the return on the intermediary's portfolio of loans to a large number of borrowers is not random. This assumption allows the intermediary to offer the households a nonrandom return on their deposits.

94.2.2 Rationing by the Number of Loans

The concavity of $\pi^F(H)$ with a turning point holds the key for credit rationing by the number of loans. In a competitive market, it is assumed that the intermediary will hold no excess reserves and loan out all its deposits; rationing loans by number means a provision of the loan size that maximizes the intermediary's return for those who receive loans while other rationed firms receive none. Whether or not the intermediary chooses to engage in number rationing depends on how plentiful the supply of credit is. If the supply of credit is sufficient to provide each loan applicant with a loan size at which the intermediary's return is maximized, the rationing by number will not occur because the intermediary would otherwise have to lower its return from each "real" dollar loaned by raising the loan size for some while rationing others. In this case, the relationship between interest rates and credit supply is negative, as traditionally expected. However, if the supply of credit is too tight to provide each firm a loan with the size that maximize the intermediary's return, the intermediary has incentive to engage in rationing by the number of loans. As a result, the level of interest rates is essentially anchored at the intermediary's optimal loan size; it is the number of loans rather than interest rates that comoves with the credit supply.

94.2.3 Rationing by the Size of Loans

Credit rationing by loan size differs from number rationing because the intermediary may no longer choose to deny loan to some firms but may stipulate, in addition to the loan rate, a ceiling of loan size to prevent firms from getting the desired amount of loans at the announced loan rate. The intermediary chooses the gross loan rate $(1 + R)$ for a loan of size H to maximize its expected return expressed in Eq. (5) and obtains its optimal loan schedule

$$I(H) \equiv \frac{\bar{\theta}f(H) - \gamma}{H} = 1 + R \quad (6)$$

The intermediary's optimal loan rate schedule further generates its schedule of expected return, $\pi^I(H)$, which can be shown to have a unique interior maximum. In addition, $\pi^I(H)$ is greater than $\pi^F(H)$ everywhere except at its tangency point with $\pi^F(H)$, H_C .⁶

As depicted in Fig. 1, when the loan size is as large as H_L , although the intermediary could raise its return by following its own loan schedule $I(H)$ and charging a loan rate of $1 + R_L^*$, the result is not attainable as the firm will not be forced to take the loan in excess of the amount that maximizes its profit. Therefore, for any loan sizes greater than H_C , it is $\pi^F(H)$ rather than $\pi^I(H)$ that determines the intermediary's expected return. When loan sizes are smaller than H_C , say H_T , the

⁶See Gray and Wu (1995) and Wu (2017) for proofs.

Becchetti et al. (2011) presents the robust evidence from Italy that the European Central Bank refinancing rate is significantly and positively related to credit rationing by loan size (partial credit rationing) but not by loan number (total credit rationing). As far as the type of credit rationing and its associated interest rate behavior are concerned, this finding is consistent with this present study has established in the previous section. However, the limitations in Becchetti et al. (2011) concern the type of interest rate, financial intermediaries, and borrowers in their dataset: it focuses exclusively on the central bank's policy rate rather than business loan rate, on the nonprofit-maximizing financial institutions rather than typical financial intermediaries as lenders, and on not-for-profit cooperatives rather than traditional for-profit industrial borrowers in the loanable funds market. In addition, Drakos and Giannakopoulos (2011) uses a micro dataset of approximately 9500 firms from 26 East European transition economies to classify credit-rationed firms by explicitly connecting between rationing and potential borrower profiles. While the survey results and the analysis from an estimated bivariate probit model identify the evidence of credit rationing by number, the model design leaves rationing by size uninvestigated. Using loan application and loan contract information from a large sample of Bulgaria, Kirschenmann (2016) measures credit rationing by the ratio of granted to requested loan amounts and provides direct evidence on the presence of loan size rationing as well as its extent and evolution over repeated interactions between small firms and their bank.

Based on an international dataset containing 18,000 business loans, Berger et al. (2018) provides their findings concerning credit rationing and interest rates in a period covering both before and during 2008–2009 financial crisis. They find that US banks appear to engage in more quantity rationing than banks from other nations and that the declines in loan quantities are larger for US banks than non-US banks and for US borrowers than non-US borrowers. Additionally, they find that as credit supply tightens, loan spreads tend to get larger for the public and relationship borrowers who experience size rationing while risky private and non-relationship borrowers could be denied from getting loans at all. While their results can still be consistent with the theoretical model developed in the Sect. 94.2 of this entry in terms of the relation between credit supply and interest rate behavior, the conceptual distinction of credit rationing by banks from credit-supply tightening in market appears ambiguous in Berger et al. (2018). More recently, employing microlevel data on small- and medium-sized enterprises collected by the European Central Bank over the period 2009–2019, Beyhaghi et al. (2020) further demonstrates not only that the equilibrium credit rationing can exist even in the presence of contract heterogeneity but also that rationing by the size rather than number of loans is most likely rationing regime in the post-financial crisis era.

94.4 Vector-Error Correction Model (1997–2010)

This section is intended to examine an extended sample period of US banking from 1997 to 2010 that covers two most recent economic recessions (the early 2000s recession from March 2001 to December 2001 and the Great Recession from

December 2007 to June 2009). With tight credit supply, the episodes of economic recession can be used as a quasi-natural experiment to test the theory of equilibrium credit rationing developed in this study, particularly the loan interest rate behavior and its relationship with loan size and credit-market conditions.

The quarterly dataset used in this study includes four major variables. Among them are the weighted-average effective loan rate (*LOANRATE*) and the average loan size (*LOANSIZE*) for all commercial and industrial loans made by all commercial banks, the net percentage of domestic banks tightening standards for commercial and industrial loans to large and middle-market firms (*TIGHTEN*), and the net percentage of domestic banks reporting stronger demand for commercial and industrial loans from large and middle-market firms (*LOAN_SD*). All these series are quarterly observations extracted from Federal Reserve Economic Database (FRED) and the Senior Loan Officer Opinion Survey on Bank Lending Practices.

In addition, an interaction term (*TIGHTEN_SIZE*) is added in order to investigate the composite impacts of loan size and tightened loan standard on the loan interest rate. Here, the effect of one variable (say, loan size) that forms the interaction depends on the level of the other variable (i.e., the net percentage of banks that tighten loans) in the interaction.

The methodology used to analyze the data is to estimate a vector-error correction model that helps understand the long-run equilibrium relationship (cointegration) among the business interest rate on loans, the size of loans, and credit market conditions. The precondition for the validity of cointegration estimation and vector-error correction analysis requires that the investigated series are nonstationary in their levels (I(1) process) but stationary in their first-order differences (I(0) process); if these conditions are met, there is possibly a linear combination of the series that is stationary, which is the so-called cointegration relation. Table 1 lists the results from three distinctive unit root tests of the five series for the cases of including intercept only and both intercept and trend, respectively. All the series satisfy the stationarity

Table 1 Unit-root test (1997Q2-2010Q4)

Info Rule	Test Type

Notes

1. For information rules, AIC stands for Akaike Information Criterion, SC Schwarz Information Criterion, and HQ Hannan-Quinn Criterion
2. The first row for each and every information rule reports the *p*-value for the unit-root tests of the group variables at their levels, and the second row the *p*-value for the unit-root tests of the same group variables in their first-order differences

conditions for cointegration analysis. Next, the Johansen cointegration test is used to determine the number and properties of the cointegration relationship; the optimal lag length used in the test is one-quarter lag according to the Schwarz information criterion and Hannan-Quinn information criterion for the estimated vector autoregressions. As Table 2 shows, both the Johansen trace test and the maximum eigenvalue test jointly support that there is a cointegration relationship at 5% significance level conditional on the assumption that the level series and the cointegrating equations have linear trends.⁷

The vector-error correction model to be estimated can be presented as the following:

$$\begin{pmatrix} \Delta \text{LOANRATE}_t \\ \Delta \text{LOANSIZE}_t \\ \Delta \text{TIGHTEN}_t \\ \Delta \text{TIGHTEN_SIZE}_t \\ \Delta \text{LOAN_SD}_t \end{pmatrix} = \begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_3 \\ \alpha_4 \\ \alpha_5 \end{pmatrix} + (\beta_1 \ \beta_2 \ \beta_3 \ \beta_4 \ \beta_5 \ \beta_6 \ \beta_7) \begin{pmatrix} \text{LOANRATE}_{t-1} \\ \text{LOANSIZE}_{t-1} \\ \text{TIGHTEN}_{t-1} \\ \text{TIGHTEN_SIZE}_{t-1} \\ \text{LOAN_SD}_{t-1} \\ \text{TREND} \\ 1 \end{pmatrix} + \begin{pmatrix} \gamma_{11} & \cdots & \gamma_{16} \\ \vdots & \ddots & \vdots \\ \gamma_{51} & \cdots & \gamma_{56} \end{pmatrix} \begin{pmatrix} \Delta \text{LOANRATE}_{t-1} \\ \Delta \text{LOANSIZE}_{t-1} \\ \Delta \text{TIGHTEN}_{t-1} \\ \Delta \text{TIGHTEN_SIZE}_{t-1} \\ \Delta \text{LOAN_SD}_{t-1} \\ 1 \end{pmatrix} + \begin{pmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \varepsilon_4 \\ \varepsilon_5 \end{pmatrix} \quad (7)$$

All the variables in the five-equation system (7), including both the first-order difference terms and the cointegration equation, are stationary. The first part on the

⁷To get this result, the Pantula principle is used to test the *joint* hypothesis of both the cointegration rank order and the deterministic components in the multivariate vector error correction model. Specifically, the test is run continuously by moving through from the most restrictive alternative ($r = 0$ and the model in which the level data have no deterministic trends and the cointegration equations have intercepts) to the least restrictive alternative ($r = n - 1$ and the model in which the level data and the cointegration equations have linear trends). At each stage, the $\lambda_{\max}$ (or λ_{trace}) test statistic is compared to its critical value and the procedure continues until the null hypothesis is not rejected. For details, see Johansen (1992).

Table 2 Johansen cointegration test (1997Q2-2010Q4)

	Eigenvalue	Null hypothesis	Alter. hypothesis	Statistic	5% C.V.	p-Value
λ_{trace} test	0.629	$r = 0^*$	$r > 0$	128.324	88.803	0.000

Notes

1. r in the table represents the number of cointegration equations. Both trace test and Max-eigenvalue test indicate two cointegrating equations at the 0.05 level
2. * denotes rejection of the hypothesis at the 5% significance level

right-hand side of Eq. (7) gives the response of the dynamic system to disturbances that let the system deviate from its long-run equilibrium. Let the vector β be a 1×7 row cointegrating vector, $y_t - 1$ the 7×1 column vector of all the variables in the cointegration equation, and α a 5×1 column vector. If $\beta y_t - 1 = 0$, the system is in its long-run equilibrium; if $\beta y_t - 1 \neq 0$, that is, the system exhibits a deviation from the equilibrium, then $\alpha \beta y_t - 1$ represents the error correction that helps move the system toward its equilibrium. The second part on the right-hand side of Eq. (7) is the traditional vector autoregression system in first differences.

The estimated cointegration equation reveals a robust long-run equilibrium relationship that provides fresh evidence for the theory of credit rationing by loan size developed in the Sect. 94.2 of this chapter. Specifically, as reported in Table 3, a decrease of an average thousand dollar in commercial and industrial loans *lowers* rather than raises the weighted average effective loan rate by 1.4 basis point.⁸ In addition, each net percentage point increase in the domestic banks tightening standards for commercial and industrial loans to large and middle-market firms *lowers* rather than raises the weighted average effective loan rate by 80 basis points. According to these two estimates, tightened loan standard by commercial banks and reduced average loan size, instead of elevating interest rates on loans (as traditionally construed) or leaving them invariant (as predicted by many equilibrium credit rationing models that focus only on rationing by loan numbers), are respectively associated with *lower* loan interest rates. In addition, each net percentage point increase in the banks reporting stronger demand for loans from firms is associated with a 25 basis-point decrease in the loan rate, as presented in the estimated cointegration equation, which further supports the theory of equilibrium credit rationing by loan size, because tight credit market conditions represent large *net* demand for credit (i.e., either strong demand for or weak supply of loans or both).

⁸One basis point is 1/100 percentage point.

The estimates with * are significant at 10% level

Given the significance of *LOANSIZE* and *TIGHTEN* in the cointegration equation, their interaction term gives additional insight of how each of them affects *LOANRATE*. On one hand, the effect of tightened loan standard on the loan rate depends on the magnitude of loan size as $\frac{\partial(\text{LOANRATE})}{\partial(\text{TIGHTEN})} = -0.8 + 0.001(\text{LOANSIZE})$, implying that banks engaged in tightening loans will reduce the loan rate to lower credit risk if the average loan size is less than \$888,880 (see Panel a of Fig. 2). On the other hand, the effect of loan size on the loan rate depends on how large the net percentage of the domestic banks tightening standards for commercial and industrial loans is. Given $\frac{\partial(\text{LOANRATE})}{\partial(\text{LOANSIZE})} = 0.01 + 0.001(\text{TIGHTEN})$, it follows that smaller loan size is associated with lower loan rates if and only if net percentage of the domestic banks loosening standards is less than 11% (i.e., those tightening standards greater than -11%, as shown in Panel b of Fig. 2). That is, it is the sufficient tightness of credit market conditions, even though the percentage of banks tightening loans falls short of the percentage of banks loosening loans when the net percentage of banks tightening is negative, that rescues a positive relationship between loan size and loan rate. These results from the interactive term analysis are well in line with not only the theory of equilibrium credit

rationing by restricting loan size in Sect. 94.2 but also with the data for the sample period. Figure 3 presents the time plots of the US average loan sizes for commercial and industrial loans and the net percentage of the domestic commercial banks tightening standard of loans from 1997 to 2010. In the sample period, the loan size is uniformly below the threshold in favor of a negative relationship between credit tightening and loan rates (panel a of Fig. 3), and the most of the observed net percentage of tightening banks is well above the threshold in support of a positive relationship between loan sizes and loan rates (panel b of Fig. 3).

While Table 3 gives all the estimates of both the error-correction part and autoregression part of the entire vector error correction model, Tables 4 and 5 report the results of likelihood-ratio test to verify the significance of the estimated cointegrating vector β and the estimated speed-of-adjustment coefficient vector α . All the endogenous variables share the common cointegration trend and are in the cointegration space. In addition, in the cointegrated system, LOANRATE is not Granger caused by other variables at the 5% significance level (the first row of Table 6). Except that LOANRATE is weakly exogenous with respect to the cointegrating vector, all the other four endogenous variables are significantly

Fig. 3 Loan size and tightening banks in the USA (1997–2010). (Panel **a**) Average loan size for commercial and industry loans. (Panel **b**) Net percentage of banks tightening loan standards

endogenous in terms of their responsive adjustment to the cointegrating vector over time (long-run Granger causality).⁹ Indeed, the exogeneity result for the loan rate is consistent with the theoretical model of loan-size rationing. Once a bank finds it

⁹The evidence from a set of diagnostic tests supports the validity of the estimated vector error-correction model. For examples, the estimated dynamic system is stable, as all the inverse roots of the characteristic autoregression polynomial lie inside the unit circle and VEC specification imposes four roots on the unit circle; the Jarque-Bera residual normality test indicates that the estimated residuals are multivariate normal; and there is no serial correlation of residuals by the VEC residual serial correlation Lagrange multiplier test and portmanteau autocorrelation test.

optimal to lower the loan rate, credit rationing on the loan size will take place and the loan standards will be tightened whereas the quantity of loans demanded is increasing at the lower loan rate.

Table 6 helps investigate the degree of endogeneity of variables and possible causality relations among them. The pairwise Granger causality test identifies the short-run causality among the variables in first differences by the significance of the pertinent coefficients (γ s), and the t-statistic for the lagged error-correction coefficient (α s) concerns the long-run causality in terms of how responsive a variable is to disequilibrium errors. In the short run, while a change in the loan size per se does not seem to cause others to respond significantly, its interaction term with the net percentage of banks tightening loan standard exhibits Granger-causality relations at the 10% level with all the other variables. Furthermore, as shown in the column entitled “Block Exogeneity,” the joint significance of all the included variables for short-run Granger causality holds only for the two dependent variables, i.e., net percentage of banks tightening loan standard and its interaction term with loan size, suggesting their strong endogeneity. Additionally, both the net percentage of banks tightening loan standard and the net percentage of banks reporting stronger loan demand Granger-cause all other variables except the loan rate. Indeed, as predicted by the theoretical model in Sect. 94.2, the loan rate either declines only with tightened credit rationing on loan size or gets anchored at its optimal level when credit rationing occurs by restricting the number of loans. In the long run, except for the loan rate, all the other variables play significant role (at the 1% level) in responding and adjusting to disequilibrium error and therefore moving to restore the long-run equilibrium relationship.

The findings from innovation accounting (impulse responses and variance decomposition) supports the results obtained from the cointegration relationship and short-run dynamic adjustment to disequilibrium errors. Figure 4 plots impulse responses based on the vector moving average representation of the expanded vector autoregression in standard form including the error-correction process, which exhibits the entire time paths of the five endogenous variables in response to the

white-noise disturbances in them respectively.¹⁰ In Fig. 4, the impulse response of LOANRATE over a period of 20 quarters to shocks on all the other four variables are consistent with what the cointegration equation tells about the long-run behavior of banks (the first row). As shown in the third row, the net percentage of banks tightening loans increases as both loan rate and loan size decrease while increasing with loan demand (the third row). In the fourth row, with *TIGHTEN_SIZE* interpreted as the average size of loans made by the net percentage of tightening banks, although its response to loan demand is positive, its impact on the loan rate is uniformly negative. These findings well echo the theoretical results of equilibrium credit rationing by loan size.

While impulse response presents the response of a variable to an impulse in another variable, the chart of variance decomposition reported in Table 7 shows how much a shock to one variable impacts the (variance of the) forecast error of a different variable. Over the entire period of as long as 20 quarters, the net percentage of tightening banks explains more than 90% of its own forecast error variance and the loan rate explains about 84% of its own forecast error variance, suggesting the strong exogeneity of these two series in the dynamic adjustment process. This can be explained by the loan-size rationing model in which loan-rate reduction and credit rationing are indeed the two sides of the same coin. In contrast, the interaction term (*TIGHTEN_SIZE*) is strongly endogenous; about 92% of its forecast error variance is explained by the net percentage of tightening banks. Meanwhile, the loan size also exhibits relatively strong endogeneity because both the net percentage of tightening banks and the demand for loans influence the forecast error variance of loan size by 35% and 15%, respectively. In addition, by the end of 20 quarters after the shocks, the shocks to the net percentage of tightening banks and loan size respectively account for 31% and 16% of the forecast error variance of loan demand, and their interaction term accounts for 42% of the forecast error variance of loan demand.

94.5 Conclusion

This study is a follow-up work to Gray and Wu (1995) with the fresh empirical evidence on the US market of commercial and industrial loans from 1997 to 2010. In the earlier theoretical framework, it was shown that the nature of the relationship between credit supply and interest rates is sensitive to the form that credit rationing takes. When credit rationing takes the form of restricting the number of loans, interest rates are insensitive to fluctuations in the credit supply. Nevertheless, the result no longer holds when it is the size rather than number of loans that is restricted to borrowers in the market for loanable funds. If rationing is allowed to take the form

¹⁰The Choleski decomposition with degree of adjustment is used in innovation accounting in order to identify the underlined structural model. Based on the matrix of pairwise cross-correlograms, the cross-correlation coefficients for the estimated residuals in the model are essentially within plus or minus two times the asymptotic standard errors of the lagged correlations. Therefore, the ordering of the variables in innovation accounting is unimportant.

of restrictions on loan size, the tight credit supply can cause banks to lower rather than raise interest rates (both the loan rate and deposit rate) when size rationing occurs in order to reduce default risk. Furthermore, even when credit is not tight enough to cause size rationing to occur, reduced supply of loans may still be associated with decreases in deposit rates. Only when credit availability is loose can a traditional negative relationship between loan supply and interest rates be honored.

The contribution of the present entry is to use a data sample of 1997–2010 US bank lending practices as a quasi-natural experiment to test the theory of equilibrium credit rationing, focusing on the loan interest rate behavior and its relationship with loan size and credit-market conditions. The vector error correction analysis finds a robust positive relationship between loan-size rationing and loan interest rates for a long-run equilibrium in the market for commercial and industrial loans. Examining the composite impacts of loan size and tightened loan standard on the loan interest rate for the sample period further suggests that it is sufficient tightness of credit market conditions that rescues a positive relationship between loan size and loan rate, especially when the economy experiences recessions. Specifically, on one hand, credit tightening lowers the loan interest rate if the loan size is less than \$888,880, and on the other hand, a smaller loan size is associated with lower loan interest rates if the net percentage of banks tightening loan standard is greater than -11% . According to Granger causality and innovation accounting analyses, the net percentage of tightening banks plays a pivotal role in interacting with loan size and loan demand to maintain the long-run equilibrium positive relationship between credit supply and interest rates.

The Effect of Basel III on Banks' Lending

95

Hao Chang and Yan Xue

Abstract

Basel III is considered as the most comprehensive set of regulations for mitigating banks' credit risk and market risk. Its major function is to encourage banks to raise more capital and carry sufficient liquid assets to avoid bank runs and defend financial crisis, thus promoting the stability of the financial system and maximizing the social welfare. Although stricter capital and liquidity requirements reduce the risk of bank runs, a voice of opposition about the negative impact of the regulations on banks' lending and profitability exists all the time. Finance researchers have conducted a number of theoretical and empirical studies to investigate how the rigorous regulations affect banks' risk and performance. This chapter summarizes this growing literature and sheds light on the future research areas on how capital and liquidity requirements in Basel III effect on Banks' lending and performance.

95.1 Introduction

The Basel Accords – a set of banking supervision regulations – were set by the Basel Committee on Banking Supervision (BCBS). The Basel Accords were developed to be the most comprehensive set of regulations for managing banks' credit risk and market risk. The key function of Basel is to encourage banks to absorb more capital and hold enough liquid assets to avoid bank runs and survive in a financial crisis. The regulations are designed to maintain the stability of the financial system by setting minimum capital and liquidity regulations on banks.

Although more stringent capital and liquidity regulations can reduce the risk of bank runs, there has been a vigorous debate about the potential negative impact of the regulations on bank lending and bank profitability. Many economists develop theoretical models or design empirical studies to explore how the tough regulations affect the risk the banks face and the banks' performance in the financial markets. A growing strand of literature discusses the impacts of capital requirements, liquidity requirements, and the joint effect of these two kinds of regulations. This chapter introduces corresponding studies and summarizes the effect of Basel III on Banks' lending.

The remainder of the chapter is organized as follows, Sect. 95.2 describes the historical evolution of Basel Accords. Section 95.3 investigates the impact of capital requirements on banks' lending. Section 95.4 discusses how the liquidity regulations affect banks' lending. Section 95.5 presents the interaction between the capital and liquidity regulations. Section 95.6 concludes.

95.2 From Basel I to Basel II

The Basel Accords are a series of banking regulation agreements. They were set by the Basel Committee on Bank Supervision (BCBS). The committee provides recommendations on banking and financial regulations about credit risk, liquidity risk, and operational risk. The Basel Accords were modified several times between 1980 and 2011 and can be broken down into Basel I, Basel II, and Basel III.

95.2.1 Basel I

Basel I, or the Basel Capital Accord, was formed in 1988. In 1980s, the number of international banks and large-size banks was growing faster and faster. The regulators realized that the failure of these banks would cause severe consequences in the economy since the cash reserves held by the banks were not sufficient. Besides that, the integration between banks increased rapidly. The deep integration might bring a crisis in multiple countries when one large bank failed in financial distress. Based on that fact, G10 countries enforced Basel I in 1992 and more than 100 countries also implemented these regulations.

Basel I is the first framework to help banks manage credit risk by governing the banks' asset allocations. The international banks are guided to allocate capital to lower-risk investments. Different kinds of assets are given different risk weights. Basel I classifies the assets into four categories based on their risk levels:

- Risk-free assets, like cash and treasury bonds (0% risk weight)
- Loans to other banks or securities (20% risk weight)
- Residential mortgages (50% risk weight)
- Corporate debts (100% risk weight)

Basel I requires a significant international bank to hold 8% of their risk-weighted assets as cash reserves and provides banks incentives to invest more in liquid securities and loans instead of risky mortgage and corporate bonds.

95.2.2 Basel II

Basel II was implemented in 2004 to extend Basel I. Regulators realized that the capital requirements in Basel I only considered credit risk while operational and market risks were ignored. As a result, Basel II strengthened the minimum capital requirements, supervisory mechanisms, and market discipline in Basel I. Banks are guided to determine their minimum capital requirements with the standardized measures of credit, operational, and market risks. Basel II attempts to create a more comprehensive framework to lower the risk of banking system.

A simple capital to asset ratio in Basel I might lead to more risky asset portfolios held by banks (Koehn and Santomero 1980; Kim and Santomero 1988). The Basel II framework makes more efforts to measure the risks of assets and introduces internal rating models to determine capital charges for individual credit risks.

In addition, there are also some key modifications in Basel II. First, it creates standardized measures for evaluating operational risk. Second, it uses market value instead of book value to calculate credit exposure. Finally, it considers the information asymmetry problem of banks. The disclosure requirements were developed to improve the supervisory mechanisms and market transparency.

95.2.3 Basel III

The Global Financial Crisis in 2008 exposed the weakness of the banking system. Therefore, Basel III was developed in November 2010. However, the tough requirements of Basel III led to a huge argument and they were not be fully implemented in the global banking systems.

The key reasons of the 2008 financial crisis include poor corporate governance, unsuccessful liquidity management, and over-leveraged capital structure.

Correspondingly, in Basel III, the minimum capital requirements were strengthened and the liquidity rules were designed to mitigate the short-term credit stress in a crisis. The liquidity rules include two key standards: the liquidity coverage ratio (LCR) and the net stable funding ratio (NSFR). Basel III requires banks to maintain the following financial ratios:

- Tier 1 capital ratio (Equity capital/Risk-weighted assets) $\geq 4.5\%$
- Leverage ratio (Tier 1 capital/Average total assets) $\geq 3\%$
- Liquidity coverage ratio (Liquid assets/Total outflows over next 30 days) $\geq 100\%$
- Net stable funding ratio (Available stable funding/Required stable funding) $\geq 100\%$

Most banks in important countries were required to comply with the new regulations between 2015 and 2019. Banks began to report the LCR in January 2015 and were fully binding in January 2019. The NSFR was fully implemented in January 2018. Since the LCR was introduced first, academia focuses more on the performance of LCR. Note that the LCR asks banks to maintain a buffer of high-quality liquid assets (HQLA) equal to or above 100% of total net cash outflows over the next 30-day calendar period. Banks report the LCR at least once a month. But the reporting frequency may be increased during a crisis. The HOLA is composed of the level 1 and level 2 assets. Level 1 assets comprise of cash, bank notes, highly liquid securities, and statutory reserves. Level 2 assets include high-grade corporate bonds, covered bonds and claims on quasi-government entities such as municipal bonds. The total net cash outflows are defined as either the bank's expected 30-day outflows less the greater of its expected 20-day inflows or 25% of its anticipated 30-day outflows.

The NSFR aims to ensure that banks maintain a stable funding structure. It is expressed as a ratio that must equal to or exceed 100%. The ratio relates the bank's available stable funding (ASF) to its required stable funding (RSF). A bank's total ASF is the portion of its capital and liabilities that will remain with the institution for more than 1 year. A bank's total RSF is the amount of stable funding that it is required to hold given the liquidity characteristics and residual maturities of its assets and the contingent liquidity risk arising from its off-balance sheet exposures. The NSFR became a minimum standard applicable to all internationally active banks on a consolidated basis on 1 January 2018, although national supervisors may also apply it to any subset of entities of large internationally active banks or to all other banks. Banks must meet the NSFR requirement on an ongoing basis and report on a quarterly basis.

Note that the US Federal Reserve exempts small banks from the Basel III liquidity requirements. The reason is that the burdens on small banks which come from the liquidity regulations outweigh the liquidity risk the small banks facing in a crisis. Besides that, the FDIC helps to resolve the distress small banks face. In contrast, the European Banking Authority requires banks of all sizes to comply with the required liquidity ratios. The European Banking Authority thinks that the credit supply of small banks is very important for the society.

In addition, Basel III includes a more complex and stringent reserve requirement and a countercyclical capital buffer to relax regulations during the financial distress.

95.3 Capital Regulation and Banks' Lending

Capital requirements are demonstrated to be effective tools to ensure the safety and soundness of banks. About 20 well-known professors once supported implementing the bank capital requirements and highlighted the important roles of capital requirements to avoid financial crises in an open letter to the Financial Times.

Although most of the economists agree with the important role of capital requirements, there is always a debate on the optimal capital requirements for banks. Some scholars prefer to loose capital requirements. They argue that a high required capital ratio would restrict banks' ability to provide credit to the economy, which reduces the consumption and economic growth. The cost of capital requirements can be reflected in the banking system: equity requirements would restrict lending and impede growth. A strand of the theoretical banking literature has argued that the tough requirements would reduce bank credit.

The capital requirements imply more equity with greater funding costs. The costliness of equity capitalization cannot be ignored. The changes in funding costs can be explained by Modigliani and Miller (1963). The banks have technological advantage in funding with deposits (Diamond and Rajan 2001). Comparing with the deposits, the equity is more expensive to adsorb. Besides the direct effect, the capital requirements raise costs by the tax subsidy of debt (Kashyap et al. 2010). In addition, the costs of equity capital could deviate from the government guarantee of bank debt (Kelly et al. 2016). Because of these types of additional costs, higher capital requirements lead banks to curtail their risk-weighted assets or lending to meet the standards.

However, Deli and Hasan (2017) argue the negative effect of capital requirements on banks' lending growth is weak. They link the effect of capital requirements with the banks' capital structure. The negative impact of capital requirements becomes low if banks are well-capitalized and disappears for banks with high capital ratios. According to their results, the cost of the capital requirements on bank's lending is not as high as expected.

Besides that, the impact of capital requirements may be tiny according to the Modigliani-Miller model. In response to higher capital requirement, the banks have to issue more equity to maintain the lending. But the deleveraging has a marginal impact on the cost of funding for banks. When the leverage become lower, the cost of equity decreases (Hanson et al. 2011).

Furthermore, some economists provide a counterintuitive suggestion that the tighter capital requirements help to increase lending. The benefits stem from two aspects. First, the capital requirements lower the probability of bank defaults in a crisis. Through increasing capital stringency, banks adjust their asset portfolio and decrease their risky investments. As a result, banks focus more on higher-quality lending and contribute to a healthy economic growth in a long run (Deli and Hasan

2017). Second, Begenau (2020) shows that more rigorous capital requirements can increase the banks' lending by lowering the deposit rate in a general equilibrium. The tough capital requirements thus help to reduce banks' funding costs and increase lending. If the deposit rate remains unchanged, the more rigorous capital requirements increase the weight on relatively expensive equity financing and raise banks' funding costs. But the deposit rates may be affected by the capital requirements. Banks would like to absorb more equity instead of deposits and the deposit rate decreases.

The old Basel frameworks introduce risk-weighted capital regulations which link capital to asset risk. But the risk-weighted capital regulations may exacerbate the procyclicality of lending (Danielsson et al. 2001; Kashyap and Stein 2004; Repullo and Suarez 2013). The rationale is that the capital requirements are enforced to a larger degree during an economy downturn. The banks constrained by the capital regulation are unable or unwilling to raise new equity in the crisis. They prefer to reduce risky loans and amplify the business cycle fluctuations. Then lending and credit availability are procyclical and amplify the business cycle (Gordy and Howells 2006; Freixas and Rochet 2008). The procyclical features of Basel II may contribute to the financial crisis (Brunnermeier 2009).

Behn et al. (2016) use the German banking data to examine how the model-based capital regulation affects the procyclicality of banking lending. They find that the countercyclicality of risk-weighted capital regulation has an important procyclical impact on banks' lending behaviors and the firms' access to funds. This chapter is the first empirical study to estimate how changes in risk-weighted capital regulation affect the supply of loans in the economy.

To solve this problem, the Basel III framework introduces a countercyclical capital buffer that reduces the pressure on banks to deleverage during the downturn. However, this may lead to higher risk in the banking system and cause unfavorable consequences for banks and economy.

Many economists attempt to identify the optimal capital requirement by quantifying the benefits and costs of capital requirements (Christiano and Ikeda 2016; Martinez-Miera and Suarez 2014; Corbae et al. 2019). Den Heuvel (2008) is the first to use a quantitative general equilibrium growth model to estimate the costs of higher capital requirements on welfare. The paper illustrates that higher capital requirements reduce financial fragility and lending amounts.

Since capital requirements have been imposed for about 30 years, a recent strand of literature empirically tests the effect of capital requirements on lending using different datasets. Aiyar et al. (2014) compare the credit distribution of the resident foreign branches with the one of the UK-owned banks which are subject to minimum capital requirements. Jiménez et al. (2017) exploit successive dynamic provisioning requirements imposed on Spanish banks in the 2000s. Fraisse et al. (2020) find that the capital requirements have a significant impact on lending. Facing the tough capital requirements, banks will shrink their risky assets and reduce lending.

95.4 Liquidity Regulation and Banks' Lending

The collapse of Lehman Brothers in September 2008 dragged other financial institutions into severe liquidity stress. Thus the need for routine liquidity management makes regulators realize that banks are exposed to liquidity risk. In addition, liquidity challenges that were experienced by the US and European banks rapidly spread into other markets through interconnections. However, banks face a dilemma on the right amount of liquidity to hold. The purpose of liquidity regulations is to ensure that banks hold adequate liquid assets in a crisis and finance their activities with stable funding sources.

A number of studies illustrate the importance of liquidity regulations. First, liquidity requirements are necessary because banks tend to hold insufficient liquidity because of the asymmetric information between depositors and banks (Diamond and Kashyap 2016). Banks have incentive to invest more in risky assets instead of liquid assets, while depositors can't get access to the perfect information about the banks' asset portfolios. As a result, banks hold insufficient liquidity and make themselves exposed to the bank-run risk. Liquidity regulations are required to restrict banks' behaviors. Second, liquidity regulations are justified firstly because of the market failures. The financial market cannot provide sufficient liquid assets when banks need more liquidity in a crisis. Liquidity requirements play an important role to avoid the liquidity squeeze. Third, liquidity regulations can supplement capital regulations in stabilizing the banking system (Calomiris et al. 2018). Finally, liquidity regulations would help to lower the chance of a bailout or a lender of last resort (LoLR) in a crisis. A bailout or an LoLR is costly because they induce moral hazard problems.

A main concern about liquidity regulations is that they are likely to harm banks' lending and profitability. The Basel III liquidity regulations are suspected to diminish banks' profitability by forcing banks to hold low-yield liquid assets and reduce lending (Banerjee and Mio 2018). Davis et al. (2020) develop a stylized interbank market environment and find that liquidity regulations reduce the incidence of bankruptcies but harm the investment efficiency. In the compound shock environment, liquidity regulations not only impose a loss of investment efficiency but also fail to reduce bankruptcies.

Although the importance of liquidity requirements had been discussed for a long time, the liquidity requirements hadn't been implemented until the launch of Basel III. As a result, the empirical studies about the effect of liquidity regulations are not as many as the capital-regulation ones. Now, there is still no conclusive empirical evidence about how liquidity regulations affect lending.

Bonner and Eijffinger (2016) study the Dutch banks and find that liquidity requirements push banks to borrow at longer terms and reduce their long-term lending. Because of the tighter interest margins by monetary policy, the Dutch banks do not change the lending rates and translate the funding costs to the lenders. Banerjee and Mio (2018) studies the impact on the UK banks and find that the limited interest rate impact is also appeared in the UK's banking system. The stricter

liquidity regulations affect banks' funding cost and have a negative impact on banks' lending and their profitability. Giordana and Schumacher (2017) investigates the impact of Basel III capital and liquidity requirements on default probability and profitability of banks in Luxembourg. They construct historical capital and liquidity ratios for the period from 2003 to 2011. They find that the impact of liquidity regulations on banks profitability is less clear-cut. The banks' funding structure is more important than the asset structure. Mashamba (2018) evaluates the effect of liquidity charges on the profitability of banks in emerging economies and find that the LCR has no detrimental effect on the performance of banks in emerging markets.

95.5 The Interaction Between Capital and Liquidity Regulations

The new Basel III intertwines the capital and liquidity regulations. The two kinds of regulations function on different parts of banks' balance sheets. Capital requirements directly restrict bank loans financed with deposits. In contrast, liquidity requirements require banks to maintain sufficient liquidity based on the deposit amounts. The two types of regulations drive banks to attract more equity and carry more liquid assets.

Liquidity and capital regulations work on bank asset and liability sides which are related to credit and liquidity risks (Bryant, 1980; Diamond and Dybvig, 1983). In the global financial crisis, credit and liquidity risks are demonstrated as the joint determinants of the financial intermediates' failure. Based on the interactive relationship between bank insolvency and illiquidity, Basel III imposes the joint regulations to protect banks and other intermediates in the future distress.

There is a growing literature on the interaction between liquidity and capital requirements. As most of theoretical models predict, the combination of equity capital and liquidity holding would stabilize the banking system. Vives (2014) uses a global game model to show that the regulations enhance financial stability by avoiding the bank run. Kara and Ozsoy (2021) argue that the liquidity regulation complements the capital requirement by allowing banks to hold more risky assets without raising fire sale risk. Walter (2019) argues that the joint regulations are efficient in internalizing the insolvency and liquidity risks.

But there are still arguments doubting the necessity of two regulations. Many economists prove that the combination of two requirements drive the implementation of Basel to be more costly. Liquidity requirements force banks to hold lower-yield liquid assets and reduce the profitable risky investments (Roger and Vlcek 2011). Capital requirements require banks to give up cheaper deposit funding and raise funding costs. The existence of both regulations reduce banks' revenues. Some banks points out that too much liquidity would reduce their solvency ability. The additional liquidity regulations harm banks' profits and raise the insolvency risk. If banks don't face high default risk, the negative effects of liquidity regulation will dominate.

Some economists prefer the liquidity requirements rather than the capital requirements. Adrian and Boyarchenko (2012) shows that liquidity requirements stabilize the financial system without harming the economic growth.

Others argue that capital requirements are sufficient in stabilizing the financial market. The new liquidity minimums in Basel III are imposed in the large banks that are already constrained by the capital requirements. The capital regulation has an effect on mitigating the liquidity risk. Some economists argue that liquidity and capital regulations are hard to be binding at the same time. Liquidity requirements tend to make capital less binding (Cecchetti and Kashyap 2018). As a result, the liquidity requirement may be redundant in stabilizing the financial market.

Many economists compare benefits and costs of two kinds of regulations. For example, Van Den Heuvel (2016) quantifies the welfare costs of requirements. According to this chapter, limited supply and important alternative uses of high-quality liquid assets make the liquidity requirement costly. But capital requirements carry higher social costs.

The interrelations of bank capital and liquidity requirements become complicated in empirically studies. For example, Schmaltz et al. (2014) simulate the likely response of banks to Basel III and find that banks will raise their stable deposit funding instead of investing in their liquid assets. However, Birn et al. (2017) show the opposite results. Distinguin et al. (2013) argues that the capital and liquidity are complements in large US banks. If large banks become illiquid, the regulatory capital ratios will decrease. But the regulatory capital ratios become higher if the smaller banks become illiquid. In the sample of small US banks, the capital and liquidity are substitutes. DeYoung et al. (2018) provide strong evidence that the small US bank can self-manage their liquidity without introducing the liquidity requirements. Their findings support the exemption of the smaller banks from the Basel III liquidity standards. According to their paper, imposing NSFR and LCR standards on small banks, like community banks, is redundant and unnecessarily costly. But the noncommunity banks may need the liquidity requirements in Basel III.

The noise in the empirical research is because that the liquidity requirements are just imposed in the financial markets. For example, the USA introduced LCR in 2015 and NSFR in 2016. Thus the impact of the joint requirements cannot be fully supported by data.

95.6 Conclusion

The Basel Accords are important for stabilizing the financial markets. Regulators should always discuss the present market conditions, learn lessons from the past, and update the Basel Accords. The global financial crisis prompts the introduction of capital and liquidity framework as main parts of Basel Accords. Following the policy development and implementation phases, it is now possible to assess the effects of the capital and liquidity regulations. This chapter reviews the recent academic evidence on this topic and summarizes major findings.

Overall, the literature to date concludes that banks respond to a binding capital or a liquidity constraint by raising long-term funding. Under normal economic conditions, banks have to bear more burdens. Their funding cost increases while risky

investments may be reduced. These effects have been illustrated by a range of theoretical models. But there is still insufficient empirical studies providing a clear conclusion about how the Basel Accords affect banks' behaviors.

Given that the LCR has been in effect in many countries since 2015, there is value in studying whether some of these model-implied effects are present in each country. As a starting point, one can measure the level of liquidity mismatch in the banking system, and document how it evolves with the LCR implementation following Bai et al. (2018), who construct a liquidity mismatch index (LMI) to gauge the difference between the market liquidity of assets and the funding liquidity of liabilities. One can also identify the extent to which capital and liquidity regulations would affect the loan amounts in each country and investigate the potential funding sources for small, mid-sized, and large banks to meet the standards.

It is meaningful to examine Basel III' effect on retail deposits. Recall that the LCR and NSFR treat retail deposits as a more stable funding source, which may be captured in their pricing. An interesting application would be to estimate this regulatory premium. In addition, how the new liquidity regulations work with other policies, like fiscal policy or monetary policy, is an interesting topic to explore. For example, Bech and Keister (2017) indicate that the introduction of an LCR requirement will make banks trade in interbank markets and affect interbank interest rates. Thus the regulations will change the impact of a central bank's monetary policy operations (OMO) which are used to control market interest rates. The model shows that steering market interest rates to a desired target level by open market operations may become more difficult when LCR requirement is implemented. The structure of an OMO becomes important since it may force banks to face LCR shortfall. The LCR requirement can change the impact of a central bank's OMO on the market interest rates. The central bank cannot use its pre-crisis operations to control market interest rates because of Basel III.

Aron Gottesman

Abstract

This chapter introduces mortgage analysis. We first review mortgage characteristics and concepts. We then explore equations and Excel functions through which mortgage cash flows are calculated, including the mortgage payments, interest payments, and principal payments. This chapter then explains mortgage sensitivity and the use of Weighted Average Life (WAL) to measure mortgage sensitivity. This chapter concludes with an exploration of prepayment, including prepayment measurement and modelling using Single Month Mortality (SMM), Conditional Prepayment Rate (CPR), and Prepayment Speed Assumptions (PSA).

96.1 Introduction

A mortgage is a lending agreement between a borrower and a lender where the borrower's real estate property is used as collateral. This chapter provides an introduction to mortgage analysis, concepts, and techniques. Among the questions that are addressed in this chapter are the following: What are the characteristics of a mortgage?

How are mortgage cash flows calculated? What Excel functions can be used to calculate mortgage cash flows? How is mortgage value sensitive to changes in mortgage rates? How is mortgage sensitivity measured? What is Weighted-Average Life (WAL) and what is its role? What is prepayment? How is prepayment measured, and modeled? What are Single Month Mortality (SMM), Conditional Prepayment Rate (CPR), and Prepayment Speed Assumptions (PSA), and what are their roles?

96.2 Mortgage Characteristics

Like a bond, in a mortgage the lender lends money to the borrower and the borrower pays interest and repays the money borrowed. The amount borrowed is referred to as the mortgage principal. The lender is referred to as the mortgagee and the borrower is referred to as the mortgagor. By a typical bond, the entire principal is paid at maturity. By a mortgage, the entire principal is not paid at maturity. Instead, through a process known as amortization, each payment that the mortgagor makes includes both principal and interest.¹

The length of the mortgage and the frequency of payments can vary. Common mortgage lengths are 15-year and 30-year mortgages.² Mortgages typically have monthly payments, though they occasionally have semi-monthly payments. The length of the mortgage is known as its “amortization term.” The amortization term is typically expressed in months, not years, hence a 15-year mortgage is referred to as a mortgage with a 180-month amortization term, and a 30-year mortgage is referred to as a mortgage with a 360-month amortization term.

The interest associated with a mortgage is known as its “mortgage rate” or “Annual Percentage Rate (APR).”³ Commonly, the frequency of compounding associated with the APR is equal to the frequency of the payments. Hence, the typical mortgage rate APR for a mortgage with monthly payments is compounded 12 times per year.

The mortgage rate may be a fixed rate of interest or a floating rate of interest that changes over time.⁴ When the mortgage rate is a floating rate of interest that changes over time, the mortgage is known as an “adjustable rate mortgage” or an ARM. The mortgage rate on an ARM is a function of an interest rate index. The period between

¹ Effectively, amortization represents an illiquid savings plan. Bernstein and Koudijs (2021) explore the important role that amortization has on household wealth building.

² Ye et al. (2014) study the relationship between mortgage rates and the choice of mortgage length.

³ McClatchey, C. and De la Torre, C. (2006) discuss other mortgage fees included in the APR and challenges associated with using APR when comparing mortgages.

⁴ Campbell (2013) Notes that long-term fixed-rate mortgages with minimal prepayment penalties hold an overwhelming majority of mortgage market share.

adjustments is the “adjustment period.” The date on which the mortgage rate adjusts is the “adjustment date.”⁵

ARMs often have initial rates that are low may have “adjustment caps” which are limits to the degree to which the mortgage rate can be adjusted on any given mortgage date, and may have “adjustment ceilings” which are limits to the level that the mortgage rate can reach, even over multiple adjustment periods. The ARM may allow the mortgagor to convert the mortgage into a fixed-rate mortgage. Such an ARM is known as a “convertible ARM.”⁶

When the mortgage rate is fixed, the mortgage rate is specified at the initiation of the mortgage and remains fixed during the amortization term. The mortgage payments made in each period consist of both interest and principal. When the mortgage rate is fixed, the total payment (i.e., the sum of the principal payment and interest payment) is the same amount every period.

An “amortization schedule” is a table that presents the mortgage payment and the interest and principal components of the mortgage payment for each month. Let’s explore the amortization schedule for the following example:

- Mortgage rate (APR_{12}): 6% (fixed rate, compounded 12 times per year)
- Frequency of mortgage payments: 12 per year (monthly)
- Amortization term: 180 months
- Mortgage principal: \$300,000

The amortization schedule for the first five and last five months of this mortgage is presented in Table 1.

As Table 1 shows, the mortgage payment (the second column of the amortization table) is \$2531.57 for each of the 180-months. In each month, the mortgagor is scheduled to make both interest and principal payments. Initially, the interest payments are a very large proportion of the mortgage payment. Towards the termination of the mortgage, the interest payments are a very small proportion of the mortgage payment.⁷

96.3 Calculating Mortgage Cash Flows

In the previous section, we learned that a mortgage payment represents the sum of the principal payment and interest payment associated with the given period. While the mortgage payment associated with a fixed-rate mortgage is the same every

⁵Bucks and Pence (2008) find that mortgage borrowers with adjustable-rate mortgages are likely to either underestimate their mortgage interest rate or be unaware of the amount by which their interest rate may change.

⁶Wang (2020) explores the role of ARM during the financial crisis of 2007–2009 and their decline in popularity.

⁷Calculation of the values specified in the amortization table will be explored in a subsequent section of this chapter.

Table 1 Amortization schedule for the first and last five months of a \$300,000 mortgage with a 180-month amortization term, monthly payments, and a fixed APR of 6% with monthly compounding

Month	Mortgage payment	Interest payment	Principal payment	Principal balance
0				\$300,000.00
1	\$2531.57	\$1500.00	\$1031.57	\$298,968.43
2	\$2531.57	\$1494.84	\$1036.73	\$297,931.70
3	\$2531.57	\$1489.66	\$1041.91	\$296,889.79
4	\$2531.57	\$1484.45	\$1047.12	\$295,842.67
5	\$2531.57	\$1479.21	\$1052.36	\$294,790.31
.	.	.	.	.
.	.	.	.	.
.	.	.	.	.
176	\$2531.57	\$62.35	\$2469.22	\$10,000.96
177	\$2531.57	\$50.00	\$2481.57	\$7519.39
178	\$2531.57	\$37.60	\$2493.97	\$5025.42
179	\$2531.57	\$25.13	\$2506.44	\$2518.98
180	\$2531.57	\$12.59	\$2518.98	\$0.00

period, the interest payment and principal payment differ each period. In this section, we will learn how to calculate the mortgage payment, the interest payment, the principal payment, and the principal balance at the end of the period.⁸

The present value of a series of cash flows can be calculated as follows:

$$PV = CF \cdot \left(\frac{1 - \frac{1}{(100\% + PER_m)^{n \cdot t_n}}}{PER_m} \right) \quad (1)$$

Where:

- PV = present value
- n = the number of times the cash flow is received
- CF = the cash flow that is received n times
- t_n = the number of years until the n th (final) cash flow takes place
- m = the frequency with which the cash flow is paid per year
- PER_m = the periodic effective rate that is compounded m times per year. The PER is the rate of interest for each compounding period.

We can use this expression to calculate the mortgage payment. To do so, recognize that when calculating a mortgage payment, our objective is *not* to identify the “present value.” We already know the present value – it’s the mortgage principal.

⁸While a typical mortgage borrower is unlikely to ever perform mortgage calculations in practice, it is interesting to note that Gerardi et al. (2013) find that numerical ability is negatively associated with mortgage default propensity.

Instead, when calculating a mortgage payment, our objective is to identify the cash flow. We can use the above equation to identify the mortgage payment as follows:

$$\text{Mortgage payment} = \text{Mortgage} / \left(\frac{1 - \frac{1}{(100\% + \text{PER}_m)^{m \cdot t_n}}}{\text{PER}_m} \right) \quad (2)$$

Unlike the mortgage payment, which is the same for every period, the interest payment is different for every period. The interest payment is calculated as follows:

$$\text{Interest payment} = \text{PER}_m \times \text{principal balance end of previous period} \quad (3)$$

Like the interest payment, the principal payment is different for every period. The principal payment is calculated as follows:

$$\text{Principal payment} = \text{Mortgage payment} - \text{Interest payment} \quad (4)$$

Since principal payments are made every period, the principal balance decreases with every period. The principal balance at the end of the period is calculated as follows:

$$\begin{aligned} &\text{Principal balance at the end of the period} \\ &= \text{Principal balance at the end of the previous period} - \text{Principal payment} \end{aligned} \quad (5)$$

For example, let's consider the cash flows associated with the second month of the mortgage presented in Table 1. The following are the inputs into the mortgage cash flow equations: $m = 12$, $\text{PER}_{12} = 6\%/12 = 0.5\%$, $t_n = 180/12 = 15$ years, and mortgage = \$300,000. The mortgage payment each month is $\$300,000 / \left(\frac{1 - \frac{1}{(100\% + 0.5\%)^{12 \cdot 15}}}{0.5\%} \right) = \$2,531.57$.

The second month's interest and principal payments are, respectively, $0.5\% \times \$298,968.43 = \$1,494.84$ and $\$2,531.57 - \$1,494.84 = \$1,036.73$. The remaining principal balance at the end of the second month is $\$298,968.43 - \$1,036.73 = \$297,931.70$.

Three functions in Excel through which mortgage cash flows can be calculated are the PMT, IPMT, and PPMT functions, which calculate the mortgage payment, interest payment, and principal payment, respectively.⁹ The inputs into these functions are PMT(rate, nper, and pv), IPMT(rate, per, nper, and pv), and PPMT(rate, per, nper, and pv), where:

- rate: The PER, compounded with the frequency that the mortgage payments take place per year
- nper: The number of payment periods over the amortization term

⁹Also see Arnold et al. (2017).

- **pv:** The mortgage principal, input with a negative sign.
- **per:** The period for which the interest or principal payment is being calculated.

Let's again consider the cash flows associated with the second month of the mortgage presented in Table 1. The following are the inputs into the Excel functions mortgage payment equation: $\text{rate} = 6\%/12 = 0.5\%$, $\text{nper} = 180$, $\text{pv} = \$300,000$, and $\text{per} = 2$. The mortgage payment, interest payment, and principal payment are calculated as follows: $\text{PMT}(0.5\%, 180, -300,000) = \2531.57 , $\text{IPMT}(0.5\%, 2, 180, -300,000) = \1494.84 , and $\text{PPMT}(0.5\%, 2, 180, -300,000) = \1036.73 .

96.4 Mortgage Sensitivity to Changes in Mortgage Rates

The value of a fixed-rate mortgage is the present value of the mortgage payments over the amortization term, discounted to the present using Eq. (1) at the current mortgage rate. The $\text{PV}()$ function in Excel can be used to discount a series of cash flows. In the context of mortgage valuation, the inputs are as follows: $\text{PV}(\text{rate}, \text{nper}, \text{and pmt})$, where rate and nper were defined earlier, and pmt is the mortgage payment, input with a negative sign.

Consider the mortgage presented in Table 1. In this case, the original mortgage rate was 6%, $\text{nper} = 180$, and $\text{pmt} = \$2531.57$. If the current mortgage rate is equal to the fixed mortgage rate of 6%, then the value of the mortgage presented in Table 1 is $\text{PV}(6\%/0.5\%, 180, -2531.57) = \$300,000$, or equal to the amount borrowed. If the current mortgage rate differs from the original mortgage rate, then the mortgage value will differ from the mortgage principal. To demonstrate, let's recalculate the mortgage value twice: assuming that the current mortgage rate is 5% and then again, assuming it is 7%. When 5%, the mortgage value is $\text{PV}(5\%/12, 180, -2531.57) = \$320,130.30$. At 7%, the mortgage value is $\text{PV}(7\%/12, 180, -2531.57) = \$281,652.24$.

The mortgage value's sensitivity to differences between the current mortgage rate and the original mortgage rate is similar to the sensitivity of a bond to difference between the yield and the bond's coupon rate. Specifically, if the current mortgage rate rises above the original mortgage rate, the value of the mortgage will decline. If the current mortgage rate falls below the original mortgage rate, the value of the mortgage will increase.

Further, the degree to which a mortgage will increase or decrease in value will depend on two key factors: The degree to which the current mortgage rate is different from the original mortgage rate and the amortization term of the mortgage. While any difference between the current mortgage rate and the original mortgage rate will result in a mortgage increasing or decreasing in value, the degree of increase or decrease depends on the degree to which the current mortgage rate is different from the original mortgage rate. If the current mortgage rate is similar to the original mortgage rate, the mortgage will not change in value very much. If the current mortgage rate is significantly different from the original mortgage rate, the mortgage will increase or decrease in value significantly. While any difference between the

current mortgage rate and the original mortgage rate will result in a mortgage increasing or decreasing in value, the degree of increase or decrease depends on the amortization term, with mortgages with longer amortization terms more sensitive.

Weighted-Average Life (WAL) is an index of mortgage sensitivity to changes in the mortgage rate. The higher that WAL is, the greater the sensitivity and vice versa. WAL is calculated as the principal-outstanding weighted average time until the mortgage payments associated with the mortgage are received.¹⁰ In equation form, WAL is specified as follows:

$$\text{WAL} = \sum_{i=1}^n t_i \cdot \frac{\text{Principal}_{t_i}}{\sum_{i=1}^n \text{Principal}_{t_i}} \quad (6)$$

where:

- n = the number of mortgage payment periods associated with the mortgage.
- t_i = the number of years until mortgage payment i occurs, where i ranges from 1 through n .
- Principal_{t_i} = the outstanding principal at the end of the payment period t_i , where i ranges from 1 through n .
- $\sum_{i=1}^n \text{Principal}_{t_i}$ = the sum of the outstanding principal at the end of all payment periods.

In this equation, $\frac{\text{Principal}_{t_i}}{\sum_{i=1}^n \text{Principal}_{t_i}}$ represents the “principal weight” of the principal outstanding at time t_i . The principal weights are multiplied by the years until each mortgage payment is received to determine the weighted average time until the mortgage payment associated with the mortgage is received.

Table 2 presents the calculation of the WAL for the mortgage presented in Table 2.

The first four columns of Table 2 are the amortization schedule. The sum of the fourth column, \$30,836,537.43 is the sum of the principal, $\sum_{i=1}^n \text{Principal}_{t_i}$. Each cell of the fifth column is principal weight for the given period, calculated as the principal outstanding at the end of the given period divided by the sum of the principal, $\frac{\text{Principal}_{t_i}}{\sum_{i=1}^n \text{Principal}_{t_i}}$. Each cell of the sixth column is the principal weight multiplied by the

¹⁰ Also see Yesayan (2009).

Table 2 Weighted-Average Life (WAL) calculations for a \$300,000 mortgage with a 180-month amortization term, monthly payments, and a fixed APR of 6% with monthly compounding; first and last five months are shown

years until the given mortgage payment, $t_i \cdot \frac{\text{Principal}_{t_i}}{\sum_{i=1}^n \text{Principal}_{t_i}}$. The sum of the sixth column,

5.3762, is the $\text{WAL} = \sum_{i=1}^n t_i \cdot \frac{\text{Principal}_{t_i}}{\sum_{i=1}^n \text{Principal}_{t_i}}$.

96.5 Prepayment

A characteristic of residential mortgages is that the mortgagee has the right to prepayment, that is, to repay mortgage principal each month, above and beyond the principal payment scheduled for the given month. The mortgagee can choose to prepay any amount of principal. For example, if the current mortgage rate falls below the given mortgage’s original mortgage rate, the mortgagee may prepay the entire mortgage. Alternatively, the mortgagee may choose to prepay a small amount of principal each month.

Single Month Mortality (SMM) is a measure of prepayment in each month. It is calculated as follows:

$$\text{SMM} = \frac{\text{Prepayment in given month}}{\text{Principal balance following the scheduled principal payment in given month}}$$

(7)

The SMMs for months 1, 2, and 3 of the mortgage presented in Table 1 are calculated, respectively, as $\frac{\$1,000}{\$298,968.43} = 0.3345\%$, $\frac{\$1,000}{\$296,935.17} = 0.3368\%$, and $\frac{\$1,000}{\$294,900.24} = 0.3391\%$

The Conditional Prepayment Rate (CPR) is an annualized measure of prepayment of the prepayment rate. It is calculated as follows:

$$\text{CPR} = 1 - (1 - \text{SMM})^{12} \quad (8)$$

If the CPR is known, we can invert this equation and calculate the SMM as follows:

$$\text{SMM} = 1 - (1 - \text{CPR})^{1/12} \quad (9)$$

The CPRs for months 1, 2, and 3 of the mortgage presented in Table 1 are calculated, respectively, as $1 - (1 - 0.3345\%)^{12} = 3.9408\%$, $1 - (1 - 0.3368\%)^{12} = 3.9673\%$, and $1 - (1 - 0.3391\%)^{12} = 3.9941\%$

The Standard Prepayment Model of The Bond Market Association makes certain “Prepayment Speed Assumptions,” known as the “PSA100.” The PSA100 assumptions are as follows: In the first month, the CPR is 0.2%. The CPR then increases by 0.2% each month until the 30th month. The CPR remains 6% until the mortgage is completely paid off.

PSA100 is perceived as a “benchmark” of prepayment. In reality, the actual prepayment may take place quicker or slower. If prepayment is quicker than the assumed prepayment in the PSA100, the “100” in the PSA100 name is replaced with a number greater than 100. Conversely, if prepayment is slower than the assumed prepayment in the PSA100, the “100” in the PSA100 name is replaced with a number less than 100.

For example, PSA200 refers to an assumed prepayment schedule that is twice as quick as the assumed prepayment in the PSA100. Hence, in the first month, the CPR was 0.4%. The CPR then increases by 0.4% each month until the 30th month. The CPR remains 12% until the mortgage is completely paid off.

Tables 3 and 4 present the mortgage provided in Table 1, assuming PSA100 and PSA 700. Observe that the WAL in the PSA100 scenario (Table 3) is 4.6467, while the WAL in the PSA700 scenario (Table 4) is 1.9663.

96.6 Conclusions

This chapter introduced mortgage analysis. The chapter first reviewed mortgage characteristics and concepts, including the concepts of mortgage principal, mortgagee, mortgagor, amortization, amortization term, payment frequency, mortgage rate, compounding, and amortization schedules. The chapter also described adjustable rate mortgages (ARM) and fixed-rate mortgages.

This chapter next explored equations through which mortgage cash flows are calculated, including the mortgage payments, interest payments, principal payments,

							Sum of principal =	\$ 9,675,709.27	WAL =	1.9663

and remaining principal balance. This chapter also explored and the Excel functions PMT(), IPMT(), and PPMT() through which these mortgage cash flows can be calculated.

This chapter then explains mortgage sensitivity. It demonstrated that if the current mortgage rate rises above the original mortgage rate, the value of the mortgage will decline. If the current mortgage rate falls below the original mortgage rate, the value of the mortgage will increase. The use of Weighted-Average Life (WAL) to measure mortgage sensitivity was also explored. It was shown that WAL is calculated as the principal-outstanding weighted average time until the mortgage payments associated with the mortgage are received.

This chapter concludes with an exploration of prepayment, which is the mortgagee's right to prepayment. It was shown that Single Month Mortality (SMM) is a measure of prepayment in a given month; the Conditional Prepayment Rate (CPR) is an annualized measure of prepayment of the prepayment rate; and that the Standard Prepayment Model of The Bond Market Association makes certain "Prepayment Speed Assumptions," known as the "PSA100."

A History of Commercially Available Risk Models

97

John Blin, John Guerard, and Andrew Mark

Abstract

Multi-factor risk models have been used in portfolio selection since the 1960s and early 1970s. The work of Barr Rosenberg led to the creation of Barra, the first major commercially available portfolio selection software. Rudd and Clasing brought Barra to the academic audience as professional managers were embracing it in industry. It is important to see how quantitative analysis was developed in investment research and analysis. Harry Markowitz, Bill Sharpe, Jan Mossin, and Jack Treynor pioneered capital market equilibrium and the creation and estimation of the Capital Asset Pricing Model. In the 1970s, multi-factor risk models were developed and estimated by Barr Rosenberg, Andrew Rudd, and their colleagues at Barra; John Blin and Steve Bender at APT; and Sebastian Ceria at Axioma. Multi-factor models pushed out the efficient frontier relative to a single factor risk model. McKinley Capital Management developed its Horse Race risk model philosophy to assess the most effective risk models for maximizing the Geometric Means, Sharpe Ratios, and Information Ratios. Several special issues of practitioner-oriented applied investment research featured the McKinley Horse Race results and reported that properly constructed multi-factor risk models created portfolios in which tilt variables that have statistically significant ICs produced statistically significant Active Returns. One must remove the market effect and extra-market covariances to properly estimate the contribution of a variable to the creation of efficient portfolios. APT and Axioma have reigned

supreme in those tests. The integration of Axioma and AAF and ITG transactions costs on the FactSet Investment have led MCM to implement an Axioma portfolio.

97.1 Introduction

Investing in stocks has always been risky, and the Crash of 1929 still has a solid place in US history. Yet over the last 70 years, the work of mathematicians has made it possible for managers to deal with that risk. In this chapter, we take a look at how this unfolded, and then we focus on three of today's leading risk-management systems.

In a breakthrough article published in 1952 in the *Journal of Finance*, Harry Markowitz introduced the portfolio risk equation. At heart, it was a simple quadratic constrained optimization problem. By then, linear programming was well understood – i.e., how to deal with the constrained optimization of linear systems. Likewise, quadratic extension methods had also been studied. Markowitz's paper was truly novel in that it applied its findings to financial portfolios. A clear-cut example of applied mathematics at its most practical.

As Markowitz recounts, when he was looking for a thesis topic, a chance conversation with a stockbroker got him thinking about the following: How do you take a group of recommended stocks and create a “good” portfolio? Was such a portfolio simply a collection of “good” stocks? Everyone knew in some form or other that “a wise man does not venture all his eggs in one basket.” But Don Quixote never said what to do about the eggs and basket. In his paper, Markowitz did more than hint about what to do, and eventually a new industry was born. Today a number of commercial risk management systems are available. Here we will be looking at three of them: Barra, APT, and Axioma.

Let's start with a quick review of the academic efforts. With his *Portfolio Selection: Efficient Diversification of Investments* (1959), Markowitz zeroed in on the risk-return trade-off. He's been expanding this effort ever since, including in his *Risk-Return Analysis* series (2013, 2016, and 2019, with a forthcoming fourth volume). Here we refer to the Markowitz Mean-Variance Model as the “MMV.” The Sharpe Diagonal Model drastically reduced the computational requirements of the MMV. It was followed by the Sharpe-Lintner-Mossin (1964, 1965, 1966) forms of the Capital Asset Pricing Model (CAPM). Estimation issues for CAPM were reported in Black et al. (1972). Aside from asset pricing models, multi-factor risk models also sprang up: King (1966), Cohen and Pogue (1967), Farrell (1974, 1997), Stone (1974), Rosenberg and McKibben (1973), Rosenberg (1974), Rosenberg and Marathe (1979), Ross (1976), Roll and Ross (1984), Rudd and Clasing (1982), Dhrymes et al. (1984, 1985), and Fama and French (1992, 1995, and 2008).

Commercial implementations soon followed: First, Barra in 1979. Then, APT (Advanced Portfolio Technologies, Inc.) in 1987. And finally, Axioma, created in the late 1990s and gaining practitioner acceptance in the 2000–2019 time period. Bloomberg will join the fray when it releases its own risk model.

In what follows we introduce readers to the three practitioners' multi-factor models and their creators: Specifically, Barra developed fundamentally based domestic and global risk models that are estimated from prespecified fundamental variables. APT developed multi-factor domestic and global risk models using principal components analysis (PCA). PCA models extract statistical factors (principal components) from the returns data, while fundamentally based models start with prespecified fundamental variables. Axioma created both fundamentally and statistically based risk models. Recently, Bloomberg has been preparing to release its own fundamentally based risk model.

We end by discussing the McKinley Capital Management (MCM) Horse Races for the 2010–2019 time period. These races were used to evaluate stock-selection models driven by (1) earnings forecasting and (2) composite variables of value, price momentum, and earnings forecasting. The portfolios built with those two sets of variables were optimized for minimum risk using the three risk models highlighted in this chapter. Thus, they are a joint test of the power of such variables *as long as* the portfolio risk is tightly controlled by different risk models.

97.2 Risk and Returns of Portfolios

In Chaps. 7 and 8 of *Portfolio Selection* (1959), Markowitz shows how to build portfolios that minimize risk. With such portfolios, no stock reshuffling can further reduce the overall portfolio risk. Mathematically, to minimize risk, each stock's first partial derivative (change in portfolio risk as the weight varies) must equal zero. In short, no increase or decrease in any stock weight can further reduce the risk of the portfolio. While varying those weights generates an infinity of feasible portfolios, only a subset of those is "efficient" – i.e., maximizing return for a given risk level. That risk is measured by the portfolio's standard deviation. The portfolio's expected return, $E(R_p)$, is the weighted sum of the stocks' expected returns, the weights being the portfolio weights. The portfolio's standard deviation is the weighted sum of the variances and covariances:

$$E(R_p) = \sum_{i=1}^N x_i E(R_i) = \sum_{i=1}^N x_i \mu_i \quad (1)$$

$$\sigma_p^2 = \sum_{i=1}^N \sum_{j=1}^N x_i x_j c_{ij} \quad (2)$$

where μ is the expected return vector, C is the variance-covariance matrix, and x is the vector of portfolio weights. The efficient frontier is traced out by the solutions to the problem:

$$\text{minimize}_{\{x_i \geq 0, x_i \leq \bar{u}\}} x^T Cx - \lambda \mu^T x \quad (3)$$

as λ varies to reflect the risk-return trade-off parameter and $\bar{u}$ is the fixed upper bound.

In 1970, Sharpe introduced the Capital Market Line (CML) to describe the return-risk trade-off when investors can borrow and lend at the risk-free rate and are compensated for bearing risk. Further, investors have a one-period horizon, pay no taxes or transactions costs (in their dreams), share the same views about stocks, and in all cases seek to hold mean-variance efficient portfolios. Specifically, all investors have identical probabilities for the distribution of future stock returns:

$$E(\tilde{R}_P) = R_F + \left[\frac{E(\tilde{R}_M) - R_F}{\sigma_M} \right] \sigma_P \quad (4)$$

where:

$E(R_P)$ = expected return on the portfolio

$E(R_M)$ = expected return on the market portfolio, where all securities are held relative to their market value

R_F = risk-free rate

σ_M = standard deviation of the market portfolio

σ_P = standard deviation of the portfolio

Note that as the portfolio's standard deviation rises, its expected return must rise.

97.3 An Introduction to Modern Portfolio Theory: The Capital Asset Pricing Model (CAPM)

Markowitz built a portfolio construction theory in which investors should be compensated with higher returns for bearing higher risk. The Markowitz framework measured risk as the portfolio's standard deviation – that is, its total risk. Further analysis of CAPM by Sharpe (1964), Lintner (1965), and Mossin (1966), as well as by Jack Treynor, shows that investors are not compensated for assuming total risk, but only for assuming *market* risk (*systematic* risk) as measured by the stock's beta. As a reminder, the beta is the slope of the market model in which the stock return is regressed on the market return. If risk can be diversified away in an optimized portfolio, investors will not be compensated for that risk. They will be compensated only for the portfolio's systematic risk.

CAPM holds that a stock's return is a function of its beta:

$$R_{jt} = R_F + \beta_j [E(R_{Mt}) - R_F] + e_j \quad (5)$$

where:

R_{jt} = expected security return at time t

$E(R_{Mt})$ = expected return on the market at time t

R_F = risk-free rate

β_j = security beta

e_j = randomly distributed error term

Now let's focus on the CAPM beta. It's the model's measure of systematic risk and it uses the Capital Market Line equilibrium condition:

$$\beta_j = \frac{\text{Cov}(R_j, R_M)}{\text{Var}(R_M)} \quad (6)$$

$$\begin{aligned} E(R_j) &= R_F + \left[\frac{E(R_M) - R_F}{\sigma_M^2} \right] \text{Cov}(R_j, R_M) \\ &= R_F + [E(R_M) - R_F] \frac{\text{Cov}(R_j, R_M)}{\text{Var}(R_M)} \\ E(R_j) &= R_F + [E(R_M) - R_F] \beta_j \end{aligned} \quad (7)$$

The Security Market Line, SML, shown in Eq. (7), captures the linear relationship between return and systematic risk as measured by beta. The second pass regression, regressing future returns on the estimated beta coefficients, produced the statistical evidence that led Black et al. (1972) to question CAPM's empirical validity.

97.4 The Barra Risk Model

As today's oldest commercially available risk model, the Barra model dates back to the mid-1970s, with many subsequent updates as described below. Note that Barra Inc. was acquired in 2004 by Morgan Stanley Capital International Inc.¹

Following publication of Black et al. (1972), multi-factor risk models became a hot topic among academics and practitioners, and the risk model developed by Barra was among the first to be commercially available. It was based on the academic research published in Barr Rosenberg and Walt McKibben (1973), Rosenberg (1974), Rudd and Rosenberg (1980), Rosenberg and Marathe (1979), and Rudd and Clasing (1982). Barr Rosenberg marketed the Barra risk model in academic circles and presented it at institutional investor meetings. As a result, the Barra risk model became the primary institutional risk model of the 1975–2005 period.

¹ Rudd and Rosenberg (1979) published one of the first academic/commercial portfolio optimization analyses in the Elton and Gruber monograph to honor Harry Markowitz. Miller, Xu, and Guerard (2014) used the Barra optimizer.

Accurate characterization of portfolio risk requires an accurate estimate of the covariance matrix of security returns. A relatively simple way to estimate this covariance matrix is to use the history of security returns to compute each variance, covariance, and security beta. Using beta (the covariance of security and market index returns) can produce an estimate of a corporation's cost of equity. However, this simple approximation doesn't yield a very accurate estimate. The simple, single-index beta estimation approach suffers from two major drawbacks:

- Estimating a covariance matrix for the Russell 3,000 stocks requires a great deal of data.
- The approach is subject to estimation error. For example, in Guerard and Schwartz (2007), the reader saw that the estimated correlation between two stocks such as DuPont and IBM had a higher correlation than that between DuPont and Dow. This is counterintuitive: One would normally expect a higher correlation between DuPont and Dow than between DuPont and IBM given that DuPont and Dow were both chemical firms.²

Taking this further, one can argue that companies with similar characteristics, such as those in the same line of business, should have returns that behave similarly. For example, DuPont, IBM, and Dow Chemical will all have a common component in their returns because of their sensitivity to news that affects the stock market, as measured by their respective betas.

By beginning with this intuition about the sources of co-movement in stocks' returns, Rosenberg (1974) made substantial progress in estimating the covariance matrix of stock returns. Specifically, it estimates three components: the covariance matrix of common sources of stock returns, the variances of stock-specific returns, and the sensitivity of stock returns to the common sources of variation in their returns. Together they form the Barra risk model. Because the common sources of risk are likely to be much fewer than the number of stocks, we can get by with a much smaller covariance matrix. This means we require a much smaller history of returns. Moreover, because similar stocks are going to have higher sensitivities to similar common sources of risk, similar stocks will be more highly correlated than dissimilar stocks.

The Barra risk model is a multiple-factor model (MFM). MFMs build on single-factor models by including and describing the interrelationships among factors.³

For single-factor models, the equation that describes the excess rate of return is:

$$\tilde{r}_j = X_j^f + \tilde{u}_j \quad (8)$$

²Dow and DuPont merged in 2015, whereas the correlation comments were made in 2007.

³The reader is referred to the BARRA (US-E3) United States Equity, Version 3, Risk Model Handbook. Guerard and Mark (2003 and 2020) and Miller, Xu, and Guerard (2014) used the US-E3 model in their analysis. The reader is also referred to Rosenberg and Marathe (1979), Rudd and Rosenberg (1980), Rudd and Clasing (1982), and Grinold and Kahn (1999).

where:

- $\tilde{r}_j$ = total excess return over the risk-free rate
- X_j = sensitivity of stock j to the factor
- $\tilde{f}_j$ = rate of return on the factor
- $\tilde{u}_j$ = nonfactor (specific) return on stock j

We can expand this model to include K factors. The total excess return equation for a multiple-factor model becomes:

$$\tilde{r}_j = \sum_{k=1}^K X_{jk} \tilde{f}_k + \tilde{u}_j \quad (9)$$

where:

- X_{jk} = risk exposure of stock j to factor k
- $\tilde{f}_k$ = rate of return on factor k

Note that when $K = 1$, the MFM equation reduces to the earlier single-factor version – the CAPM discussed in the previous chapter.

When a portfolio consists of only one stock, Eq. (3) describes its excess return. But most portfolios comprise many stocks, each representing a proportion, or weight, of the total portfolio. When weights $h_{p1}, h_{p2}, \dots, h_{pN}$ reflect the proportions of N stocks in portfolio P, we express the excess return in the following equation:

$$\tilde{r}_p = \sum_{k=1}^K X_{Pk} \tilde{f}_k + \sum_{j=1}^N h_{pj} \tilde{u}_j \quad (10)$$

where:

$$X_{Pk} = \sum_{j=1}^N h_{pj} X_{jk}$$

This equation includes the risk from all sources and lays the groundwork for further MFM analysis.

Investors look at the variance of their total portfolios to make a comprehensive assessment of risk. To calculate the variance of a portfolio, one needs to calculate the covariances of all the constituent components. Without the framework of a multiple-factor model, estimating the covariance of each asset with every other asset would be a computational nightmare and subject to significant estimation errors. With this in mind, let's examine the risk structure of the Barra MFM.

The Rosenberg MFM framework was developed and estimated in Rosenberg's study with McKibben (1973) and the Rosenberg extra-market component study (1974), in both of which stock-specific risk could be modeled as a function of financial descriptors or financial characteristics of the firm. The financial characteristics that were statistically associated with beta during the 1954–1970 period were:

1. Latest annual proportional change in earnings per share
2. Liquidity, as measured by the quick ratio
3. Leverage, as measured by the senior-debt-to-total-assets ratio
4. Growth measure of earnings per share
5. Book-to-price ratio
6. Historical beta
7. Logarithm of stock price
8. Standard deviation of earnings per share growth
9. Gross plant per dollar of total assets
10. Share turnover

The statistically significant determinants of the security systematic risk became the basis of the Barra E1 Model risk indices. Rudd and Clasing (1982) provides a complete discussion of the initial US-E1 Barra system.

By 1998, the domestic Barra E3 (US-E3) model had grown to include 13 sources of factor, or systematic, exposures: volatility, momentum, size, size nonlinearity, trading activity, growth, earnings yield, value, earnings variation, leverage, currency sensitivity, dividend yield, and non-estimation universe. The multiple-factor model significantly reduces the number of calculations. For example, in the US Equity Model (US-E3), 65 factors capture the risk characteristics of equities. This reduces the number of covariance and variance calculations; moreover, since there are fewer parameters to determine, they can be estimated with greater precision. The Barra US-E3 factor index definitions are shown in Appendix 1. The Barra risk management system begins with the MFM equation:

$$\tilde{r} = X\tilde{f} + \tilde{u} \quad (11)$$

where:

$\tilde{r}$ = excess return on asset I

X = exposure coefficient on the factor

$\tilde{f}$ = factor return

$\tilde{u}$ = specific return

Substituting this relationship in the basic equation, we find that:

$$\text{Risk} = \text{Var}(\tilde{r}) \quad (12)$$

$$= \text{Var}(X\tilde{f} + \tilde{u}) \quad (13)$$

Using the matrix algebra formula for variance, the risk equation becomes:

$$\text{Risk} = XFX^T + \Delta \quad (14)$$

where:

X = exposure matrix of companies to factors

F = covariance matrix of factors

X^T = transpose of X matrix

Δ = diagonal matrix of specific risk variances

This is the basic equation that defines the matrix calculations used in risk analysis in the Barra equity models.

Let's look at three examples of applying Barra risk models to portfolio construction and management. We begin with the results of the Guerard and Mark (2003) study, which used estimated earnings forecasting components of a composite model (CTEF) for the Russell 3000 universe during the 1990–2001 period. This composite model combined four earnings forecasting yields: the 1-year-ahead and 2-year-ahead forecasted earnings per share divided by the stock price, the monthly 1-year-ahead and 2-year-ahead earnings revisions, the monthly 1-year-ahead and 2-year-ahead breadth, and the number of analysts raising EPS estimates *less* the number of analysts lowering EPS estimates *divided by* the total number of analyst estimates.⁴ The CTEF model produced higher information coefficients (ICs) as well as higher and more statistically significant asset selections than its components in the Russell 3000 universe.⁵ Guerard and Mark (2003) and Guerard and Schwartz (2007) reported the effective performance of domestic and international CTEF portfolios. Table 1 shows the earnings component results for the Russell 3000 for portfolios of about 100 stocks, each tilted on individual and component CTEF factors.

The CTEF variable produces statistically significant total active returns and asset selection. The CTEF variable loading on the risk index is statistically significant at the 10% level because of its loading on the earnings yield and nonlinear size indexes, as was the case with its breadth components. There are no statistically significant sector exposures in the CTEF variable. The CTEF model offers statistically significant asset selection in a multiple-factor model framework.

⁴The reader is referred to Bruce and Epstein (1994) for a collection of published earnings forecasting research during the 1968–1992 time period, and to Brown (1998 and 2008) for a comprehensive annotated bibliography of this research.

⁵The forecast earnings per share for the 1-year-ahead and 2-year-ahead periods, FEP1 and FEP2, offer negative, but statistically insignificant, asset selection. The total active returns are positive, and not statistically significant. The asset selection is negative, because the FEP variables have positive and statistically significant loadings on the risk indices – particularly the earnings yield index. The factor loading of the FEP variables on the earnings yield risk index is not unexpected given that the earnings yield factor index in the US-E3 includes the forecast earnings-to-price variable. Thus, there is no multiple-factor model benefit to the FEP variables. The monthly revision variables, the RV variables, offer no statistically significant total active returns, or asset selection abilities. The breadth variables, BR, produce statistically significant total active returns and asset selection, despite statistically significant risk index loadings. The breadth variable loads on the earnings yield and growth risk indices. Taking a closer look at the BR1 factor risk index loading, the BR1 variable leads a portfolio manager to have a positive average active exposure to the earnings yield index, which incorporates the analyst predicted earnings-to-price and historical earnings-to-price measures. The BR1 tilt has a negative and statistically significant average exposure to size, nonlinearity, and the cube of normalized market capitalization. This result is consistent with analyst revisions being more effective in smaller-capitalized securities.

Table 1 Components of the composite earnings forecasting variable, 1990–2001

R3000 earnings analysis	Total active	T-stat	Asset Selection	T-stat	Risk Index	T-stat
FEP1	2.14	1.61	−1.18	−1.17	4.20	4.42
FEP2	1.21	0.91	−1.43	−1.35	3.33	3.35
RV1	0.76	0.69	0.34	0.42	0.92	1.46
RV2	1.40	1.37	1.09	1.31	0.81	1.42
BR1	2.59	2.83	1.85	2.43	1.08	2.15
BR2	2.43	2.36	1.51	1.75	1.09	2.04
CTEF	2.87	2.81	2.07	2.66	1.19	1.70

Bold figures denote statistically significant coefficients at the 10% level.

Table 2 Risk and return of mean-variance efficient portfolios, 1990–2001

Universe	Total active	t-value	Asset selection	t-value	Risk index	t-value
RMC	1.98	1.37	0.99	0.86	0.97	1.45
R1000	2.47	2.52	1.85	2.12	0.82	2.13
R2500	7.76	4.37	6.48	3.96	1.61	2.85
R2000	9.68	5.83	8.81	5.57	0.90	2.36

Where RMC = Frank Russell Mid-Cap Universe; R1000 = Frank Russell Largest 1000 Stock Universe; R2000 = Frank Russell Small-Cap Universe; R2500 = Frank Russell Small- and Mid-Cap Universe

Active returns rise as the average stock size declines – a result consistent with the inefficient markets literature summarized in Dimson (1988) and Ziemba (1993). The highest total active returns are found in the Russell 2000 stocks, which are the smallest stocks in the 3000 universe each year (see Table 2). The CTEF tilt variable does produce statistically significant sector exposures in the Russell 2000 stocks (again, see Table 2), just as we previously noted in the Russell 3000 universe.

The CTEF variable produces statistically significant asset selection in the Russell universes, with the exception of the mid-cap universe during the 1990–2001 period. In 2002, Guerard and Mark expanded CTEF testing to worldwide stock markets. We call this Global CTEF variable the Global Analyst Forecasting Efficiency Model – GAFEM. Table 3 reports the GAFEM information coefficients for the 1990–2001 period. It was computed in the same way as the US and non-US CTEF variables. GAFEM was highly statistically significant in all countries at the 10% level. All countries or index constituents were statistically significant at the 5% level, with the exceptions of the Russell 1000 stocks and German stocks during the 1990–2001 time period.

Miller et al. (2014) updated Guerard and Mark (2004) using US-E3 for CTEF and the nine-factor USER Model for the 1979–2009 time period. Miller et al. (2014) reported a “beautiful trade-off curve” and highly statistically significant positive management returns (active returns) and asset selection (stock selection). A slightly edited form is in Guerard et al. (2019). As one increases the portfolio lambda, thereby decreasing the risk aversion level, the number of assets in the portfolio

Table 3 Global Analysts' earnings forecast efficiency, 1990–2001

Universe	Factor	U Return	Q1 Return	Q5 Return	Q1-Q5	Q1 Xs	Batting Avg.	IC	T-Stat
Japan All	CTEF	−2.60	6.99	−9.57	16.56	9.59	77.25	0.067	3.33
UK All	CTEF	11.03	21.35	−0.23	21.58	10.32	73.05	0.073	2.88
Germany All	CTEF	6.27	13.41	−4.85	18.26	7.14	57.49	0.063	1.84
France All	CTEF	14.04	23.71	0.73	22.98	9.67	67.07	0.078	2.19
Australia All	CTEF	12.50	25.43	−1.49	26.92	12.93	72.62	0.085	2.33
US R1000	CTEF	13.95	16.62	9.75	6.87	2.67	59.65	0.032	1.79
US R2000	CTEF	12.58	21.66	−10.53	32.19	9.08	71.93	0.058	5.64

falls, the managed returns rise, and the information ratio rises versus either the Russell 3000 Growth Index or the S&P 500 Index (see Table 4). Asset selection is statistically significant and substantial, exceeding 350 basis points for the 30-year backtest. It generated statistically significant portfolio returns, passing the Markowitz-Xu (1994) Data Mining Corrections test.

Barra re-estimated its risk models, creating GEM2 in 2010, the first global equity model revision in over 20 years, and creating US-E4 and GEM4 in mid-2015 – all under the direction of Jose Menchero.⁶ In Table 5, we summarize the risk and return

⁶Jose Menchero updated the Barra Global Equity Model (GEM) in 2010, see Menchero et al. (2010). Menchero, Morozov, and Shepard estimated the GEM2 Model, which had eight style factors: volatility, momentum, size, value, growth, nonlinear size, liquidity, and leverage. The original Global Equity Model (GEM) Model that was in place when John Guerard became Director of Quantitative Research at McKinley Capital Management, in 2005, had four style factors: size (the logarithm of market capitalization), success (composed of relative strength), value (composed of earnings to price, book to price, dividend yield, and analyst predicted earnings to price), and variability in markets (historical sigma). Menchero et al. (2010) created three sets of factor portfolios. First, simple factor returns, with factors standardized to have cap-weighted mean 0 and standard deviation 1, producing factor-replicating portfolios that go long stocks with positive factor exposures and short stocks with negative factor exposures. Simple factor portfolios can have significant exposures to other factors. Second, pure factor exposures in which every stock has unit exposure to the World factor and exposures of 0 and 1 to country and industries. Pure factor-replicating portfolios go long stocks with positive factor exposures and short stocks with negative factor exposures and have zero exposures to other style factors. The third set of factor portfolios are optimized factor portfolios which have unit exposure to the particular factor and zero exposures to all other factors. The GEM2 momentum factor enhanced wealth in simple and pure factor models portfolios, which dominated the optimized momentum factor portfolio for the 1996–2010 time period. Optimized factor portfolios for size, nonlinear size, liquidity, and leverage underperformed the simple and pure factor portfolios, implying that the impact of these variables weakened owing to country, industry, and style factor interactions. See Menchero et al. (2010) in Guerard (2010) and Lee et al. (2013), Chap. 25, written by Menchero, Morozov, and Guerard.

Risk	USA	Momentum	7.08	6.48	6.39
IR	USA	Momentum	0.19	0.26	0.29
Return	International	Momentum	3.30	4.52	5.16
Risk	International	Momentum	5.05	4.18	3.87
IR	International	Momentum	0.65	1.08	1.33

Source: Menchero and Nagy (2017)

characteristics of the various pure factor portfolios. Pure style factor portfolios have unit exposure to a particular style and zero exposure to all other styles and industries. Several points are worth highlighting: For earnings yield, we see that the cap-weighted strategy outperformed the equal-weighted strategy. For momentum, however, the opposite was true. Hence, smaller stocks had more momentum returns relative to risk. We also see that the equal-weighted regressions produced the lowest-volatility portfolios. This was due to excessive concentration in the portfolios constructed using cap-weighted regression. Finally, we note that the International strategies had much higher information ratios than their USA counterparts in both earnings yields and momentum. This was due to the combined effect of higher returns and lower risk.

97.5 The APT Risk Model

John Blin and Steve Bender created APT in 1987. John Blin et al. (1997) and Guerard (2012) demonstrated the effectiveness of the APT (later SunGard APT, and now FIS APT) systems in portfolio construction and management. Below we start with an overview of the APT approach to portfolio construction.

The estimation of security weights, w , in a portfolio is the primary calculation of Markowitz's portfolio management approach. In APT, the security weight is the proportion of the portfolio's market value invested in the individual security:

$$w_s = \frac{MV_s}{MV_p} \quad (15)$$

where

w_s = portfolio weight in security

MV_s = value of security s within the portfolio

MV_p = the total market value of the portfolio

The active weight of the security is calculated by subtracting the security weight in the (index) benchmark b , from the security weight in the portfolio p

$$w_{sp} - w_{sb} \quad (16)$$

The APT Analytics Guide (2005) builds upon the foundations of the Blin and Bender APT system. See Blin et al. (1997). The following analysis draws upon APT analytics. Volatility can be broken down into systematic and specific risk:

$$\sigma_p^2 = \sigma_{\beta p}^2 + \sigma_{ep}^2 \quad (17)$$

where

σ_p = total portfolio volatility

$\sigma_{\beta p}^2$ = systematic portfolio volatility

σ_{ep} = specific portfolio volatility

Blin and Bender created a multi-factor risk model within their APT risk model based on forecast volatility:

$$\sigma_p = \sqrt{52 * \left(\sum_{c=1}^C \sum_{i=1}^S w_i \beta_{i,c} \right)^2 + 52 * \sum_{i=1}^S w_i^2 \varepsilon_i^2} \quad (18)$$

where

σ_p = forecast volatility of annual portfolio return

C = number of statistical components in the risk model

w_i = portfolio weight in security i

$\beta_{i,c}$ = loading (beta) of security i on risk component c

$\varepsilon_{i, week}$ = weekly specific volatility of security i

The multiplier 52 is the annualization factor because there are 52 weeks per year and the calculations use weekly returns.

Tracking error is a measure of volatility applied to the active return of funds (or portfolio strategies) against a benchmark, which is often an index. Portfolio tracking error is defined as the standard deviation of the portfolio return *less* the benchmark return over 1 year.

$$\sigma_{te} = \sqrt{E((r_p - r_b) - E(r_p - r_b))^2} \quad (19)$$

where

σ_{te} = annualized tracking error

r_p = actual portfolio annual return

r_b = actual benchmark annual return

The systematic tracking error of a portfolio is a forecast of the portfolio's active annual return as a function of the securities' returns associated with APT risk model components. Portfolio-specific tracking error can be written as a forecast of the annual portfolio active return associated with each security's specific behavior:

$$\sigma_{ste} = \sqrt{52 \sum_{i=1}^{N_s} (w_{i,p} - w_{i,b})^2 \varepsilon_{i,week}^2 R_p} \quad (20)$$

The APT calculated portfolio tracking error versus a benchmark is:

$$\sigma_{p-b} = \sqrt{52 (w_p - w_b)^T (b^T b + \varepsilon^T \varepsilon) (w_p - w_b)}, \quad (21)$$

where

σ_{p-b} = forecast tracking error

$b = a$ ($N_c \times N_s$) matrix of component loadings; N_c components in the model and N_s securities in the portfolio

ε = a diagonal matrix $N_c \times N_s$ of the specific loadings

$w_p - w_b$ = the (N_s -dimensional) security active-weights vector

Thus the forecast tracking error is:

$$\sigma_{p-b} = \sqrt{52 \left[\left(\sum_{c=1}^{N_c} \sum_{s=1}^{N_s} (w_{sp} - w_{sb}) b_{sc} \right)^2 + \sum_{s=1}^{N_s} (w_{sp} - w_{sb})^2 \varepsilon_s^2 \right]} \quad (22)$$

where

$w_{sp} - w_{sb}$ = portfolio active weights in security s

b_{sc} = the loading of security s on component c

ε_s = weekly specific volatility of security s

The marginal tracking error is a measure of the sensitivity of the tracking error of an active portfolio to changes in the active weight of a specific security.

$$\partial_s [\sigma_{p-b}] = \frac{\partial \sigma_{p-b}}{\partial w_{s,p-b}} \quad (23)$$

where $w_{s,p-b}$ = active portfolio weights in security s .

The APT calculated contribution-to-risk of a security is:

$$\Delta[\sigma_p] = \frac{52(b^T b + s^T s)w}{\sqrt{52(b^T b + s^T s)w}} \quad (24)$$

where $\Delta[\sigma_p] = A$ ($N_s - \text{dimensional}$) vector of contribution to volatility for securities in the portfolio with N_s securities.

The portfolio Value-at-Risk (VaR) is a measure of the distribution of expected outcomes. If one is concerned with a 95% confidence level α and a 30-day time horizon T , then the 95%, 30-day VaR of the portfolio is the minimum we would expect to lose and is characterized by

$$P[V_T < V_0 - v(\alpha, T)] = 1 - \alpha \quad (25)$$

where

$v(\alpha, T)$ = VaR at the confidence interval α for time T

V_T = portfolio value at time T

α = required confidence level

If the portfolio returns are normally distributed:

$$v_s(\alpha, T) = V_0 - E(V_T) - V_0 \phi^{-1}(\alpha) \sigma_p^T \quad (26)$$

where

$v_s(\alpha, T)$ = Gaussian VaR

σ_p^T = forecast portfolio volatility

$\phi^{-1}(\alpha)$ = inverse cumulative normal distributed function

then the total VaR is:

$$v_c(\alpha, T) = V_0 \sqrt{\frac{\alpha}{1-\alpha} \left(\sigma_{\beta p}^T + \phi^{-1}(\alpha) \sigma_{sp}^T \right)^2} \quad (27)$$

The Tracking-at-Risk (TaR) is a measure of portfolio risk estimating the magnitude that the portfolio return may deviate from the benchmark return over time. The maximum deviation of a portfolio return over the time horizon T at given confidence level α is

$$v_{p-b}(\alpha, T) = \sqrt{\left(\frac{1}{\sqrt{1-\alpha}} \sigma_{\beta, p-b}^T \right)^2 + \phi^{-1}\left(\frac{1+\alpha}{2}\right) \sigma_{s, p-b}^2} \quad (28)$$

How relevant is APT and Markowitz Mean-Variance analysis? We shall see shortly. Spoiler alert: Harry Markowitz (1952 and 1959) produces statistically significant portfolio Active Returns and Specific Returns (stock selection) when used with a statistically significant tilt variable. An excellent and fairly recent book

on portfolio risk is Connor et al. (2010). Korajczyk provides a comprehensive bibliography on APT and multi-factor risk models at the following link: <https://www.kellogg.northwestern.edu/faculty/korajczyk/htm/aptlist.htm>.

The reader is also referred to Lee et al. (2013), Chap. 13, for a very useful discussion of multi-index and APT models.

Blin et al. (1997) used an estimated 20-factor beta model of covariances based on 3.5 years of weekly stock return data. The Blin and Bender Arbitrage Pricing Theory (APT) Model followed the Ross factor modeling theory, but Blin and Bender estimated betas from at least 20 orthogonal factors. Empirical support is reported in Guerard, Chettiappan, and Xu (2010), Guerard (2012), and Guerard, Markowitz, and Xu (2015) for the application of mean-variance and mean-variance Tracking-at-Risk optimization techniques.

It is well known that as one raises a portfolio's lambda, the expected return of the portfolio rises and the number of securities in that optimal portfolio falls. See Blin et al. (1997). Lambda, a measure of risk aversion (the inverse of the risk-aversion acceptance level of the Barra system), is a decision variable to control the optimal number of securities in a portfolio. As lambda increases, the number of stocks in the portfolio falls and the Sharpe ratio rises. A more aggressive, growth-maximizing asset manager will prefer a higher lambda.

Although the Markowitz Mean-Variance (M59) portfolio construction and management analysis is six decades old, it performs well in terms of maximizing the Sharpe ratio, geometric mean, and information ratio relative to newer approaches. See Table 6 for a streamlined version of the Markowitz Mean-Variance and Mean-Variance Tracking-at-Risk (MVTaR) simulations of Guerard, Markowitz, and Xu (2015). A lambda of 200, an aggressive risk-tolerance parameter, is sufficient in the USA and global markets to maximize the geometric mean, Sharpe ratio, and information ratio for the MCM variables.⁷ A lambda of 200 MVTaR GLER simulation outperforms a portfolio based on Markowitz's 1959 *Portfolio Selection* (M59) on an information ratio (IR) basis: 0.97 versus 0.85. MVTaR does not dominate the traditional Markowitz Mean-Variance model, but it does produce lower tracking errors and higher IRs. Now, to illustrate an enhanced-index-tracking (EIT) portfolio strategy, we use a much lower lambda of 5.⁸ Guerard, Markowitz, and Xu (2015) updated Guerard and Mark (2004),

⁷Guerard and Schwartz (2007), Chap. 15, identified a lambda of 200 as the Sharpe-Ratio-maximizing lambda. Further support can be found in Guerard, Rachev, and Shao (2013), reprinted in Guerard and Ziemba (2020).

⁸A very important result of APT portfolio modeling is reported in Guerard, Krauklis, and Kumar (2012) for the application of mean-variance, enhanced index tracking and Tracking-at-Risk optimization techniques for the 1997–2009 time period. We can optimize the US stocks to create portfolios in the Russell 3000 universe for the 12-year backtest period, 1997–2009, where the absolute value of the stock weight cannot deviate by more than 2%. Guerard, Krauklis, and Kumar labeled these as (1) an EIT portfolio or (2) an EAW2 (equal active weight of 2%) portfolio. For a lambda of 200, 99 stocks are needed in the mean-variance portfolios and 108 stocks in the EAW2 portfolios. For a lambda of 10, we need 159 stocks in the mean-variance portfolios and 158 stocks in the EAW2 portfolios. An index-hugging portfolio – one designed by a manager to avoid taking active bets – would use a lambda of 10. An even less aggressive manager would need 161 stocks in an EAW1 portfolio for a lambda of 10, whereas a manager using a Sharpe-Ratio-maximizing lambda of 100 would need 131 stocks.

Table 6 Efficient frontier of the global stock selection model, GLER, with various portfolio optimization techniques and universes: (1) the global I/B/E/S stocks with at least two analysts, 1999–2011 and (2) the largest 7,500 global stocks (in USD)

APT Risk Model and Optimization System

Earnings	Mean-					
Model or	Variance		Annualized	Sharpe	Information	Tracking
Component	Methodology	Lambda	Return	Ratio	Ratio	Error

		500	15.91	0.651	0.90	11.44
		200	16.09	0.691	0.97	10.83
		100	14.18	0.591	0.77	11.23
		5	8.51	0.344	0.33	8.75

Constraints:

- 1. Turnover is 8% (buys) monthly;
- 2. Long-only holdings (a 4% maximum stock weight); and
- 3. Threshold positions of 35 basis points.

Table 6 (continued)

highlighting further evidence of the continued statistical significance of earnings forecasting analysis. In the world of applied investment research, the authors of this chapter believe that all three levels of portfolio testing must be passed to achieve statistical significance.⁹

⁹Guerard brought the Blin and Bender APT system to MCM in August 2005. The APT system produced real-time portfolios that generated statistically significant Active Returns and Specific Returns. See Guerard, Deng, Gillam, Markowitz, and Xu (2019). The real-time Specific Returns exceeded 300 basis points, very consistent with the model’s backtests. See Guerard and Markowitz (2018). Full disclosure: Guerard worked with APT as a client from 1988 until early 2008, when Blin and Bender sold the company to SunGard.

97.6 The Axioma Statistical and Fundamental Risk Models

The Axioma Robust Risk Model is a multi-factor model, in the tradition of the Barra model and Eq. (20) above.¹⁰ Axioma offers both the US and World Fundamental and Statistical Risk Models. The Axioma Risk Models use several statistical techniques to efficiently estimate factors. The ordinary least squares residuals (OLS) are not homoscedastic; that is, when one minimizes the sum of the squared residuals to estimate factors using OLS, one finds that large assets exhibit lower volatility than smaller assets. A constant variance of returns is not found. Axioma uses a weighted least squares (WLS) regression, which scales the asset residual by the square root of the asset market capitalization (to serve as a proxy for the inverse of the residual variance). Robust regression, using the Huber M-Estimator, addresses the issue and problem of outliers. Asymptotic principal components analysis (PCA) is used to estimate the statistical risk factors. A subset of assets is used to estimate the factor returns, and the exposures and factor returns are applied to the other assets.

The Axioma World-Wide Equity Risk Factor Model (AX-WW2.1) seeks to forecast medium-term horizon risk, or risk 3–6 months ahead. The Equity Risk Factor, or Fundamental, Model uses nine style factors: exchange rate sensitivity, growth (historical earnings and sales growth), leverage (debt-to-assets), liquidity (1-month trading volume divided by market capitalization), medium-term momentum (cumulative returns of the past year, excluding the previous month), short-term momentum (last month return), size (natural logarithm of issuer market capitalization), value (book-to-price and earnings-to-price ratios), and volatility (3-month average of absolute returns divided by cross-sectional standard deviation). The Axioma Statistical Risk Model estimates 15 factors using principal components.

97.7 The MCM Horse Races: Who Has the Better Risk Models for Growth Variables?

In 2011, McKinley Capital Management, LLC (MCM) initiated a “Horse Race” testing procedure to find out whether all risk models and optimizers were created equal. Bottom line: They are not. The results appeared in the Spring 2012 *Journal of Investing*, a special edition devoted to Quantitative Risk Management. It featured articles by Markowitz; Tsuchida, Zhou, and Rachev (the Cognity system of FinAnalytics); Wormald and van Der Merwe (APT); Saxena and Stubbs (Axioma); and Guerard, Xu, and Gültekin (APT, Barra, and Cognity). In 2011, APT and

R3000G	–0.074			19.73	1.73		

Where SHR = Sharpe ratio, IR = Information ratio, TE = Tracking error, SD = Portfolio standard deviation, AR = Average annual return, Asset selection = Barra-attributed stock selection

Axioma were the winners among five risk models and optimization systems using the MCM US “Public Models” CTEF and USER. As Table 7 shows, both APT and Axioma optimization systems produced highly statistically significant asset selection, exceeding 600 basis points annually (the Barra attribution system was used as a judge).

What factor contributions of the Axioma portfolio were rewarded by the market for 1998–2009? The answer is small size (the exposure of –1.17 produced 329 basis points of return with a corresponding t-statistic of 3.16) and earnings yield (the exposure of 0.09 produced 41 basis points of return with a corresponding t-statistic of 1.85, statistically significant at the 10% level). Growth, leverage, and yield produced negative statistically significant factor returns in the Barra USER attributions for 1998–2009. APT and Axioma both had statistically based risk models; Axioma and Barra had fundamentally based risk models.

In 2012, MCM ran a second Horse Race competition using a two-I/B/E/S analyst, 7500-largest market-capitalized global universe. The Axioma Statistical Risk Model produced higher geometric means, Sharpe ratios, and information ratios using GLER data than its Fundamental (WW21AxiomaMH) Model generated.

Guerard, Markowitz, and Xu (2014 and 2015) reported efficient frontiers using both of the Axioma Risk Models. As noted above, the Axioma Statistical Risk Model, which the authors denoted as “STAT,” produced geometric means, Sharpe ratios, and information ratios that were higher than those generated by the Axioma Fundamental Risk Model, denoted as “FUND.” The geometric means and Sharpe ratios increase with the targeted tracking errors; however, the information ratios are higher in the lower tracking error range of 3–6%, with at least 200 stocks, on average, in the optimal portfolios. See Table 8. The Guerard et al. (2013, 2015) studies assumed 150 basis points, each way, of transaction costs. The use of ITG cost curves produced about 115–125 basis points of transaction costs, well under the assumed costs. The Guerard et al. studies also used the SunGard APT statistical model, which produced statistically significant asset selection in the US and global portfolios. In the MCM Horse Races, 2010–2017, the most consistent finding is the superior performance of statistical models.¹¹

¹¹ In 2017, MCM ran its third Horse Race using Axioma with integrated ITG transactions costs, in the MSCI Non-US (XUS), Global (GL), and Emerging Markets (EM) universes. The XUS, GL, and EM reported results show much higher Active and Specific Returns in non-US markets than in the US market. International markets are more inefficient than the US markets, as was reported in Guerard and Mark (2020).

Table 8 Axioma analysis of the FactSet global 7500-stock data Universe, AWCG Universe, January 1999 – December 2011. Transactions costs: 150 basis points each way, respectively

Return model	Risk model	Tracking error	Sharpe ratio	Information ratio	Ann. active return	Ann. active risk	N
GLER	STAT	4	0.554	1.475	9.99	6.78	144

		8	0.647	1.281	12.75	9.95	71

97.8 Summary and Conclusions

Multi-factor risk models may be used to analyze a stock selection or evaluate a variable. Blin et al. (1997), Guerard et al. (2014, 2015), Guerard and Mark (2004, 2020), and Blin et al. (1997) reported that properly constructed risk models created portfolios in which tilt variables that have statistically significant ICs produced statistically significant Active Returns. One must remove the market effect and extra-market covariances to properly estimate how much a variable contributes to the creation of efficient portfolios.

It is useful to see how quantitative analysis was developed in investment research and analysis. Harry Markowitz, Bill Sharpe, Jan Mossin, and Jack Treynor pioneered capital market equilibrium and the creation and estimation of the Capital Asset Pricing Model. In the 1970s, multi-factor risk models were developed and estimated by Barr Rosenberg, Andrew Rudd, and their colleagues at Barra; John Blin and Steve Bender at APT; and Sebastian Ceria at Axioma. Recent research and ongoing implementation by APT and Axioma have further refined portfolio optimization. MCM developed its Horse Race risk model philosophy to assess the most effective risk models for maximizing the geometric means, Sharpe ratios, and information ratios. APT and Axioma have reigned supreme in those tests. The integration of Axioma and AAF and ITG transactions costs on the FactSet Investment have led MCM to implement an Axioma portfolio.

Acknowledgments The authors would like to thank research conversations with Doug Martin, Bijan Beheshti, and Sebastian Ceria. Any errors remaining are the sole responsibility of the authors.

Appendix 1: US-E3 Descriptor Definitions

This appendix gives detailed definitions of the descriptors that underlie the risk indices in US-E3. The method of combining these descriptors into risk indices is proprietary to Barra.

1. Volatility

(i) *BTSg: Beta times sigma*

This is computed as $\sqrt{\beta\sigma_e}$, where β is the historical beta and σ_e is the historical residual standard deviation. If β is negative, then the descriptor is set equal to zero.

(ii) *DASTD: Daily standard deviation*

This is computed as:

$$\sqrt{N_{\text{days}} \left[\sum_{t=1}^T w_t r_t^2 \right]}$$

where r_t is the return over day t , w_t is the weight for day t , T is the number of days of historical returns data used to compute this descriptor (we set this to 65 days), and N_{days} is the number of trading days in a month (we set this to 23).

(iii) *HILO: Ratio of high price to low price over the last month*

This is calculated as:

$$\log \left(\frac{P_H}{P_L} \right)$$

where P_H and P_L are the maximum price and minimum price attained over the last 1 month.

(iv) *LPRI: Log of stock price*

This is the log of the stock price at the end of last month.

(v) *CMRA: Cumulative range*

Let Z_t be defined as follows:

$$Z_t = \sum_{s=1}^t \log(1 + r_{i,s}) - \sum_{s=1}^t \log(1 + r_{f,s})$$

where $r_{i,s}$ is the return on stock i in month s , and $r_{f,s}$ is the risk-free rate for month s . In other words, Z_t is the cumulative return of the stock over the risk-free rate at the end of month t . Define $Z_{\max}$ and $Z_{\min}$ as the maximum and minimum values of Z_t over the last 12 months. CMRA is computed as:

$$\log \left(\frac{1 + Z_{\max}}{a + Z_{\min}} \right)$$

(vi) *VOLBT: Sensitivity of changes in trading volume to changes in aggregate trading volume*

This may be estimated by the following regression:

$$\frac{\Delta V_{i,t}}{N_{i,t}} = a + b \frac{\Delta V_{M,t}}{N_{m,t}} + \xi_{i,t}$$

where $\Delta V_{i,t}$ is the change in share volume of stock I from week t-1 to week t, $N_{i,t}$ is the average number of shares outstanding for stock I at the beginning of week t-1 and week t, $\Delta V_{M,t}$ is the change in volume on the aggregate market from week t-1 to week t, and $N_{M,t}$ is the average number of shares outstanding for the aggregate market at the beginning of week t-1 and week t.

(vii) *SERDP: Serial dependence*

This measure is designed to capture serial dependence in residuals from the market model regressions. It is computed as follows:

$$\text{SERDP} = \frac{\frac{1}{T-2} \sum_{t=3}^T (e_t + e_{t-1} + e_{t-2})^2}{\frac{1}{T-2} \sum_{t=3}^T (e_t^2 + e_{t-1}^2 + e_{t-2}^2)}$$

where e_t is the residual from the market model regression in month t , and T is the number of months over which this regression is run (typically, $T = 60$ months).

(viii) *OPSTD: Option-implied standard deviation*

This descriptor is computed as the implied standard deviation from the Black-Scholes option pricing formula using the price on the closest to at-the-money call option that trades on the underlying stock.

2. Momentum

(i) *RSTR: Relative strength*

This is computed as the cumulative excess return (using continuously compounded monthly returns) over the last 12 months – i.e.,

$$\text{RSTR} \rightleftharpoons = \sum_{t=1}^T \log(1 + r_{i,t}) - \sum_{t=1}^T \log(1 + r_{f,t})$$

where $r_{i,t}$ is the arithmetic return of the stock in month I , and $r_{f,t}$ is the arithmetic risk-free rate for month i . This measure is usually computed over the last 1 year – i.e., T is set equal to 12 months.

(ii) *HALPHA: Historical alpha*

This descriptor is equal to the alpha term (i.e., the intercept term) from a 60-month regression of the stock's excess returns on the S&P 500 excess returns.

3. Size

(i) *LNCAP: Log of market capitalization*

This descriptor is computed as the log of the market capitalization of equity (price times number of shares outstanding) for the company.

4. Size nonlinearity

(i) *LCAPCB: Cube of the log of market capitalization*

This risk index is computed as the cube of the normalized log of market capitalization.

5. Trading activity

i) *STOA: Share turnover over the last year*

STOA is the annualized share turnover rate using data from the last 12 months – i.e., it is equal to $V_{\text{ann}} / \bar{N}_{\text{out}}$, where V_{ann} is the total trading volume (in number of shares) over the last 12 months and $\bar{N}_{\text{out}}$ is the average number of shares outstanding over the previous 12 months (i.e., it is equal to the average value of the number of shares outstanding at the beginning of each month over the previous 12 months).

ii) *STOQ: Share turnover over the last quarter*

This is computed as the annualized share turnover rate using data from the most recent quarter. Let V_q be the total trading volume (in number of shares) over the most recent quarter and let $\bar{N}_{\text{out}}$ be the average number of shares outstanding over the period (i.e., $\bar{N}_{\text{out}}$ is equal to the average value of the number of shares outstanding at the beginning of each month over the previous 3 months). Then, STOQ is computed as $4V_q / \bar{N}_{\text{out}}$.

iii) *STOM: Share turnover over the last month*

This is computed as the share turnover rate using data from the most recent month – i.e., it is equal to the number of shares traded last month divided by the number of shares outstanding at the beginning of the month.

iv) *STO5: Share turnover over the last 5 years*

This is equal to the annualized share turnover rate using data from the last 60 months. In symbols, STO5 is given by:

$$\text{STO5} = \frac{12 \left[\frac{1}{T} \sum_{s=1}^T V_s \right]}{\sigma_\varepsilon}$$

where V_s is equal to the total trading volume in months, and $\bar{N}_{\text{out}}$ is the average number of shares outstanding over the last 60 months.

v) *FSPLIT: Indicator for forward split*

This descriptor is a 0–1 indicator variable to capture the occurrence of forward splits in the company's stock over the last 2 years.

vi) *VLVR: Volume to variance*

This measure is calculated as follows:

$$\text{VLVR} = \log \frac{\frac{12}{T} \left[\sum_{s=1}^T V_s P_s \right]}{\sigma_\varepsilon}$$

where V_s equals the number of shares traded in month s , P_s is the closing price of the stock at the end of month s , and σ_ε is the estimated residual standard deviation. The sum in the numerator is computed over the last 12 months.

6. Growth

(i) *PAYO: Payout ratio over 5 years*

This measure is computed as follows:

$$\text{PAYO} = \frac{\frac{1}{T} \sum_{t=1}^T D_t}{\frac{1}{T} \sum_{t=1}^T E_t}$$

where D_t is the aggregate dividend paid out in year t and E_t is the total earnings available for common shareholders in year t . This descriptor is computed using the last 5 years of data on dividends and earnings.

(ii) *VCAP: Variability in capital structure*

This descriptor is measured as follows:

$$\text{VCAP} = \frac{\frac{1}{T-1} \sum_{t=2}^T (|N_{t-1} - N_t| P_{t-1} + |LD_{t-1} - LD_t| + |PE_t - PE_{t-1}|)}{CE_T + LD_T + PE_T}$$

where N_{t-1} is the number of shares outstanding at the end of time $t-1$; P_{t-1} is the price per share at the end of time $t-1$; LD_{t-1} is the book value of long-term debt at the end of time period $t-1$; PE_{t-1} is the book value of preferred equity at the end of time period $t-1$; and $CE_T + LD_T + PE_T$ are the book values of common equity, long-term debt, and preferred equity as of the most recent fiscal year.

(iii) *AGRO: Growth rate in total assets*

To compute this descriptor, the following regression is run:

$$TA_{it} = a + bt + \xi_{it}$$

where TA_{it} is the total assets of the company as of the end of year t , and the regression is run for the period $= 1, \dots, 5$. AGRO is computed as follows:

$$AGRO = \frac{b}{\frac{1}{T} \sum_{t=1}^T TA_{it}}$$

where the denominator average is computed over all the data used in the regression.

(iv) *EGRO: Earnings growth rate over last 5 years*

First, the following regression is run:

$$EPS_t = a + bt + \xi_t$$

where EPS_t is the earnings per share for year t . This regression is run for the period $t = 1, \dots, 5$. EGRO is computed as follows:

$$EGRO = \frac{b}{\frac{1}{T} \sum_{t=1}^T EPS_t}$$

(v) *EGIBS: Analyst-predicted earnings growth*

This is computed as follows:

$$EGIBS = \frac{(EARN - EPS)}{(EARN \leftrightarrow + \leftrightarrow EPS)/2}$$

where EARN is a weighted average of the median earnings predictions by analysts for the current year and next year, and EPS is the sum of the four most recent quarterly earnings per share.

(vi) *DELE: Recent earnings change*

This is a measure of recent earnings growth and is measured as follows:

$$\text{DELE} = \frac{(\text{EPS}_t - \text{EPS}_{t-1})}{(\text{EPS}_t + \text{EPS}_{t-1})/2}$$

where EPS_t is the earnings per share for the most recent year, and EPS_{t-1} is the earnings per share for the previous year. We set this to missing if the denominator is nonpositive.

7. Earnings Yield

(i) *EPIBS: Analyst-predicted earnings-to-price*

This is computed as the weighted average of analysts' median predicted earnings for the current fiscal year and next fiscal year divided by the most recent price.

(ii) *ETOP: Trailing annual earnings-to-price*

This is computed as the sum of the four most recent quarterly earnings per share divided by the most recent price.

(iii) *ETP5: Historical earnings-to-price*

This is computed as follows:

$$\text{ETP5} = \frac{\frac{1}{T} \sum_{t=1}^T \text{EPS}_t}{\frac{1}{T} \sum_{t=1}^T P_t}$$

where EPS_t is equal to the earnings per share over year t , and P_t is equal to the closing price per share at the end of year t .

8. Value

(i) *BTOP: Book-to-price ratio*

This is the book value of common equity as of the most recent fiscal year-end divided by the most recent value of the market capitalization of the equity.

9. Earnings Variability

(i) *VERN: Variability in earnings*

This measure is computed as follows:

$$\text{VERN} = \frac{\left(\frac{1}{T-1} \sum_{t=1}^T (E_t - \bar{E})^2 \right)^{1/2}}{\frac{1}{T} \sum_{t=1}^T E_t}$$

where E_t is the earnings at time t ($t = 1, \dots, 5$), and $\bar{E}$ is the average earnings over the last 5 years. VERN is the coefficient of variation of earnings.

(ii) *VFLO: Variability in cash flows*

This measure is computed as the coefficient of variation of cash flow using data over the last 5 years – i.e., it is computed in an identical manner to VERN, with cash flow being used in place of earnings. Cash flow is computed as earnings plus depreciation plus deferred taxes.

(iii) *EXTE: Extraordinary items in earnings*

This is computed as follows:

$$EXTE = \frac{\frac{1}{T} \sum_{t=1}^T |EX_t + NRI_t|}{\frac{1}{T} \sum_{t=1}^T E_t}$$

where EX_t is the value of extraordinary items and discontinued operations, NRI_t is the value of nonoperating income, and E_t is the earnings available to common before extraordinary items. The descriptor uses data over the last 5 years.

(iv) *SPIBS: Standard deviation of analysts' prediction to price*

This is computed as the weighted average of the standard deviation of IBES analysts' forecasts of the firm's earnings per share for the current fiscal year and next fiscal year divided by the most recent price.

10. Leverage

(i) *MLEV: Market leverage*

This measure is computed as follows:

$$MLEV = \frac{ME_t + PE_t + LD_t}{ME_t}$$

where ME_t is the market value of common equity, PE_t is the book value of preferred equity, and LD_t is the book value of long-term debt. The value of preferred equity and long-term debt are as of the end of the most recent fiscal year. The market value of equity is computed using the most recent month's closing price of the stock.

(ii) *BLEV: Book leverage*

This measure is computed as follows:

$$BLEV = \frac{CEQ_t + PE_t + LD_t}{CEQ_t}$$

where CEQ_t is the book value of common equity, PE_t is the book value of preferred equity, and LD_t is the book value of the long-term debt. All values are as of the end of the most recent fiscal year.

(iii) *DTOA: Debt-to-assets ratio*

This ratio is computed as follows:

$$DTOA = \frac{LD_t + DCL_t}{TA_t}$$

where LD_t is the book value of long-term debt, DCL_t is the value of debt in current liabilities, and TA_t is the book value of total assets. All values are as of the end of the most recent fiscal year.

(iv) *SNRRT: Senior debt rating*

This descriptor is constructed as a multi-level indicator variable of the debt rating of a company.

11. Currency Sensitivity

(i) *CURSENS: Exposure to foreign currencies*

To construct this descriptor, the following regression is run:

$$r_{it} = \alpha_1 + \beta_1 r_{mt} + \varepsilon_{it}$$

where r_{it} is the excess return on the stock and r_{mt} is the excess return on the S&P 500 Index. Let ε_{it} denote the residual returns from this regression. These residual returns are in turn regressed against the contemporaneous and lagged returns on a basket of foreign currencies, as follows:

$$\varepsilon_{it} = c_1 + \gamma_{11}(FX)_t + \gamma_{12}(FX)_{t-1} + \gamma_{13}(FX)_{t-2} + \mu_{it}$$

where ε_{it} is the residual return on stock I , $(FX)_t$ is the return on an index of foreign currencies over month t , $(FX)_{t-1}$ is the return on the same index of foreign currencies over month $t-1$, and $(FX)_{t-2}$ is the return on the same index over month $t-2$. The risk index is computed as the sum of the slope coefficients γ_{11} , γ_{12} , and γ_{13} – i.e., $CURSENS = \gamma_{11} + \gamma_{12} + \gamma_{13}$.

12. Dividend Yield

(i) *P_DYLD: Predicted dividend yield*

This descriptor uses the last four quarterly dividends paid out by the company along with the returns on the company's stock and future dividend announcements made by the company to come up with a Barra-predicted dividend yield.

13. Non-estimation Universe Indicator

(i) *NONESTU: Indicator for firms outside US-E3 estimation universe*

This is a 0–1 indicator variable: It is equal to 0 if the company is in the BARRA estimation universe and equal to 1 if the company is outside the BARRA estimation universe.

Short Selling Activity and Effects on Financial Markets and Corporate Decisions

98

Xu Guo and Chunchi Wu

Abstract

We review the current state of research on short sales, including the information content in short interest, information advantages of short sellers, and firms' reactions to the short-selling threat. We also discuss the data and metrics commonly used in short selling studies and summarize important empirical findings. Finally, we suggest several future directions to improve our understanding of the role of short sellers in capital market development and in influencing corporate decisions.

98.1 Introduction

Short selling activities are prevalent in the US financial markets, and there has been a substantial increase in shares held short by investors in the past several decades. A vast literature has been devoted to understanding the effects of short selling activity. Despite the enormous amounts of studies, the role of short sellers in financial

markets remains controversial. On the one hand, they are blamed for manipulating and depressing share values, and increasing market volatility and instability (Allen and Gale 1992; Brunnermeier and Oehmke 2014; Goldstein and Guembel 2008; Ljungqvist and Qian 2016). On the other, they are credited with improving financial markets' information efficiency and strengthening the price discovery process in financial markets and corporate governance (Boehmer et al. 2008; Diether et al. 2009a; Boehmer and Wu 2013; Curtis and Fargher 2014). Because of its important role, issues related to short sales have continued to attract considerable attention from academics and policy makers.

In a short sale, investors or short sellers go against the common trading rule by selling a security with the expectation of buying it back after a price drop, realizing a profit from the loss in the share price. Typically, short sellers do not own the shares before the transaction, but borrow (equity loan) them from another investor or institution. The risk to the short seller is that the security's price could increase and he or she may have to buy it back at a higher price. In addition, short sellers are exposed to the recall risk, which refers to the situation when the borrowed stock is recalled by the lender unexpectedly and a short seller is forced to close his position.

Miller (1977) suggests that dispersion of investor opinions in the presence of short sale constraints leads to stock overvaluation, as short sale constraints impede the adjustment of stock prices to negative private information. Short sale constraints include various costs and risks of shorting, as well as legal and institutional restrictions. Generally, it is easy and cheap to borrow most large cap stocks, but it can be difficult to borrow small firm stocks that have smaller amounts of share supply, have low institutional ownership, or are in high demand from borrowers. Aside from the problems in the stock lending market, there are a variety of other short sale constraints. US equity markets are not set up to make shorting easy. Regulators, the Federal Reserve, various stock exchanges, and individual brokerage firms can mechanically impede short selling. For example, the uptick rule on the NYSE, established by the Securities and Exchange Commission (SEC), requires short sales to be conducted at a higher price than the previous trade or at an uptick. For NASDAQ stocks, the bid-price rule requires that a short sale must be executed above the previous inside bid.¹ In addition to regulations, short sellers face hostility from society at large, especially during the financial crisis.

There is an extensive literature exploring the relationship between short interest (as a proxy for short selling activity) and future stock abnormal returns. Earlier studies provide mixed evidence, but the recent literature tends to reach a consensus that short sellers are indeed informed traders. There is also substantial evidence that short selling activity influences corporate and accounting decisions. Short sellers play a disciplining role by exposing corporate fraud and force managers to take corrective actions.

¹Shorting restrictions can date back to the 1930s. For example, the 1931 downtick shorting prohibition, the 1932 rule that requiring written authorization to lend shares, and the strict uptick rule in 1938. See Jones (2012) for more details.

A large literature focuses on the information advantages of short sellers, which confirms their superior ability to collect and process public information and acquire private information. The sources for public information are financial statements (Dechow et al. 2001; Hirshleifer et al. 2011; Park 2017) or media coverage (Hobbs et al. 2012). There is considerable evidence that short sellers can successfully predict a series of bad corporate events such as analysts' downgrades, earnings restatements, financial fraud, insider sales, etc., suggesting that private information plays an important role in the actions of short sellers.

Many studies explore firms' behaviors in the presence of a short selling threat. To mitigate the adverse effect of price pressure caused by elevated short interest, managers attempt to improve their financial reporting quality (Fang et al. 2016), increase cash dividends (Chen et al. 2019), reduce investment and equity issues (Grullon et al. 2015) while simultaneously improving investment efficiency (Deng et al. 2020).

In this chapter, we provide a comprehensive review on the functions of short sales and the short-selling process, short sales activities and regulations, theoretical explanations for short sales, and important empirical evidence. In addition, we review the current state of short sale research and discuss possible future directions.

The remainder of this chapter is organized as follows. In Sect. 98.2, we discuss the functions and processes of short sales. In addition, we describe the rationales for short selling as well as various short sale constraints. In Sect. 98.3, we present theories of short selling, and in Sect. 98.4, we review various functions of short sales short selling. In Sect. 98.5, we report important empirical evidence in more detail and discusses the data/metrics used in short-selling studies. Finally, we offer suggestions for future research in Sect. 98.6 and conclude in Sect. 98.7.²

98.2 The Short-Selling Process, Institutional Structure, and Activities

98.2.1 Why Going Short?

A number of studies have attempted to explain why going short in the first place. The literature has suggested that underlying fundamentals, arbitrage, hedging, speculation, and tax-related considerations are important factors behind the motivation of short sellers. Dechow et al. (2001) find that firms with low ratios of fundamentals (e.g., earnings and book values) to market values have high short interest. Geczy et al. (2002) show that short selling can be driven by stylized patterns and behavior in stock prices, such as the size, book-to-market, and momentum effects. On the other

²To our best knowledge, Reed (2013) and Jiang et al. (2020a) also give a review of the short-sale literature.

hand, Lamont and Stein (2004) show that short interest does not seem to be related to market-wide valuation trends.

Brent et al. (1990) suggest that short selling can be triggered by factors such as deferring capital gains taxes, hedging needs, exploiting the overpriced stocks, or speculation. The tax motivation refers to the situation that when going short in the same stock that is held long, an investor can lock in a profit, but delay the recognition of a capital gain, which is particularly important if the investor will be taxed at a lower rate in the subsequent tax period. Consequently, based on the tax motivation, one should observe an increase in short interest primarily at the end of the tax year (Dyl 1978).

Arbitrage and hedging are also important in explaining short interest as going short is an integral part of arbitrage strategies. For example, investors can engage in shorting the acquiring firm's stock in a merger situation while simultaneously going long in the target firm's stock (Baker and Savaşoglu 2002). Short sellers can also sell securities short to arbitrage a price differential between the stock and the corresponding convertible bond.

Investors can also speculate through shorting and expect to profit from a decline in the security's price. Short sellers have beliefs that deviate from consensus beliefs impounded in the existing prices, which is consistent with the view that short interest is a measure of heterogeneous investor opinion. The existing literature supports the argument that short sellers help to facilitate the price discovery process, which is attributed to their extraordinary skills in exploiting both public and private information.

98.2.2 The Security Lending Process

To do short selling, a potential short seller must find a party who is willing to lend the shares. In the USA, most exchange procedures require that the short seller delivers shares to the buyer on the third day after the transaction ($t + 3$). The proceeds from the short sale are deposited with the lender of the stock. For stocks, the lender typically requires 102% of the loan's value in collateral. The value of the security loan is marked to market daily. An increase in the stock price will result in the lender requiring additional collateral for the loan. Conversely, a decrease in the stock price will result in the lender returning some of the collateral to the borrower. All collateral must return to the borrower upon the return of shares to the lender. The process of delivery and payment is referred to as settlement or clearing. While a stock is on loan, the lender invests and receives interest on the collateral. Part of this earned interest goes to the borrower in the form of a negotiated rebate rate.

98.2.3 Short-Selling Activities in the Market

The equity lending market is an over-the-counter market. Detailed data on the aggregate short-selling activities are scarce. Aggregating a monthly firm-level

short interest data into a short interest index, Rapach et al. (2016) show there is a strong upward trend in the short selling activity in the USA. They argue that the expanded equity lending market as well as the significant increase in the amount of capital devoted to short arbitrage could be the explanation for their finding. Indeed, short selling is a common phenomenon in stock markets and there are many short sale orders executed in margin accounts on any given day. Using a randomly selected sample of common stocks from the CRSP, Asquith et al. (2010) report that short sales account for 29.7% of all stock trades and 27.9% of the total trading volume. Diether et al. (2009b) report similar findings with short sales representing 24% of NYSE and 31% of NASDAQ volume. Short sellers also trade in newly issued stocks. Edwards and Hanley (2010) report that short selling occurs on the offer day in 99.5% of the IPOs they studied.

98.2.4 Short Sale Constraints

Short selling can be expensive (high borrow cost), difficult (hard to find lender), and risky (potential loss). Impediments to short selling include the expense and difficulty of borrowing stocks, legal and institutional restrictions, regulation rules and trading mechanisms, and the risk that the short position may be involuntarily closed due to a recall by the lender. Yet, there are other forms of short sale constraints. Firms targeted by short sellers can take a variety of actions to impede the short selling of their stocks. For example, firms can accuse short sellers of illegal activities and hire private investigators to probe them or even request authorities to investigate their activities. Lamont (2012) studies legal battles between short sellers and firms. Using a sample of 266 firms who threaten, take action against, or accuse short sellers of illegal activities or false statements, the author shows that the sample firms earn negative abnormal returns in the subsequent year as these actions create short sale constraints that lead to overpriced stocks.

Past studies report mixed findings in relation to the benefits of short selling constraints, especially those regulatory restrictions of short selling. Brunnermeier and Oehmke (2014) show temporary and targeted short sale restrictions can save vulnerable stocks. On the other hand, a number of studies suggest that short selling constraints distort the market efficiency by slowing down the impounding of negative private information (Choy and Zhang 2019; Ho 1996; Hasan et al. 2015; Shyu et al. 2018; Cheng et al. 2012), reduce hedging effectiveness (Brunnermeier and Oehmke 2014), and contribute to IPO underpricing (Boulton et al. 2020).

Generally, for stocks with tight short sale constraints, the overpricing can be very large. Consistent with this view, Asquith et al. (2005) investigate a group of constrained stocks with a strong demand to sell short and a limited supply of shares to borrow, that is, the short sale constraints are binding for these stocks. They find the constrained stocks underperform by more than 2% per month. However, they point out short interest and institutional ownership could not be short sale constraints for the majority of stocks.

Short sale constraints are used to explain the idiosyncratic volatility puzzle: stocks with high idiosyncratic volatility (IVOL) are associated with low future returns. Stambaugh et al. (2015) argue the IVOL-return relation is negative among overpriced stocks but positive among underpriced stocks, but due to the arbitrage asymmetry caused by short sale constraints, the negative relation among overpriced stocks dominates, resulting in an overall negative relation. In a separate vein, Jiang et al. (2014) find investor overconfidence with binding short sale constraints can explain the negative IVOL-return relation, and they use three natural experiments to support their argument.

98.2.5 Short-Selling Costs and Rebate Rates

It is well documented in the literature that short positions can be expensive or impossible and can be involuntarily terminated. An investor must generally borrow shares they shorted, and then deliver them to the buyer. Thus, the cost, availability, and dependability issues related to shorting generally result from the pricing (loan fees), availability (loan supply), and termination of equity loans.

An equity loan is a temporary swap of ownership. The equity lender transfers legal ownership of a block of shares to the borrower, who simultaneously transfers collateral (usually cash). Upon the loan origination, the parties negotiate a rebate rate, which is the amount of interest on the collateral that the lender will rebate to the borrower. Thus, a high rebate rate indicates a low borrowing cost, *ceteris paribus*. Jones and Lamont (2002) argue that the rebate rate is probably the best proxy for measuring the magnitude of short sale constraints. However, because the stock lending market is extremely opaque, rebate rates are never transparent.

Using the proprietary data from a large financial institution, D'avolio (2002) finds overall, it is easy to borrow stocks with an average loan fee of about 25 basis points per annum. They also find less than 10% of stocks are expensive to borrow (loan fees above 1% per annum) and the value-weighted mean loan fees are only 17 basis points for the remaining 90% of stocks. These results suggest that stocks are generally inexpensive to borrow. Geczy et al. (2002) study another proprietary equity loan data and report similar findings for the low cost of short selling.

Chague et al. (2017) study the Brazilian equity lending market and provide evidence that the lending market is relationship-based: well-connected borrowers face low search costs and pay lower loan fees, which confirm the prediction made in Duffie et al. (2002). Engelberg et al. (2018) use the variance of loan fees as a proxy for short selling risk and find that stocks with higher short selling risk are associated with lower future returns, poorer price efficiency (measured by price delay as in Hou and Moskowitz (2005)), and less short selling. Evans et al. (2009) and Lin and Lu (2016) show empirically, and Atmaz and Basak (2019) demonstrate theoretically a higher shorting cost leads to higher bid-ask spreads for typical options, and higher apparent put-call parity violations.

98.3 Theory of Short Sales

Miller (1977) first shows that the presence of short sale constraints impedes the adjustment of stock prices to negative information, which results in higher stock prices when investor beliefs are heterogeneous. Along a similar line, Hong and Stein (2003) argue short sale constraints sideline bearish investors to trade and lead to elevated stock prices if investors are of different opinions. When the market is falling, the private information of bearish investors accumulates and heightens the likelihood of a market crash. Hong et al. (2006) link short sale constraints, heterogeneous beliefs, limited asset float (tradable shares) to speculative bubbles.

In a separate vein, Jarrow (1980) shows that short sale constraints can cause stock prices to rise or fall if investors have heterogeneous expectations (beliefs) but disagree about the covariance matrix of future prices. Short sale constraints will inflate risky asset prices only under the condition of homogeneous beliefs for the covariance matrix of future prices. Diamond and Verrecchia (1987) find short sale constraints eliminate informative trades but do not bias stock prices upward if investors are rational and fully aware of the effects of short sale constraints.

Duffie et al. (2002) model the structure of the equity lending market in which search cost is a key variable. The existence of search cost lowers the frequency at which borrowers can find lenders, resulting in lenders acting as monopolists and charge higher loan fees. Moreover, if lendable securities are difficult to locate, then the price of the security is initially elevated, and the price could be even higher than the most optimistic buyer's valuation due to the prospect of lending fees. As time passes, short interest increases and unfilled shorts are reduced, so that each share is expected to be lent at a smaller number of future times, which depresses the lending fee and causes the future price to decline. The Duffie et al. (2002) model offers an explanation for the dynamic price behavior of stocks sold short in a market where opacity increases the frictions of short sellers.

Atmaz and Basak (2019) provide a dynamic analysis of option prices in the presence of costly short selling and option market makers. They find that call and put bid-ask spreads increase with the shorting fee for typical options because an increase in the shorting fee not only raises short-selling costs but also partially increases the benefit of holding a share long, leading to higher bid-ask spreads for typical options. They further show that put bid and ask prices as well as the put option implied volatilities, increase with the shorting fee as a higher shorting fee increases both the market makers' cost of and the proceeds from the hedge portfolios as a put seller and buyer, respectively. As implied stock prices decrease in the shorting fee, there is a larger deviation from the underlying stock prices, leading to higher apparent put-call parity violations, since the implied stock is equivalent to the stock but without the short-selling costs and lending benefits.

Moreover, Atmaz and Basak (2019) show that the effects of short-selling costs on option bid-ask spreads are more pronounced for relatively illiquid options with lower trading activity. The reason is that market makers are more likely to hedge the relatively illiquid options via hedge portfolios, through which short-selling costs affect option prices directly. In an extended analysis, they show that higher stock

short-selling costs lead to lower corporate bond prices or higher yields. In addition, stock short-selling fees increase bid-ask spreads for corporate bonds.

98.4 Literature Review

98.4.1 Short Sale Supply

Beneish et al. (2015) explore the determinants and consequences of the short sale supply. They find that the lendable supply is sensitive to borrowing costs and firm characteristics. Special (hard-to-borrow) stocks with the lowest supply have the strongest negative returns. In addition, they find that the short side returns of nine well-known market anomalies are due to those constrained, hard-to-borrow special stocks. For stocks that are not special, the short side returns are less significant. Finally, if short sellers' costs are considered, the profitability of the short side is severely limited. However, in the equity lending market, lendable supply, demand for borrowing, the price for borrowing, quantity borrowed, and short interest are closely related (Reed 2015), and lendable supply should not be considered as a distinct element. This endogeneity problem is explained in greater detail in Reed (2015). He considers a potentially new take and suggests that one should consider short selling demand as one of the only exogenously determined variables in the equilibrium relationship.

Several papers use natural experiments to address the endogeneity issue in short sale tests. Thornock (2013) examines the effects of dividend taxation between the lender and the short seller. Lenders often reduce loan supply around the dividend record date since after-tax dividends usually exceed the substitute payments reimbursed from short sellers. The tax-driven exogenous shock allows the paper to determine the effect of loan supply on loan prices and short selling. Using the same experimental setup, Blocher et al. (2013) find that when supply is reduced around dividend record dates, prices of hard-to-borrow stocks increase 1.1% while prices of easy-to-borrow stocks are unaffected. Moreover, they document the hard-to-borrow stocks are associated with lower 3-month returns.

98.4.2 Cross-Sectional Return Predictability

The short interest in a stock is often viewed as a measure of the heterogeneity of investor opinion. A number of studies have investigated the information content in equity short interest, and the negative relationship between the short interest levels and future stock returns is well-established (Desai et al. 2002; Nagel 2005; Diether et al. 2009b; Boehmer et al. 2010; Takahashi 2010; Pownall and Simko 2005). For example, Desai et al. (2002) examine the relationship between the short interest levels and stock returns of NASDAQ firms. They find firms with a high level of short interest experience negative and significant abnormal returns. Boehmer et al. (2010), on the other hand, find the absence of short selling is a positive signal about future

returns. Moreover, these positive future returns are larger in magnitude than the negative returns on heavily shorted stocks. The key question is how we should interpret the fact that short sellers can successfully time their trades when the stocks are overvalued.

Diether et al. (2009b) provide several possible explanations. The first one falls into the informed trading story that short sellers are either corporate insiders or traders who can have access in advance to material nonpublic information. The second explanation is that short sellers engage in short selling to provide liquidity. When there is a significant and temporary buy-order imbalance in the market, short sellers step in and trade. As the buying pressure extenuates or even vanishes, prices will go down and short sellers make a profit. The third explanation, supported by the model of Diamond and Verrecchia (1987) that argue short sales by liquidity traders are less likely due to the costly nature of short selling, recognizes that short sellers are sophisticated traders. As such, short sellers can successfully locate and exploit overpriced stocks, when the overpricing could be triggered by market frictions or behavioral biases. The last explanation is that short sellers play a role in providing additional risk-bearing capacity in periods of elevated uncertainty.

Short sellers also present skills in exploiting industry information. Huszár et al. (2017) find most-shorted stocks in industries with the highest aggregate shorted values substantially underperform other most-shorted stocks in less shorted industries. Short sellers specifically target complex or informationally diverse industries to maximize their profits.

98.4.3 Time Series Return Predictability (Aggregate Short Interest)

Another strand of research investigates the relationship between market-level short sale activities and market returns. An early study by Seneca (1967) finds that high aggregate short interest amount is associated with a low S&P 500 index level. Using daily short interest data, Lynch et al. (2014) also document that an increase in aggregate shorting is associated with a decrease in market excess returns over the following 5–20 days. Lastly, the detrended aggregate short interest, denoted as short interest index (SII) in Rapach et al. (2016), is a powerful predictor of aggregate stock returns. High detrended short interest predicts low market returns.

98.4.4 Short Interest and Corporate Events/Firm Performance

The information advantages of short sellers arise from their abilities to predict a variety of bad corporate events from changes in analysts' earnings estimates and recommendations (Christophe et al. 2010; Meng et al. 2017) to negative earnings surprises (Christophe et al. 2004), earnings restatements (Desai et al. 2006), financial frauds (Karpoff and Lou 2010), insider sales (Chakrabarty and Shkilko 2013; Khan and Lu 2013), private placements (Berkman et al. 2017), asset write-downs (Liu

et al. 2012), negative operating performance (Deshmukh et al. 2015; Akbas et al. 2017), and accounting irregularities (Dechow et al. 1996).

Christophe et al. (2010) study short selling prior to the release of analyst downgrades and document abnormal levels of short selling in the 3 days before downgrades are publicly announced. Using the data from China, Meng et al. (2017) find evidence of abnormal short selling in the days before downgrade announcements that are made by star analysts.

Christophe et al. (2004) study short selling activities 5 days prior to earnings announcements. For a subset of firms with negative earnings surprises, their pre-announcement short selling is significantly higher, which suggests the existence of informed traders. Christensen et al. (2014) find short selling is significantly high around earnings announcements that contain pro forma earnings disclosures, suggesting short seller view pro forma earnings disclosures as a strong signal of overvaluation. Indeed, firms that make pro forma earnings disclosures and have high short interest experience negative abnormal returns subsequently.³

Desai et al. (2006) examine the behavior of short sellers around the time when firms publicly acknowledge material errors in their previously reported financials (earnings restatements) and link short selling to questionable financial reporting. The results of their event study show that short sellers can identify the restatements before their public disclosure, and they build up short positions in the restating firms in the months leading up to the restatement announcement.⁴

Karpoff and Lou (2010) find that short sellers can detect financial misconducts. In anticipating the revelations of such misrepresentations, short sellers accumulate their short positions during the 19-month period before the revelations. Chakrabarty and Shkilko (2013) document that short sellers can detect insider trading. Specifically, short selling increases before insider sales are publicly reported and often before insiders finish selling. The superior timing ability of short sellers stems from the monitoring of order flow and price-relevant information received from brokerages that execute insider sales. In addition, Khan and Lu (2013) find evidence that short sellers front-run large insider sales.

Berkman et al. (2017) show there is a significant increase in the short interest surrounding the preannouncement of stock private placements, suggesting short sellers receive information from the insiders. Financial firms have experienced large asset write-downs during the 2007–2008 subprime mortgage crisis. Liu et al. (2012) find short sellers accumulate short positions prior to write-down announcements, suggesting the existence of information advantages of short sellers.

Short sellers also possess superior skills in exploiting public information, such as news releases, past stock prices, financial statements, and media information.

³When standard GAAP earnings are released, companies sometimes announce an adjusted earning that excludes one or more income statement line items from net income, which is known as pro forma earnings. The exclusion of some transitory items from GAAP income will overstate operating results and even misleads investors.

⁴However, Drake et al. (2015) find that short sellers do not appear to anticipate restatement announcement, but take actions when restatements are announced.

Engelberg et al. (2012) show the well-documented negative relation between short interest and future returns is twice as large on news days and four times as large as on days with negative news. Lee and Piqueira (2017) find short selling is negatively associated with the nearness of the price to the 52-week high. Dechow et al. (2001) show that short sellers target stocks with low ratios of fundamentals to market values that are likely to have systematically lower future returns. Accrual anomaly suggests that firms with high operating accruals will have low future abnormal returns (Sloan 1996). Thus, short sellers are inclined to target firms with high accruals. Hirshleifer et al. (2011) find a positive association between short selling and accruals during 1988–2019. In addition, short sellers also target firms with more earnings management activities (Park 2017) or firms that are about to disclose first-time internal control material weaknesses (ICMWs) under Section 404 of the Sarbanes-Oxley Act.

Drake et al. (2011) show short sellers interpret 11 variables properly in accordance with how these information variables affect future stock returns, whereas analysts tend to positively recommend stocks with high growth, high accruals, and low book-to-market ratios, which have a negative relationship with future returns.⁵ There is evidence that short sellers pay attention to media information. Hobbs et al. (2012) find a positive relationship between short selling and *Mad Money* buy recommendations, which are assembled from Jim Cramer's television show. The recommended stocks experience a positive abnormal return in the short run followed by a quick reversal; short sellers thus step in and seize this opportunity to exploit the short-term overpricing arising from the behavioral biases.

Despite the information advantages that are possessed by short sellers, which allow them to take actions before various adverse corporate events become public, short sellers also trade after the information is released. For example, Blau et al. (2013) show short selling activities increase significantly on and shortly after the announcement of an auditor change. Berkman and McKenzie (2012) find short sellers take short positions immediately after earnings announcement. These findings suggest that short sellers may have multiple information signals or they can update their information conditional on the new information released.

98.4.5 Consequences of Short Selling

In the presence of short selling threats, firms will likely change their investment activities, financing decisions, tax avoidance, and other corporate policies to cope with it. For example, Chen et al. (2019) find pilot firms that are more vulnerable to the short-selling threat will increase their cash dividends during the Reg SHO program,

⁵The 11 variables are earnings surprise, total accruals, capital expenditures, market-value-of-equity, earnings-to-price ratio, book-to-market ratio, stock turnover, sales growth, forecasted long-term growth, earnings forecast revision, and price momentum, which are all constructed from publicly available information.

which conveys a signal to the market that stocks are undervalued. Also under the Reg SHO program, Grullon et al. (2015) show that the constrained firms in the pilot program reduce investment and equity issues when there is a big increase in short selling activity. Deng et al. (2020) find pilot firms improve investment efficiency, which results in a decrease in stock price crash risk. Chen et al. (2020) report pilot firms issue more long-run good news forecasts to discourage short sellers. Similarly, Li and Zhang (2015) discover pilot firms will reduce the precision of bad-news forecasts and the readability of bad-news annual reports in response to short selling threats. Fang et al. (2016) find pilot firms are less likely to engage in earnings management activities. De Angelis et al. (2017) show pilot firms tend to grant more stock options to the managers to alleviate the adverse effects of the bear raids by incentivizing the managers. Last but not least, Gong (2020) document firms choose conservative financial policies and reduce corporate leverage when facing short-selling threat.

Tax avoidance is a bad signal to the outsiders, and firms are thus less willing to engage in corporate tax avoidance strategies, hoping to impede the short selling (Guo et al. 2018). However, their findings fail to reconcile the fact that tax avoidance is also beneficial for shareholders (Edwards et al. 2016).

Corporate social responsibility (CSR) has become increasingly important in recent years. Hou et al. (2019) find firms are more likely to engage in corporate philanthropic activities in response to an increase in short selling activities through investigating data from China.

98.4.6 The Role of Short Interest in Other Asset Markets

Short interest also appears to play an important role in the corporate bond market. Specifically, Kecskés et al. (2013) find that firms with high short interest have lower credit ratings, and the bonds are more likely to have their ratings downgraded. Moreover, firms with highly shorted stocks are associated with a higher cost of debt. Henry et al. (2015) also show that short sellers start to build up their positions several months ahead of a bond downgrade. Moreover, they provide empirical evidence of informed trading as short interest is higher for unanticipated downgrades. In addition to rating changes, Shi et al. (2017) study short selling and crediting rating agency (CRA) announcements, which include rating changes and credit watch placements. They find that short selling predicts negative credit watches.

Last but not least, equity short interest is a powerful predictor in the CDS market. Griffin et al. (2016) document a negative relation between short interest and future returns on credit default swaps.

98.4.7 Short Sale Ban in the History

Despite the controversial opinions against short sellers, for the most part, they are considered to be the “good guys.” A large body of literature has shown that short sellers are sophisticated (informed) traders that help markets correct short-term

deviations of stock prices from the fundamental value and contribute to efficient stock prices. However, when share prices fall sharply, they tend to be the scapegoats. In September 2008, the US Securities and Exchange Commission (SEC) surprised the investment community by adopting an emergency order that temporarily banned most short sales in nearly 1,000 financial stocks.⁶ Grundy et al. (2012) find the short sale ban is associated with a decline in trade in put options on the banned stock, suggesting option strategies are not effective substitutes for short sales during a short sale ban.

The last time shorting was banned in the United States was in September 1931, when the NYSE banned all short sales in the wake of England's announcement that it was abandoning the gold standard. Boehmer et al. (2013) study this unexpected event and find the market quality was severely compromised. The ban had substantial effects on larger stocks, and those stocks suffered severe degradation in market quality (i.e., effective spreads, price impacts, and realized spreads).

The short selling bans are not solely implemented in the United States. Beber and Pagano (2013) study the short sale bans that 30 countries imposed during the period of the global financial crisis from 1 January 2008 to 23 June 2009. They find short sale bans or regulatory constraints on short selling are harmful to liquidity and slows the price discovery process. Frino et al. (2011) study the 2008 short selling bans on 14 equity markets and document a similar negative impact.

98.5 Data and Empirical Evidence

In this section, we first describe several databases that are commonly used in short selling studies. Following this, we discuss important empirical evidence.

98.5.1 Reg SHO Data – NYSE Short Sales (TAQ)

On 23 June 2004, the SEC adopted Regulation SHO to establish uniform locate-and-delivery standards, created uniform marking requirements for sales of all equity securities, and temporarily suspended the price tests for a set of pilot securities.⁷ The SEC mandated that all self-regulatory organizations make tick data on short sales publicly available starting from 2 January 2005. Short sales reported to the NYSE for NYSE-listed and trades securities can be accessed from the TAQ tape of the WRDS research database. The sample period is from 2 January 2005 to 6 June 2007. Only trades that have a short sale component are included. The data contain ticker, price,

⁶See Boehmer et al. (2013) for more details and the timeline of events.

⁷Sell orders are marked as “long,” “short” “short exempt” where “long” refers to regular sell, “short” refers to short sale, and “short exempt” refers to short sale exempted from the uptick rule regulation. More information on Reg SHO can be found at <https://www.sec.gov/investor/pubs/regsho.htm>

short size, time, listing market, and short type (exempt or nonexempt from the short sale rules). Short trade prints that contain both exempt and nonexempt components are indicated on separate records.

98.5.2 Supplemental Short Interest File (Compustat)

Compustat provides supplement short interest files from 1973. All member firms of NYSE, AMEX, and NASDAQ are required to report the aggregate number of shares sold short over all accounts as of the middle of each month. The Compustat Supplemental Short Interest file contains data for NYSE and AMEX firms beginning in 1973 and for NASDAQ beginning in 2003. Note that raw short interest numbers are reported twice a month from 2007, one in the middle and the other at the end of the month.

98.5.3 Markit Data Explorers (DXL) Equity Lending Data

DXL (Data Explorers was acquired by Markit in 2012) is a research firm that collects data from the securities lending desks at more than 100 of the world's leading institutional traders, which collectively represent the largest pool of loanable equity inventory in the world. Lending data at the stock level are available from May 2002. DXL provides the data at monthly frequency in 2002 and 2003, at weekly frequency from July 2004, and at daily frequency after 2006. Studies that exploit this database include Beneish et al. (2015), Chang et al. (2019), Massa et al. (2015), Saffi and Sigurdsson (2011), etc.

98.5.4 WRDS European Short Data

Following the global financial crisis of 2008, European Securities and Markets Authority (ESMA) launched policy EU N236/2012 on short selling and certain aspects of credit default swaps. The purpose of this EU-wide reporting regulation is to increase market stability by reducing the opaqueness of market activities through mandatory daily reporting by institutional investors. Significant net short positions in shares must be reported to the relevant competent authorities when they are at least equal to 0.2% of company issued share capital and every 0.1% above that, and disclosed to the public when they are at least equal to 0.5% of company issued share capital and every 0.1% above that. The coverage includes Austria, Belgium, Czech Republic, Denmark, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Luxembourg, Netherlands, Norway, Poland, Spain, Sweden, and the UK. As each of the participating EU markets has its own site for data downloading and there is not a centralized database that consolidates this relatively new data, WRDS scrape the participating markets reporting website to collect the data on a quarterly basis, which starts from 1 January 2010. The data contain variables such as

country, issuer (the underlying stock), position holder, and its net position (percentage of shares shorted by the position holder as a fraction of issuer's total shares outstanding).

98.5.5 Short Selling Metrics

Two common metrics are used to track the short selling activity on a stock.

- (a) Short interest ratio (SIR): Also known as the short interest level, measures the ratio of shares that are currently being shorted compared to the total number of shares outstanding (see Senchack and Starks 1993; Desai et al. 2002; Boehmer et al. 2010; Shkilko et al. 2012). A high SIR is a negative signal, which is associated with future negative abnormal returns.⁸
- (b) Short interest to trading volume ratio: Also known as the days-to-cover ratio, defined by the total shares that are held short divided by the average daily trading volume (see Diether et al. 2009b). A high days-to-cover ratio is also a bearish indicator.⁹

Short selling activities have increased over time, which could be attributed to many market-wide institutional factors, such as the ease of short selling as a result of continued development of the equity lending market, an increase in the number of hedge funds in existence, and an increase in the supply of loanable shares. In light of this phenomenon, many studies try to detrend the short interest, as the trend in short interest would obscure the true information content buried under the short interest. For example, Rapach et al. (2016) construct an aggregate short interest index and suggest that it is the strongest predictor of aggregate stock returns. They first compute the monthly equal-weighted mean of all stock-level short interest ratio (*EWSI*), which is further detrended using the following regression:

$$\log(EWSI_t) = a + bTREND_t + u_t \quad (1)$$

The standardized fitted residual from the above estimation is the aggregate short interest index, which can be interpreted as a measure of market pessimism.

On the other hand, Guo and Wu (2019) take a simple approach by taking the first difference in SIR and find that the change in the short interest ratio is more

⁸Purnanandam and Seyhun (2018) use a standardized measure of SIR, which reflects the deviation from the average level of shorting of a stock after accounting for its variance.

⁹Traders could get the idea of potential future buying pressure from this ratio. Short sellers usually want to buy the shares back at the lowest price possible. However, it will drive prices higher as short sellers buy to cover. The longer the buyback process takes, as referenced by the 'days to cover' metric, the longer the price rally may continue based solely on the need of short sellers to close their positions. Additionally, a high 'days to cover' ratio often signal a potential short squeeze, a situation that stock price increases rapidly due to short sellers covering their positions.

informative. They also document that the predictability of short interest for future returns is concentrated in worst-rated stocks, similar to the momentum anomaly (Avramov et al. 2007).

There are other short selling metrics used in the literature; for example, Bao et al. (2019) construct the residual short interest, which are the residuals from the following regression:

$$SIR_{i,t} = \alpha + \beta_1 IO_{i,t} + \beta_1 CONVERT_{i,t} + \beta_3 TREND_t + \epsilon_{i,t} \quad (2)$$

where *SIR* is short interest, *IO* is the institutional ownership, which is a proxy for the supply of loanable shares, *CONVERT* is a dummy variable that indicates whether firm *i* has convertible bonds or convertible preferred stocks outstanding, which can control the hedging-based shorting that is unrelated to negative private information. Finally, the time trend in short interest is removed. The regression residual is then used as a measure of negative private information.

Lamont and Stein (2004) study the aggregate short interest during the dot-com bubble period and the aggregate short interest is defined as the scaled value-weighted short-interest ratio (100 times the market value of shares sold short, divided by the value of shares outstanding). They find total short interest moves in a countercyclical pattern. Unlike the contrarian nature of the stock-level short interest, aggregate short interest displays extrapolative behavior: fewer investors are willing to bet on the market going down after a period in which it has been rising, such as the dot-com bubble period. This puzzle could be explained by the open-end nature of professional money management: fund managers are forced to reduce their aggregate short positions due to the redemptions from their clients, who are unwilling to lose money when the market is rising.

98.5.6 Empirical Evidence

Desai et al. (2002) find firms with a high level of short interest experience negative and significant abnormal returns when examining the relationship between the short interest level and stock returns of Nasdaq firms. The monthly short interest data are obtained from the Nasdaq. Using a calendar-time portfolio approach, at the beginning of each month, they form equal-weighted portfolios of stocks based on four thresholds of short interest in the previous month. For the 2.5% portfolio (i.e., stocks have at least 2.5% short interest in the previous month), the risk-adjusted return is -0.76% per month with a *t*-value of -3.34 . The risk-adjusted return decreases monotonically if higher thresholds of short interest level are used in constructing portfolios. For example, limiting the sample to stocks with at least 10% short interest level, the risk-adjusted return is -1.13% per month. Moreover, heavily shorted firms are more likely to incur liquidations or forced delisting than their size-, book-to-market-, and momentum-matched control firms. Thus, large short positions are bearish signals.

Two necessary conditions for Miller's (1977) hypothesis are the existence of short sale constraints and dispersion of investor opinion. Boehme et al. (2006) examine Miller's hypothesis in a two-dimensional framework that accounts for differences of opinion and short sale constraints.¹⁰ The authors obtain daily short stock rebate and fee data from a major broker-dealer for the period from March 2001 to December 2002. Using a calendar-time methodology and the four-factor asset pricing model, the authors show portfolios with high short sale constraints are associated with lower abnormal returns. However, results are weaker when sorting by dispersion. Finally, when double sorting by constraint and dispersion, the portfolio with the highest dispersion and constraints has a 1-month abnormal return of -1.64% , while it is 0.49% for the portfolio with the highest dispersion but least constraint. These findings support the argument that firms subject to both high short sale constraints and high dispersion of investor opinion are likely to be overvalued.

Diether et al. (2009b) investigate short selling based on Reg SHO data. They measure daily stock-level shorting activity (*relss*) as the number of shorted shares divided by traded shares per day and show short sellers increase their shorting activity after periods of positive returns, on days with significant buying pressure, and on days with high levels of asymmetric information, which are consistent with three types of trading strategies: trading on short-term overreaction, acting as voluntary liquidity provider, and opportunistically providing risk-bearing services. Moreover, through portfolio analysis and regression framework, the authors show high short selling activity is associated with negative future abnormal returns.

Boehmer et al. (2010) take a new perspective by studying the performance of stocks with low short interest. The short interest data are obtained directly from the NYSE, Amex, and Nasdaq. Three heavily shorted and three lightly shorted portfolios are formed each month based on the short interest ratio (SIR) distribution in the previous month. The lightly shorted portfolios include stocks from the 1st, 5th, and 10th SIR percentiles, while the heavily shorted portfolios include stocks from the 99th, 95th, and 90th SIR percentiles. The authors are particularly interested in the three lightly shorted portfolios. Empirical results show the absence of short selling is a positive signal about future returns. For example, the SIR 1% portfolio realizes a 2% raw return or 1.4% adjusted return (alpha from the four-factor model of Fama and French (1993) and Carhart (1997)). Moreover, these positive future returns are larger in magnitude than the negative returns on heavily shorted stocks. Their findings cast doubt on existing theories about the impact of short sale constraints. Short sale constraints impede the incorporation of negative information in stock prices, thus result in overpricing (Miller 1977; Diamond and Verrecchia 1987). However, as there are no restrictions on going long, positive information should be incorporated in stock prices very quickly. The avoidance of short sellers for

¹⁰Previous empirical tests of Miller's hypothesis only focus on one of these two necessary conditions. For example, see Figlewski (1981) and Desai et al. (2002) for studies that examine the effect of short sale constraints on overvaluation; see Diether et al. (2002) and Danielsen and Sorescu (2001) for studies that examine the effect of dispersion of opinion on overvaluation.

undervalued stocks suggests that positive information is not incorporated in stock prices promptly, which undermines the critical asymmetry between the way good and bad news is revealed to the market. It seems that there are other frictions in the market, which lead to the predictability of future returns for stocks with low short interest level.

Engelberg et al. (2018) measure short selling risk by projecting the variance of loan fees (data from Markit) on several equity lending market characteristics and firm characteristics. Each month, equal-weighted quintile portfolios are formed based on the previous month's short selling risk. Stocks in the low (high) short selling risk quintile earn a monthly return of 0.58% (−0.49%) per month, suggesting short selling risk negatively predicts future returns. To control for the effect of short interest level, the authors perform 5×5 sorting, where stocks are first ranked by short interest level and then within each short interest quintiles, stocks are further sorted by short selling risk. The long-short portfolio returns range from 0.63% to 1.19%, so the effect of short selling risk is not subsumed by the well-established relation between short interest level and returns. Moreover, the authors document short selling risk is positively related to the Hou and Moskowitz (2005) measure of price delay, and negatively associated with short volume.

Bao et al. (2019) study whether managers have a tendency to disclose or withhold bad news through a proxy (residual short interest) for manager's private bad news. The novel approach tackles the challenge that researchers cannot observe the negative private information directly. The residual short interest contains negative information that is yet to be reflected in the stock price as it negatively predicts future abnormal stock returns. Moreover, the authors show that residual short interest is associated with insider trading and stock repurchases, indicating it indeed captures manager's negative private information. After validating residual short interest's effectiveness in proxying for negative private information, the authors further document a negative relation between bad-news disclosure and residual short interest, suggesting that managers withhold bad news in general.

In what follows, we review three papers on the effects of short selling on managerial decisions. Grullon et al. (2015) study the effects of short selling constraints on firm's investment and financing decisions. Short selling constraints can lead to overvaluation and overvaluation can cause overinvestment by artificially reducing the firm's cost of capital (Gilchrist et al. 2005). Thus, when short selling constraints are muted for pilot firms, we should observe lower investment. Consistent with this view, exploiting the regulatory change of Regulation SHO program, the authors find pilot firms with an increase in short selling activity exhibit larger reductions in investment and equity issuance. In the univariate difference-in-difference test, the estimator is −0.60 for capital expenditures, −0.52 for equity issuance, and −1.38 for debt issuance.

De Angelis et al. (2017) study short selling threat and the design of executive incentive contracts. Exploiting the natural experiment of Reg SHO program and the difference-in-difference approach, the authors show pilot firms whose short selling constraints are relaxed tend to increase the convexity of the compensation payoff. Further analysis shows that pilot firms do this by substituting away from restricted

stock and toward stock options in their new equity grants. Therefore, firms incentivize managers to alleviate the adverse effects of unrestrained short selling when facing the threat. The authors also find pilot firms adopt new antitakeover provisions.

Chang et al. (2019) examine the merger and acquisition (M&A) under the short selling threat. Managers face the temptation of pursuing private benefits when considering a deal, however, they are less likely to conduct value-destroying deals when there is a strong short selling threat. Examining 452 completed US domestic M&A from 2003 to 2012, the authors find acquirers with higher short interest gain higher M&A announcement returns, which lends support to the hypothesis. Further examination reveals that the effect is stronger when acquirers are more likely to be targets of subsequent hostile takeovers and when their managers' wealth is more linked to stock prices.

98.6 Future Research

98.6.1 CSR and Short Interest

As there is an increasing awareness of sustainability and corporate social responsibility (CSR), whether short sellers target firms with poor CSR performance is an open question and remains unexplored. Whether firms engage in CSR practices in the presence of increased threat from short selling is also an interesting avenue for future research. CSR is a broad concept that can take many forms depending on the types of company and industry. Using the data from China, Hou et al. (2019) document that a firm responds to the surge in short selling with an engagement in corporate philanthropic (CP) activities. Empirical evidence shows that a firm will use CP activities to divert public attention when it faces weaknesses such as the threat of short selling. However, the CP variable (whether or not a firm makes CP in a given year) they consider fails to capture the bigger dimension of CSR activities. Jain et al. (2016) find that short sellers avoid firms with high environmental, social, and governance (ESG) scores and tend to target firms with low ESG scores. Nevertheless, ESG also fails to capture the broad picture of CSR. An integration study between CSR and short selling is thus in great need.

98.6.2 The Information Role of Short Interest in Other Asset Markets

We notice that the information role of short interest in other asset markets is not fully understood. A smaller subset of papers focuses on this direction. For example, Kecskés et al. (2013) and Henry et al. (2015) find short interest can predict bond downgrades. Griffin et al. (2016) show short interest is a strong predictor of CDS returns. Meanwhile, a few studies focus on the substitution role of put option on short selling (Ackert and Athanassakos 2005; Grundy et al. 2012). We believe the role of short interest in the options market as well as other asset markets offers a promising avenue for further research.

98.6.3 Heterogeneity in Short Sellers

Short sellers are not homogeneous as the motivation for short selling varies in the first place. Brunnermeier and Oehmke (2014) study the behavior of predatory short sellers as their short selling pressure forces a financial institution to fire sell long-term assets to repay debt and satisfy the leverage constraints imposed by short-term creditors. Kelley and Tetlock (2017) find retail short selling predicts negative stock returns, and the return predictability is not subsumed by institutional short selling, which they attribute to the unique insights that retail short sellers have. Comerton-Forde et al. (2016b) find two distinct types of short sales by examining returns, order flows, and market conditions in the minutes before, during, and after NYSE and Nasdaq short sales, which they refer to as liquidity-supplying shorts and liquidity-demanding shorts. Liquidity-supplying short sellers trade when spreads are unusually wide, whereas liquidity-demanding short sellers trade when spreads are narrow and there is a decline in short-term price. Using the equity lending data of the Brazilian market, Chague et al. (2019) find that skilled short sellers present out-of-sample performance persistence while unskilled short sellers are likely to display the disposition effect.

Reed et al. (2019) differentiate the trading venues through which the short orders are executed, namely, exchange versus dark pools, which can answer the question regarding where short sellers exploit their information advantage. The authors find that the exchange short sales are more informative about future prices than dark pool short sales.

To summarize, different types of short sellers use different sets of information through different venues to exploit their information advantages, which warrant further investigation.

98.6.4 Endogeneity Problem

The endogeneity problem is unavoidable and present in many short selling studies. For example, Jain et al. (2019) find short interest decreases with an increase in accounting conservatism, while Jin et al. (2018) and Young (2016) document that firms will report more conservatively in the presence of short-selling threats.¹¹ In other words, conservatism determines the short selling in Jain et al. (2019), but is the consequence of short selling in Jin et al. (2018) and Young (2016). Short sellers target firms with poor financial reporting quality in the first place, and firms, in turn, respond with disciplined management and improved financial reporting quality, which will result in reverse causality.

Some studies employ the two-stage instrumental method to overcome or alleviate the endogeneity concern. However, the selection of an appropriate instrumental

¹¹ In a separate study, Mashruwala and Mashruwala (2018) find accounting conservatism alleviates the overvaluation for firms with the highest short selling constraints.

variable is a challenge. Hirshleifer et al. (2011) investigate whether short sellers target firms with high accruals, and the instrumental variable used in this study is institutional ownership, which acts as the proxy for the ease of short arbitrage. The use of institutional ownership as an instrument helps allay concern that the relation between accruals and short interest is driven by omitted variables rather than arbitrage activity. However, due to the monitoring function of institutional investors, the overall institutional ownership is not an appropriate instrument in most cases. For this reason, the literature (e.g., Massa et al. 2015; Meng et al. 2020) identifies an alternative instrumental variable, i.e., the ownership of exchange-traded funds (ETFs). ETFs have the lowest management fee among ETFs, brokerages, and banks, which are the main sources of lendable shares for the short selling market; short sellers thus have the highest incentive to borrow shares from ETFs. Moreover, ETFs are passive investors who typically track a stock market index and are less concerned about specific firm performance (Massa et al. 2015).

Meanwhile, many studies use difference-in-difference tests to tackle the endogeneity problem. For example, using the natural experiment of Reg SHO, Young (2016) find a decrease in short selling constraints causes a decrease in conditional conservatism in financial reporting. The regulatory change provides an ideal setting that frees the tests from the endogeneity concern. However, these studies are limited to the US, China, or Hong Kong markets because only these equity markets have experienced regulatory changes that affect the short selling activities.

98.6.5 International Evidence

Thus far, the cross-country studies are still quite limited. Existing studies mainly focus on a single country or market. While studies that use the US data account for the highest proportion of short sale research, we notice there are papers that investigate UK (Andrikopoulos et al. 2012; Au et al. 2009), China (Chang et al. 2014; Meng et al. 2017; Meng et al. 2020; Zhao et al. 2014; Hu et al. 2020; Ni and Zhu 2016; Chen et al. 2018), Canada (Ackert and Athanassakos 2005), Brazil (Chague et al. 2019), Australia (Comerton-Forde et al. 2016a; Aitken et al. 1998), Turkey (Sobaci et al. 2014), and Hong Kong market (Bai and Qin 2014, 2015; Chang et al. 2007; Chen and Rhee 2010; Choy and Zhang 2019; McKenzie and Henry 2012). A few papers conduct analysis globally; for example, Beber and Pagano (2013) find short sale bans or regulatory constraints on short selling are harmful to the liquidity and will slow the price discovery process in 30 countries in their sample. Bris et al. (2007) study the data from 46 countries and document that allowing short sales will improve market efficiency. Saffi and Sigurdsson (2011) study a global dataset from 26 countries and find stocks with higher short sale constraints have lower price efficiency; most importantly, relaxing short sale constraints is not associated with an increase in market instability. Massa et al. (2015) explore the relationship between short selling and earnings management using a global sample from 33 countries. Jiang et al. (2020b) extend Massa et al.'s (2015) research by showing that a short-selling threat constrains real earnings management

internationally. The development of financial markets at different levels across countries, different roles of institutions play in those markets, as well as heterogeneities of investors' financial literacy warrant further investigation.

98.7 Conclusion

Short sales have profound impacts on asset price behaviors, market equilibrium, and corporate finance and investment decisions. As such, short sellers' activity has received a considerable amount of attention from academics and policy makers. In this chapter, we review the current state of research on short sales and suggest several future directions for this line of research in order to improve our understanding of the role of short sellers in capital market development and in influencing corporate decisions.

A clear consensus in the literature is the finding that short sellers are knowledgeable traders who are capable of collecting both public and private information to facilitate their trading decisions. Short selling activity has significant impacts on information dissemination, price discovery, market efficiency, and corporate decision-making. Restricting short sales has adverse effects on pricing efficiency and price discovery.

We review the literature on the information content in short interest, information advantages of short sellers, and firms' reactions to the short selling threat. In addition, we discuss the data and metrics commonly used in short sales studies, and summarize important empirical findings. We highlight some limitations of current research and areas that require further investigation to improve our understanding of the role of short sellers. In particular, we need to understand the sources of information possessed by short sellers and the effects of short selling in different environments (e.g., investment sentiment and financial distress).

Although several theoretical models have been developed to explain the effects of short selling, our knowledge for the role of short sellers in affecting corporate governance and decisions remains quite limited, and many issues related to short sales are unresolved. It is therefore important for financial researchers to develop better models to explain these unresolved issues and provide guided empirical analysis to further improve our understanding of the role of short selling in financial markets and corporate managers' decision-making.

Simultaneous Equation Models for Financial Planning and Forecasting

99

Cheng-Few Lee, Alice C. Lee, and Wen-chi Yeh

Abstract

This chapter first discusses Warren and Shelton (J Finance, 26:1123–1142, 2007) and Francis and Rowell's (Financ Manag 7:29–44, 1978) simultaneous equation models for financial planning and forecasting in detail. Then we use Johnson & Johnson's 2018 financial data in terms of Excel programming to demonstrate how Warren and Shelton's model can be used for financial analysis, planning, and forecasting. Data from 2019 and 2020 is used to evaluate the performance of Warren and Shelton's model. In addition, sensitivity analysis is used to demonstrate how the change of growth rate, debt equity ratio, and P/E ratio can affect the price per share for Johnson & Johnson.

Keywords

Simultaneous equation · Financial planning and forecasting · Sustainable growth rate · Debt equity ratio · Payout ratio · P/E ratio · Sensitivity analysis

99.1 Introduction

This chapter covers alternative financial planning models and their use in financial analysis and decision-making. The approach taken in this chapter gives the student an opportunity to combine information (accounting, market, and economic), theory, and methodology (regression and Excel programming).

We begin by presenting the procedure for financial planning and analysis in Sect. 99.2. This is followed by a discussion of the Warren and Shelton algebraic simultaneous equations planning model in Sect. 99.3. Section 99.4 discusses the importance of sensitivity analysis and its application to Warren and Shelton's financial planning model, Sect. 99.5 discusses the Francis and Rowell model, and Sect. 99.6 offers a summary of the chapter. Appendix A is a description of parameter inputs used to forecast Johnson & Johnson's financial statements and share price. Appendix B shows the procedure of how to use Excel to implement the FinPlan program.

99.2 Procedures for Financial Planning and Analysis

Before discussing the various financial planning models, we must first be sure of our understanding of what the financial planning process is all about. Otherwise, we run the risk of too narrowly defining financial planning as simply data gathering and running computer programs. In reality, financial planning involves a *process* of analyzing alternative dividend, financing, and investment strategies, forecasting their outcome and impact within various economic environments, and then deciding how much risk to take on and which projects to pursue. Thus, financial planning models are merely tools to improve forecasting as well as to help managers better understand the interactions of dividend, financing, and investment decisions.

More formally, we can outline the financial planning process as follows:

1. *Utilize* the existing set of economic, legal, accounting, marketing, and company policy information.
2. *Analyze* the interactions of the dividend, financing, and investment choices open to the firm.
3. *Forecast* the future consequences of present decisions to avoid unexpected events as well as to aid in understanding the interaction of present and future decisions.
4. *Decide* which alternatives the firm should undertake, the explicit outline for which is contained in the financial plan.
5. *Evaluate* the subsequent outcome of these decisions once they are implemented against the objectives set forth in the financial plan.

So where does the financial planning model come in? To clarify its role in this process, look at Fig. 1, which presents a flowchart of a financial planning model. The

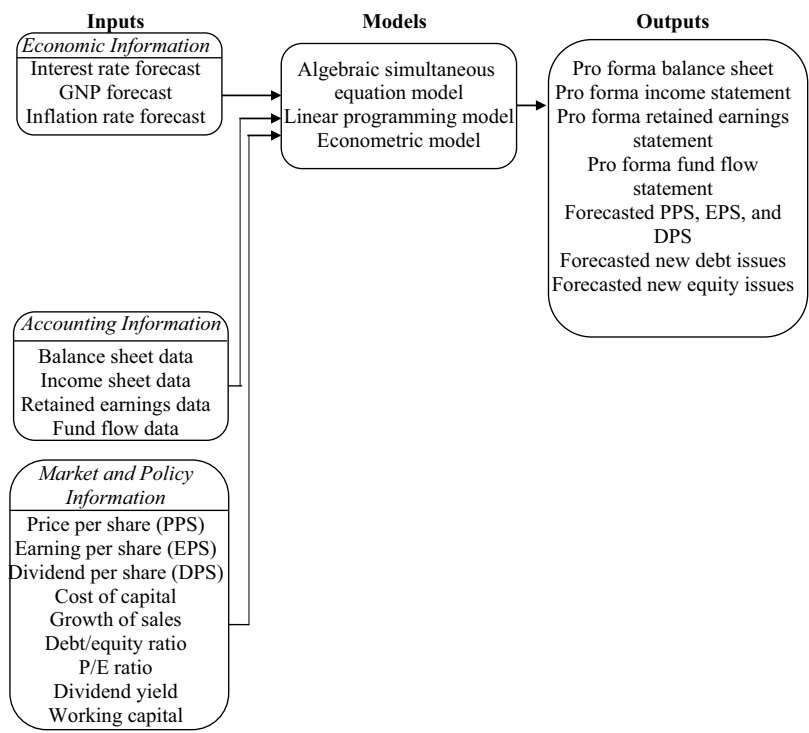

Fig. 1 Inputs, models, and outputs for financial planning and forecasting Models

inputs to the model are economic and accounting information and market and policy information. Two alternative financial planning, analysis, and forecasting models are (1) Warren and Shelton’s model and (2) Francis and Rowell’s model.¹ The outputs of the financial planning and forecasting model are pro forma financial statements, forecasted PPS, EPS, and DPS, new equity issued, and new debt issued. Essentially, the benefit of the model is to efficiently and effectively handle the analysis of information and its interactions with the forecasting of future consequences within the planning process.

Hence, the financial planning model efficiently improves the depth and breadth of the information the financial manager uses in the decision-making process. Moreover, before the finalized plan is implemented, an evaluation of how well subsequent performance stands up to the financial plan provides additional input for future planning actions.

A key to the value of any financial planning model is how it is formulated and constructed. That is, the credibility of the model’s output depends on the underlying assumptions and particular financial theory the model is based on, as well as its ease

¹This chapter discusses two alternative financial planning models. The simultaneous equation model can be found in Lee and Lee’s (2017), Chap. 24.

of use for the financial planner. Because of its potentially great impact on the financial planning process and, consequently, on the firm's future, the particular financial planning model to be used must be chosen carefully. Specifically, we can state that a useful financial planning model should have the following characteristics:

1. The model results and assumptions should be credible.
2. The model should be flexible so that it can be adapted and expanded to meet a variety of circumstances.
3. The model should improve on current practice in a technical or performance sense.
4. The model inputs and outputs should be comprehensible to the user without extensive additional knowledge or training.
5. The model should take into account the interrelated investment, financing, dividend, and production decisions and their effect on the firm's market value.
6. The model should be fairly simple for the user to operate without extensive intervention of nonfinancial personnel and tedious formulation of the input.

On the basis of these guidelines, we now present and discuss the simultaneous equations, linear programming, and econometric financial planning models, which can be used for financial planning and analysis.

99.3 Percentage of Sales Method for Financial Planning and Forecasting

Ross et al. (2019) and Lee et al. (1997) have shown how percentage sales method can be used to develop financial analysis, planning, and forecasting. Financial planning is the process of analyzing alternative investment, financing, and dividend strategies in the context of various potential economic environments. Planning involves forecasting both the outcomes of different strategies and their risks. Thus, financial planning models are tools to help managers improve their forecasts of important accounts of financial statements and better understand the interactions of investment, financing, and dividend decisions.

In developing a long-term financial plan, these three decisions (policies) can be described more explicitly as follows.

1. *The firm's investment decision.* This refers to the amount of cash needed for the firm's investment in a new asset (it is also called the *capital budgeting decision*). In addition, it also refers to the amount of working capital needed on an ongoing basis (also referred to as the *working capital decision*).
2. *The firm's financing decision.* This refers to new borrowing or new equity issued for financing the firm's investment in new assets. This decision is influenced by the degree of financial leverage the firm chooses to employ and how it plans to raise the necessary new funds.

3. *The firm's dividend decision.* This refers to the amount of cash the firm thinks is necessary and appropriate to pay equity holders as cash dividends.

At the most basic level, a planning model is a tool that uses inputs supplied by managers in the form of economic, accounting, market, and policy information. Depending on its sophistication, the output of the financial planning and forecasting model may include simple estimates of growth rates or complex pro forma financial statements, with projected financial statement data, and forecasts of stock price, earnings per share, dividends per share, new equity issues, and new debt issues.

The procedure of using percentage sales methods for financial planning and forecasting can be briefly described as follows:

1. Calculate by dividing company sales into both balance sheet and income statement to obtain standardized financial statements.
2. Forecast growth rate and outside financing.
3. Forecast external financing needs.
4. Combine information from steps 1, 2, 3 to obtain pro forma financial statements.
5. Use pro forma financial statements to perform future financial planning and forecasting.

99.4 The Algebraic Simultaneous Equations Approach to Financial Planning and Analysis

In this section, we present the financial planning approach of Warren and Shelton (1971), which is based on a *simultaneous equations* concept. The model, called FINPLAN, deals with overall corporate financial planning as opposed to just single planning, such as capital budgeting. The objective of the FINPLAN model is not to optimize anything, but, rather, to serve as a tool to provide relevant information to the decision-maker. One of the strengths of this planning model, in addition to its construction, is that it allows the user to simulate the financial impacts of changing assumptions regarding such variables as sales, operating ratios, price-to-earnings ratios, retention rates, and debt-to-equity ratios.

The advantage of utilizing a simultaneous equation structure to represent a firm's investment, financing, production, and dividend policies is the enhanced ability for the interaction of these decision-making areas. The Warren and Shelton (WS) model is a system of 20 equations, which are listed in Table 1. These equations are segmented into distinct subgroups corresponding to sales, investment, financing, and per share (return to investors) data. The flowchart describing the interrelationships of the equations is shown in Fig. 2.

The key concepts of the interaction of investment, financing, and dividends are the basis of the FINPLAN model, which we now consider in some detail. First, we discuss the inputs to the model; second, we delve into the interaction of the equations in the model; and third, we look at the output of the FINPLAN model.

Table 1 Warren and Shelton Model

Section 1 – Generation of Sales and Earnings before Interest and Taxes for Period t .

$$(4) FA_t = RFA_t SALES_t$$

$$(5) A_t = CA_t + FA_t$$

Section 3 – Financing the Desired Level of Assets.

$$(6) CL_t = RCL_t SALES_t$$

$$(7) NF_t = (A_t - CL_t - PFDSK_t) - (L_{t-1} - LR_t) - S_{t-1} - R_{t-1} - b_r \{ (1 - T_t) [EBIT_t - i_{t-1} (L_{t-1} - LR_t)] - PFDIV_t \}$$

$$(8) NF_t + b_t (1 - T_t) [i_t^e NL_t + U^l_t NL_t] = NL_t + NS_t$$

$$(9) L_t = L_{t-1} - LR_t + NL_t$$

$$(10) S_t = S_{t-1} + NS_t$$

$$(11) R_t = R_{t-1} + b_t \{ (1 - T_t) [EBIT_t - i_t L_t - U^l_t NL_t] - PFDIV_t \}$$

$$(12) i_t = i_{t-1} \left(\frac{L_{t-1} - LR_t}{L_t} \right) + i_t^e \frac{NL_t}{L_t}$$

$$(13) \frac{L_t}{S_t + R_t} = K_t$$

Section 4 – Generation of Per Share Data for Period t

$$(14) EAFCD_t = (1 - T_t) [EBIT_t - i_t L_t - U^l_t NL_t] - PFDIV_t$$

$$(15) CMDIV_t = (1 - b_t) EAFCD_t$$

$$(16) NUMCS_t = NUMCS_{t-1} + NEWCS_t$$

$$(17) NEWCS_t = \frac{NS_t}{(1 - U^s_t) P_t}$$

$$(18) P_t = m_t EPS_t$$

$$(19) EPS_t = \frac{EAFCD_t}{NUMCS_t}$$

$$(20) DPS_t = \frac{CMDIV_t}{NUMCS_t}$$

Source: Lee and Lee (2017), page 1166.

There are 20 equation and 20 unknowns for this model. The unknowns are listed and defined in Table 2. In addition, Table 2 lists and defines parameters (inputs)

The inputs to the model are shown in Table 2b. The driving force of the WS model is the sales growth estimates ($GSALS_t$). Equation (1) in Table 1 shows that sales for period t is the product of sales in the prior period multiplied by the growth rate in sales for period t . $EBIT$ is then derived, by expressing $EBIT$ as a percentage of sales ratio, as in Equation (2) of Table 1. Current and fixed assets are then derived in Eqs. 3 and 4 of the table through use of the $CA/SALES$ and $FA/SALES$ ratios. The sum of CA and FA is the total assets for the period.

Financing of the desired level of assets is undertaken in Section 3 of the table. In Eq. 6, current liabilities in period t are derived from the ratio of $CL/SALES$ multiplied by $SALES$. Equation 7 represents the funds required (NF_t). FINPLAN assumes that the amount of preferred stock is constant over the planning horizon. In determining what funds are needed and where they are to come from, FINPLAN uses a source-and-use-of-funds accounting identity. For instance, Eq. 7 shows that the assets for period t are the basis for the firm's financing needs. Current liabilities, as determined in the prior equation, are one source of funds and therefore are subtracted from asset levels. As mentioned above, preferred stock is a constant and therefore must be subtracted also. After the first term in Eq. 7, $(A_t - CL_t - PFDSK_t)$, we have the

Fig. 2 Flow chart of a simplified financial planning model

financing that must come from internal sources (retained earnings and operations) and long-term external sources (debt and stock issues). The term in the second parenthesis, $(L_{t-1} - LR_t)$, takes into account the remaining old debt outstanding, after retirements, in period t . Then the funds provided by existing stock and retained

Table 2 List of unknowns and list of parameters provided by management

A. Unknowns	
1. $SALES_t$	Sales
2. CA_t	Current assets
3. FA_t	Fixed assets
4. A_t	Total assets
5. CL_t	Current payables
6. NF_t	Needed funds
7. $EBIT_t$	Earnings before interest and taxes
8. NL_t	New debt
9. NS_t	New stock
10. L_t	Total debt
11. S_t	Common stock
12. R_t	Retained earnings
13. I_t	Interest rate on debt
14. $EAFC D_t$	Earnings available for common dividends
15. $CMDIV_t$	Common dividends
16. $NUMCS_t$	Number of common shares outstanding
17. $NEWCS_t$	New common shares issued
18. P_t	Price per share
19. EPS_t	Earnings per share
20. DPS_t	Dividends per share
B. Provided by Management	
21. $SALES_{t-1}$	Sales in previous period
22. $GSALS_t$	Sustainable growth rate
23. RCA_t	Current assets as a percent of sales
24. RFA_t	Fixed assets as a percent of sales
25. RCL_t	Current payables as a percent of sales
26. $PFDSK_t$	Preferred stock
27. $PFDIV_t$	Preferred dividends
28. L_{t-1}	Debt in previous period
29. LR_t	Debt repayment
30. S_{t-1}	Common stock in previous period
31. R_{t-1}	Retained earnings in previous period
32. b_t	Retention rate
33. T_t	Average tax rate
34. i_{t-1}	Average interest rate in previous period
35. i_t^e	Expected interest rate on new debt
36. $REBIT_t$	Operating income as a percent of sales
37. U_t^I	Underwriting cost of debt
38. U_t^S	Underwriting cost of equity
39. K_t	Ratio of debt to equity
40. $NUMSCS_{t-1}$	Number of common shares outstanding in previous period
41. m_t	Price-earnings ratio

Source: Lee and Lee (2017), page 1168

earnings are subtracted out. The last quantity is the funds provided by operations during period t .

Once the funds needed for operations are defined, Eq. 8 specifies that new funds, after taking into account underwriting costs and additional interest costs from new debt, are to come from long-term debt and new stock issues. Equations 9 and 10 simply update the debt and equity accounts for the new issues. Equation 11 updates the retained-earnings account for the portion of earnings available to common stockholders from operations during period t . Specifically, b^t is the retention rate in period t and $(1 - T^t)$ is the after-tax percentage, which is multiplied by the earnings from the period after netting out interest costs on both new and old debt. Since preferred stockholders must be paid before common stockholders, preferred dividends must be subtracted from funds available for common stockholders. Equation 12 calculates the new weighted-average interest rate for the firm's debt. Equation 13 is the new debt-to-equity ratio for period t .

Section 4 of Table 1 applies to the common stockholder; in particular, dividends and market value. Equation 14 represents the earnings available for common dividends and is simply the firm's after-tax earnings. Correspondingly, Eq. 15 computes the earnings to be paid to common stockholders. Equation 16 updates the number of common shares for new issues.

As Eq. 17 shows, the number of new common shares is determined by the total new stock issue divided by the stock price after discounting for issuance costs. Equation 18 determines the price of the stock through the use of a price-earnings ratio (m^t) of the stock purchase. Equation 19 determines *EPS*, as usual, by dividing earnings available to common stockholders by the number of common shares outstanding. Equation 20 determines dividends in a similar manner.

Tables 3, 4, and 5 illustrate the setup of the necessary input variables and the resulting output of the pro forma balance sheet and income statement for the Exxon Company. As mentioned, the WS equation system requires values for parameter inputs, which for this example are listed in Table 3. The first column represents the value of the input, while the second column corresponds to the variable number. The third and fourth columns pertain to beginning and ending periods for the desired planning horizon.

From Tables 4 and 5 you can see the type of information the FINPLAN model generates. With 2016 as a base year, planning information is forecasted for the firm over the period 2017–2020. Based on the model's construction, its underlying assumptions, and the input data, the WS model reveals the following:

1. The amount of investment to be carried out
2. How this investment is to be financed
3. The amount of dividends to be paid
4. How alternative policies can affect the firm's market value

Even more important, as we will explore later in this chapter, this model's greatest value (particularly for FINPLAN) arises from the sensitivity analysis that can be

Table 3 FINPLAN inputs

	Value of data	Variable number	Beginning period	Last period
The number of years to be simulated	4	1	0	0

will discuss how we can use the data from Table 3 to calculate by hand the unknown variables in terms of Johnson & Johnson's 2018 annual report.

Section 1: Generation of Sales and Earnings before Interest and Taxes for Period t

$$\begin{aligned}
 (1) \quad Sales_t &= Sales_{t-1} \times (1 + GSALS_t) \\
 &= 81,581 \times 1.1076 \\
 &= 90,359.1156 \\
 (2) \quad EBIT_t &= REBIT_{t-1} \times Sales_t \\
 &= 0.2329 \times 90,359.1156 \\
 &= 21,044.64
 \end{aligned}$$

Section 2: Generation of Total Assets Required for Period t

$$\begin{aligned}
 (3) \quad CA_t &= RCA_{t-1} \times Sales_t \\
 &= 0.5643 \times 90,359.1156 \\
 &= 50,989.65 \\
 (4) \quad FA_t &= RFA_{t-1} \times Sales_t \\
 &= 1.3106 \times 90,359.1156 \\
 &= 118,424.66 \\
 (5) \quad A_t &= CA_t + FA_t \\
 &= 50,989.65 + 118,424.66 \\
 &= 169,414.31
 \end{aligned}$$

Section 3: Financing the Desired Level of Assets

$$\begin{aligned}
 (6) \quad CL_t &= RCL_{t-1} \times Sales_t \\
 &= 0.3828 \times 90,359.1156 \\
 &= 34,589.47 \\
 (7) \quad NF_t &= (A_t - CL_t - PFDSK_t) - (L_{t-1} - LR_t) - S_{t-1} - R_{t-1} - b_t \times \{(1 - T_t) \\
 &\quad [EBIT_t - i_{t-1}(L_{t-1} - LR_t)] - PFDIV_t\} \\
 &= (169,414.31 - 34,589.47 - 0) - (27,684 - 1,555) - 3,120.0 - 106,216 - \\
 &\quad 0.3794 \times \{(1 - 0.1501) \times [21,044.64 - 0.0363 \times (27,684 - 1,555)] - 0\} \\
 &= -7,120.21
 \end{aligned}$$

Please note that we solve the first seven equations step-by-step; however, Eq. 8 through Eq. 13 are interrelated. Therefore, we need to solve these equations in terms of simultaneous equation system approach. To solve this six-equation system, we first start with Eq. 12 as follows. We substitute parameters into Equation 12 and obtain the following result.

$$\begin{aligned}
 (12) \quad i_t L_t &= i_{t-1}(L_{t-1} - LR_t) + i^e_{t-1} \times NL_t \\
 &= 0.0363 \times (27,684 - 1,555) + 0.0363 \times NL_t \\
 &= 948.4827 + 0.0363 \times NL_t
 \end{aligned}$$

We then substitute related parameters into Equations 8, 9, 10, 11, and 13 to create new a simultaneous equation system to solve unknowns NL_t , NS_t , L_t , S_t , R_t , and i_t .

$$(8) \quad NF_t + b_t(1 - T)[i_{t-1} \times NL_t + U^L_t \times NL_t] = NL_t + NS_t$$

$$-7,120.21 + 0.3794 \times (1 - 0.1501) \times (0.0363 \times NL_t + 0.02 \times NL_t) = NL_t + NS_t$$

$$-7,120.21 + 0.01815 \times NL_t = NL_t + NS_t$$

$$(a) \quad NS_t + 0.98185NL_t = -7,120.21$$

$$(9) \quad L_t = L_{t-1} - LR_t + NL_t$$

$$(b) \quad L_t = 27,684 - 1,555 + NL_t$$

$$L_t - NL_t = 26,129$$

$$(10) \quad S_t = S_{t-1} + NS_t$$

$$(c) \quad -NS_t + S_t = 3,120.0$$

$$(11) \quad R_t = R_{t-1} + b_t\{(1 - T_t)[EBIT_t - i_tL_t - U^L_tNL_t] - PFDIV_t\}$$

$$= 106,216 + 0.3794 \times \{(1 - 0.1501) \times [21,044.64 - i_tL_t - 0.02 \times NL_t] - 0\}$$

Substitute (12) into (11)

$$6480.047315952 - 0.018154050978 \quad NL_t$$

$$R_t = 110,551 + 0.3794 \times \{0.8499 \times [21,044.64 - (948.4827$$

$$+ 0.0363 \times NL_t) - 0.02 \times NL_t]\}$$

$$= 117,031.04731 - 0.01815NL_t$$

$$(d) \quad 117,031.04731 = R_t + 0.01815NL_t$$

$$(13) \quad L_t = (S_t + R_t)K_t$$

$$L_t = 1.5598S_t + 1.5598R_t$$

$$(e) \quad L_t - 1.5598S_t - 1.5598R_t = 0$$

$$(b) - (e) = (f)$$

$$26,129 = 1.5598S_t + 1.5598R_t - NL_t$$

$$(f) - 1.5598(c) = (g)$$

$$21,262.424 = 1.5598NS_t - NL_t + 1.5598R_t$$

$$(g) - 1.5598(d) = (h)$$

$$-NL_t + 1.5598NS_t - 0.0283NL_t = -161,282.6036$$

$$-161,282.6036 = 1.5598NS_t - 1.0283NL_t$$

$$(h) - 1.5598(a) = (i)$$

$$-1.0283NL_t - 1.5315NL_t = -150,176.5$$

$$NL_t = 150,176.5/2.5598 = 58667.279$$

Substitute NL_t in (a)

$$NS_t = -64,722.677$$

Substitute NL_t in (b)

$$L_t = 84,796.279$$

Substitute NS_t in (c)

$$S_t = -61,602.677$$

Substitute NL_t in (d)

$$R_t = 118,095.8584$$

Substitute NL_tL_t in (12)

$$i_t = 0.0363$$

Section 4: Generation of Per Share Data for Period t

$$\begin{aligned} (14) \quad EAFCD_t &= (1 - T_t)(EBIT_t - i_tL_t - U^L_tNL_t) - PFDIV_t \\ &= (1 - 0.1501) \times [21,044.64 - 0.0363 \times 84,796.279 - 0.02 \times (58667.279)] - 0 \\ &= 14,272.532 \end{aligned}$$

$$\begin{aligned} (15) \quad CMDIV_t &= (1 - b_t)EAFCD_t \\ &= (1 - 0.3794) \times (14,272.532) \\ &= 8,857.533 \end{aligned}$$

Please note that we solve Eqs. 14 and 15 step-by-step; however, there are simultaneous equation relationships among Eqs. 16, 17, 18, 19, and 20. Now we show how this five-equation system can be used to solve $NUMCS_t$, $NEWCS_t$, P_t , EPS_t , and DPS_t .

$$(16) \quad NUMCS_t = X_1 = NUMCS_{t-1} + NEWCS_t$$

$$X_1 = 2,681.50 + NEWCS_t$$

$$(17) \quad NEWCS_t = X_2 = NS_t/(1 - U^E_t)P_t$$

$$X_2 = -64,722.677/(1 - 0.01)P_t$$

$$(18) \quad P_t = X_3 = m_tEPS_t$$

$$X_3 = 22.3099(EPS_t)$$

$$(19) \quad EPS_t = X_4 = EAFCD_t / NUMCS_t$$

$$X_4 = 14,272.532 / NUMCS_t$$

$$(20) \quad DPS_t = X_5 = CMDIV_t / NUMCS_t$$

$$X_5 = 8,857.533 / NUMCS_t$$

$$(A) = \text{For (18) and (19), we obtain } X_3 = 22.3099(14,272.532 / NUMCS_t) \\ = 318,418.76166 / X_1$$

Substitute (A) into Eq. (17) to calculate (B)

$$(B) = X_2 = -64,722.677 / [(1 - 0.01) \times 318,418.76166 / X_1]$$

$$(B) = X_2 = -0.2053X_1$$

Substitute (B) into Eq. (16) to calculate (C)

$$(C) = X_1 = 2,681.50 - 0.2053X_1$$

$$(C) = X_1 = 2224.7573 = NUMCS_t$$

Substitute (C) into (B)

$$(B) = X_2 = -456.74 = NEWCS_t$$

From Eqs. (19) and (20) we obtain X_4, X_5

$$X_4 = 6.42 = EPS_t$$

$$X_5 = 3.98 = DPS_t$$

From Eq. (18) we obtain X_3

$$X_3 = 143.2296 = P_t$$

Now we summarize the forecasted variables for 2019 as follows:

- Sales = \$90,359.1156
- Current Assets = \$50,989.65
- Fixed Assets = \$118,424.66
- Total Assets = \$169,414.31
- Current Payables = \$34,589.47
- Needed Funds = (\$7,120.21)
- Earnings before Interest and Taxes = \$21,044.64
- New Debt = \$58,667.279
- New Stock = (\$64,722.68)
- Total Debt = \$84,796.279

Table 6 Mean absolute deviation errors for comparing actual vs. forecasted numbers for 2019

	2019 Forecast	2019 Actual	Mean absolute deviation error for forecast variables
Sales	90,357.06	82,059	10.11%
Operating income	21,048.35	23,416	10.11%
Interest expense	3,010.16	318	846.59%
Income before taxes	16,917.74	17,328	2.37%
Taxes	2,539.68	2,209	14.97%
Net income	14,378.06	15,119	4.90%
Preferred dividends	0	0	0.00%
Common dividends	14,378.06	9,917	44.98%
Debt repayments	1,555	2,823	44.92%
Assets			
Current assets	50,984.99	45,274	12.61%
Fixed assets	118,423	17,658	570.65%
Total assets	169,407.99	157,728	7.41%
Liabilities and net worth			
Current liabilities	34,589.56	35,964	3.82%
Long-term debt	82,151.15	26,494	210.07%
Preferred stock	0	0	0.00%
Common stock	-59,003.12	3,120	1991.13%
Retained earnings	111,670.4	110,659	0.91%
Total liabilities and net worth	169,407.99	176,237	3.87%
Computed DBT/EQ	1.56	1.65	5.58%
Int. rate on total debt	0.04	0.01	233.3%
Per share data			
Earnings	6.4109	5.72	12.08%
Dividends	3.9789	3.75	-6.10%
Price	143.0258	145.75	1.87%

- Common Stock = (\$61,602.677)
- Retained Earnings = \$118,095.86
- Interest Rate on Debt = 3.63%
- Earnings Available for Common Dividends = \$14,272.532
- Common Dividends = \$8,857.53
- Number of Common Shares Outstanding = 2,224.76
- New Common Shares Issued = (456.74)
- Price per Share = \$143.23
- Earnings per Share = \$6.42
- Dividends per Share = \$3.98

The above forecasted variables are almost identical to the numbers for 2019 presented in Tables 4 and 5. We use mean absolute deviation error criteria to

compare these forecasted numbers with actual numbers, and the results are presented in Table 6.

99.5 Sensitivity Analysis

The efficiency of the financial planning and forecasting model will depend solely on how it is used. This section looks at alternative uses of financial planning models to improve their information dissemination. One of the most advantageous ways to use these financial planning models is to perform *sensitivity analysis*. The purpose of sensitivity analysis is to hold all but one or perhaps a couple of variables constant and then analyze the impact of their change on the predicted outcome.

Financial planning models are merely forecasting tools to help the financial manager analyze the interactions of important company decisions with uncertain economic elements. Since we can never be precisely sure what the future holds, sensitivity analysis stands out as a desirable manner of examining the impact of the unexpected as well as of the expected.

The simultaneous equations approach, as embodied in Warren and Shelton’s FINPLAN, offers the best method for performing sensitivity analysis. By changing the parameter values, we can compare new outputs of the financial statements with those such as in Tables 4 and 5. The difference between the new statement and the statements in Tables 4 and 5 reflects the impact of potential changes in such areas as *economic conditions* (reflected in the interest rate, tax rate, and sales growth estimates) and *company policy decisions* (reflected in the maximum and minimum limits specified for the maturity and amount of debt and in the dividend policy as reflected in the specified payout ratio).

To perform sensitivity analysis, we change growth in sales (variable 3), operating income as a percentage of sales (variable 17), the P/E ratio (variable 22), the expected interest rate on new debt (variable 16), and long-term debt-to-equity ratio (variable 20). The new parameters are listed in Table 7. Summary results of the alternative sensitivity analyses for *EPS*, *DPS* and price per share (*PPS*) are listed in

Table 7 Sensitivity analysis parameters

Model variable number	Parameter	Alternative values	Sensitivity analysis number
3	Growth in sales	.20	1
		.15	2
20	Long-term debt-to-equity ratio	.10	3
		.5	4
17	Operating income as a percentage of sales	.20	5
		.50	6
22	Price-to-earnings ratio	5	7
		30	8
16	Expected interest rate on new debt	.005	9
		.05	10

Table 8. The results indicate that changes of key financial decision variables will generally affect *EPS*, *DPS*, and *PPS*.

99.6 Francis and Rowell Model

Francis and Rowell (1978) extended Warren and Shelton's (1971) model from 4 sectors into 10 sectors. The object of their model is to generate *pro forma* financial statements that describe the future financial condition of the firm for any assumed pattern of sales. Parameters of various equations in the system can be changed to answer "what if" questions, perform sensitivity analysis, and explore various paths toward some goals or goals that may or may not be optimal. The variable used by the FR model is presented in Table 9. The completed equation system is presented in Table 10.

The model incorporates an explicit treatment of risk by allowing for stochastic variability in industry sales forecasts. The exogenous input of sales variance is transformed (through simplified linear relations in the model) to coefficients of variation for *EBIT* and net income after taxes (*NIAT*). These are used in risk–return functions that determine the costs of new financing.

Lee and Rahman (1997) use dynamic optimal control model to discuss the interactions of investment, financing, and dividend decisions. Lee and Rahman's approach can integrate with Francis and Rowell's model.

The model also incorporates some variables external to the firm that are important from a financial-planning viewpoint. These industry or economy-wide variables are introduced in every sector to enable the financial planner to explore their influence on plans. They include: market share, an industry capacity-utilization index, the tax rate, and a GNP component price index for explicit analysis of the effects of inflation.

The *FR* model explicitly allows for divergence between planned (or potential) and actual levels in both sales and production. That is, sales forecasts and production potential are compared to determine the existence of slack or idle capacity and company expansion possibilities. Any positive difference between potential or forecasted company sales and actual company sales is decomposed into the portion facilities. As a result, a forecasted sales increase need not lead to investment in new capital. Likewise, a forecasted sales downturn would not lead to a divestiture of capital. An advantage of this disaggregation is that it allows for greater realism – that it, it permits both a lagged production response to sales upturns and downturns, as well as lags, overadjustment, and under adjustment in new investment decisions.

The *FR* model offers a disaggregation of the sales equation into separate market share, production, and pricing equations, which has several distinct advantages. It offers the opportunity to treat sales forecast in physical units that can be compared to technical production capabilities in physical units for both potential and actual levels of sales and production. Such disaggregation also allows distinction between physical units of sales and production and dollar units. Therefore, the pricing decision can

Table 8 Summary results of sensitivity analysis for EPS, DPS, and PPS (2017–2020)

Original analysis	2017	2018	2019	2020
<i>EPS</i>	6.73	7.18	7.63	8.10

be treated separately. This feature is helpful in analyzing the effect of changing prices.

Another aspect of the *FR* financial-forecasting model is the econometrical advantage. The *FR* model's risk–return function and its production function are estimated econometrically. Additionally, standard econometric techniques to evaluate goodness-of-fit and predictive power of a simultaneous equation system are reported. In the remaining subsections of this section, the *FR* model is explained in its general form. Then the coefficients of the equations are set to equal to the values that characterize the operations of an existing company, and then the active operations of a well-known firm are simulated, to test this financial model empirically.

99.6.1 The FR Model Specification

The *FR* model is composed of 10 sectors: (1) industry sales, (2) production sector, (3) fixed capital-stock requirements, (4) pricing, (5) production costs, (6) income, (7) new financing required, (8) risk, (9) costs of financing, and (10) common stock valuation.

Looking more deeply reveals that the *FR* model is, to a large extent (but not entirely), recursive between sectors. All entries of the sector-interdependence table, with the exception of one (between sectors seven and nine), are below the diagonal. It has been structured in this manner for the specific purpose of ease of exposition and computation. The simultaneity of the *FR* model is primarily within each sector's equations.

99.7 Summary

Entry 102 has examined three types of financial planning models available to the financial manager for use in analyzing the interactions of company decisions: the algebraic simultaneous equations model, the linear programming model, and the econometric model. We also have discussed the benefits of sensitivity analysis for determining the impact on the company from changes (expected and unexpected) in economic conditions.

The student should understand the basic functioning of all three models, along with the underlying financial theory. Moreover, it is essential to understand that a financial planning model is an aid or tool to be used in the decision-making process and is not an end in and of itself.

The computer-based financial modeling discussed in this chapter can be performed on either a mainframe computer or a PC. An additional dimension is the development of electronic spreadsheets. These programs simulate the matrix or spreadsheet format used in accounting and financial statements. Their growing acceptance and popularity is due to the ease with which users can make changes

in the spreadsheet. This flexibility greatly facilitates the use of these programs for sensitivity analysis.

Appendix A – Description of Parameter Inputs Used to Forecast Johnson & Johnson’s Financial Statements and Share Price

In our financial planning plan program, there are 20 equations and 20 unknowns. To use this program, we need to input 21 parameters. These 20 unknowns and 21 parameters can be found in Table 21.2.

We use 2016 as the initial reference year and input the 21 parameters, the bulk of which can be obtained or derived from the historical financial statements of JNJ. The first input is $SALE_{t-1}$ (\$71,890), defined as fiscal 2016 net sales and can be obtained from the income statement of JNJ. The second input is $GCALS_{t-1}$. This parameter can be calculated by either the percentage change method: $\frac{Sales_{t-1} - Sales_{t-2}}{Sales_{t-2}} = 2.59\%$ or sustainability growth rate: $\frac{ROE_{t-1} * b_{t-1}}{1 - ROE_{t-1} * b_{t-1}} = 12.7\%$.

The third input is RCA_{t-1} (90.46%), defined as current assets divided by total sales, and the fourth input is RLA_{t-1} (1.0596), defined as total asset minus current asset divided by net sales. The next parameter is RCL_{t-1} (36.57%), defined as current liabilities as a percentage of net sales. The sixth parameter is preferred stock issued (PKV), with a value of 0, as JNJ does not currently have any preferred stock outstanding. The inputs for the aforementioned three parameters are all obtained from the JNJ’s fiscal 2016 balance sheet. The seventh input is JNJ’s preferred stock dividends, and since there is no preferred stock outstanding, it is correspondingly 0. The eighth input is LR_{t-1} (\$22,442), defined as long-term debt, coming from the balance sheet of JNJ for the fiscal year 2016, and the ninth input is LR_{t-1} (\$-2,223), defined as long-term debt retirement, from the 2016 statement of cash flows.

The tenth input is S_{t-1} (\$3,120), which represents common stock issued, and the eleventh input is retained earnings (R_{t-1} =\$110,551). Both of these two variables can be found in the balance sheet for JNJ’s fiscal year 2016. The twelfth input is the retention rate (b_{t-1} = 47.88%), defined as $1 - \frac{Dividend\ payout_{t-1}}{Net\ income_{t-1}}$. The thirteenth input, the average tax rate (T_{t-1}), is assumed to be 15%. The fourteenth input is the weighted average effective interest rate (I_{t-1} = 3.33%), which JNJ provides in its annual report (page 53 of the respective 10-K filing). The fifteenth input is expected interest on new debt (ie_{t-1} = 3.68%), calculated as the average of the weighted average interest rates in previous two periods.

The next input is $REBIT_{t-1}$ (28.71%), defined as operating income as a percentage of sales. However, JNJ does not explicitly list operating income in its income statements. Thus, we defined operating income as JNJ’s earnings before provision for taxes on income, with interest expense added back and interest income subtracted out. We also adjusted for non-recurring expenses and added back other income/losses (related primarily to hedging activities, write-downs, and

restructuring charges) to get to an adjusted and normalized operating income figure.

The seventeenth input is the underwriting cost of debt (UL) that we assume to be 2%, and the eighteenth parameter is the underwriting cost of equity (UE = 1%). The nineteen input is the ratio of long-term debt to equity ($K_{t-1} = 31.87\%$), defined as long-term debt divided by total equity. The twentieth input is the number of common shares outstanding ($NUMCS_{t-1} = 2,737.3$) listed in the JNJ's Balance Sheet for fiscal year 2016. The last input is P/E ratio ($m_{t-1} = 19.075$), which is calculated as JNJ's closing share price on the last trading day of 2016 divided by fiscal 2016 net income.

Appendix B – Procedure of Using Excel to Implement the FinPlan Program

This appendix describes the detailed procedure of using Excel to implement the FinPlan program. There are four steps to use the FinPlan program.

Step 1. Open the Excel file of FinPlan Example.

Step 2. Click the “Tools” and see “Macros.” Another way to find it is under “View” and see “Macors.”

Step 3. Choose “Macros” and then click “Run.”

After we obtain the forecasted values from the model, we compare them with the actual data of JNJ in 2019 via calculating the absolute percentage change of error. The following table shows results.

Alternative Errors-in-Variables Models and Their Applications in Finance Research

100

Hong-Yi Chen, Alice C. Lee, and Cheng-Few Lee

Abstract

Specification error and measurement error are two major issues in finance research. The main purpose of this chapter is (i) to review and extend existing errors-in-variables (EIV) estimation methods, including classical method, grouping method, instrumental variable method, mathematical programming method, maximum likelihood method, LISREL method, and the Bayesian approach; (ii) to investigate how EIV estimation methods have been used to finance related studies, such as cost of capital, capital structure, investment equation, and test capital asset pricing models; and (iii) to give a more detailed explanation of the methods used by Almeida et al. (*Review of Financial Studies*, 23, 3279–3328, 2010).

Keywords

Measurement error · Errors-in-variables · Cost of capital · Capital structure · Investment equation · Capital asset pricing model

This chapter is the revised and updated version of our entry entitled “Alternative Errors-in-Variables Models and their applications in Finance Research” which was published in *The Quarterly Review of Economics and Finance* in 2015.

100.1 Introduction

Specification error and measurement error are two major issues in applying the econometric model to economic and finance research. Studies by Miller and Modigliani (1966) and Roll (1969) are two of the earliest finance-related research studies to apply errors-in-variables (EIV) model in their empirical works. Miller and Modigliani (1966) show that, in determining the cost of capital, anticipated average earnings are unobservable and using accounting estimates of earnings as the proxy may result in measurement error problems. Roll (1969, 1977) and Lee and Jen (1978) show that the observed market rate returns in terms of stock market index are measured with errors since the stock market index does not include all assets that can be invested by investors. Roll (1969, 1977) argues that testing capital asset pricing model suffers from an EIV problem and concludes that no correct and unambiguous test of the theory can be accomplished. Lee and Jen (1978) have theoretically shown how beta estimates and Jensen performance measures can be affected by both constant and random measurement errors of the market rate of return and risk free rate. Other issues such as the determination of the capital structure and investment functions also suffer EIV problems.¹

Understanding the existence of measurement error problems on finance-related studies, a large extent of the literature subsequently tries to mitigate biased results from measurement errors. For the issue of the estimation of the cost of capital, Miller and Modigliani (1966) use the instrumental variable approach to resolve the measurement error problem and get consistent estimators in determining the cost of capital. Zellner (1970) and Lee and Wu (1989) also use various estimation methods to deal with potential EIV problems on estimating the cost of capital. For the issue of the capital asset pricing test, Lee and Jen (1978) argue that both market return and beta coefficient are subjected to measurement error, and show how the beta coefficient can be estimated. Lee (1984) shows that the most generalized beta estimate can be decomposed into three components; bias due to specification error, bias due to measurement error, and interaction bias. Therefore, the evidence of failure in capital asset pricing model or the finding of new risk factors might result from model misspecification error or EIV problem. Gibbons and Ferson (1985), Green (1986), Roll and Ross (1994), and Diacogiannis and Feldman (2011) have argued that market portfolio measure with errors is an inefficient portfolio and show how the

¹For the measurement problems related to the determinants of the capital structure, please see Titman and Wessels (1988), Chang et al. (2009), and Yang et al. (2009). For the measurement problems related to the investment function, please see Erickson and Whited (2000, 2002) and Almeida et al. (2010).

inefficient benchmark can affect the theoretical CAPM derivation. For the issue of the determinants of the capital structure, Titman and Wessel (1998), Chang et al. (2009), and Yang et al. (2009) apply structure equation models to investigate determinants of the capital structure. For the measurement error problems related to Tobin's q in investment function, Erickson and Whited (2000) use generalized method of moments (GMM) to obtain consistent estimators in testing q theory. Most recently, Almeida et al. (2010) propose an alternative instrumental method to deal with measurement error problems in Tobin's q and support the q theory.

The main purpose of this chapter is to study existing EIV estimation methods and to discuss how these estimation methods have been used in finance research. We first show how EIV problems affect estimators in the regression model. We further demonstrate seven alternative estimation methods dealing with EIV problems. Classical method, grouping method, instrumental variable method, mathematical programming method, maxima likelihood method, LISREL method, and Bayesian approach will be discussed. Finally, we conduct a survey on various studies and investigate the effect that resulted from EIV problems associated with cost of capital, capital asset pricing model, capital structure, and investment equation. We also investigate the correction models used in such studies to mitigate the problem raised from measurement errors.

The remainder of this chapter is organized as follows. Section 100.2 shows the classical EIV problems and how they affect estimators of the linear regression model. Section 100.3 provides seven alternative correction methods in dealing with EIV problems. Section 100.4 presents the effects of EIV problems on the empirical research of cost of capital, asset pricing, capital structure, and investment decision. Finally, section 100.5 presents the conclusion.

100.2 Effects of Errors-in-Variables in Different Cases

100.2.1 Bivariate Normal Case

Suppose we have a two variate structural relationship

$$V_i = \alpha + \beta U_i \quad (1)$$

Both V_i and U_i are unobserved, while we can observe $Y_i = V_i + \eta_i$ and $X_i = U_i + \varepsilon_i$. We assume that.

- (a) $\varepsilon_i \sim N(0, \sigma_\varepsilon^2)$ and $\eta_i \sim N(0, \sigma_\eta^2)$.
- (b) $E(\varepsilon_i U_i) = 0$, $E(\varepsilon_i V_i) = 0$, $E(\varepsilon_i \eta_i) = 0$, $E(\eta_i U_i) = 0$, and $E(\eta_i V_i) = 0$.
- (c) $U_i \sim N(E(X), \sigma_U^2)$ and $V_i \sim N(\alpha + \beta E(X), \beta^2 \sigma_U^2)$.

This results in measurement error on the estimates of α and β implying that the asymptotic biases for β and α are

$$\text{plim} \hat{\beta} - \beta = \frac{-\beta \sigma_1^2}{\sigma_U^2 + \sigma_1^2} \quad (2a)$$

$$\text{plim} \hat{\alpha} - \alpha = \frac{\beta \sigma_1^2}{\sigma_U^2 + \sigma_1^2} E(X). \quad (2b)$$

Equation (2) implies that $\hat{\beta}$ is downward biased and $\hat{\alpha}$ is upward biased.

100.2.2 Multivariate Case

Suppose we have a trivariate structural relationship

$$W_i = \alpha + \beta U_i + \gamma V_i \quad (4)$$

W_i , U_i , and V_i are unobserved, but we can observe $Z_i = W_i + \tau_i$, $X_i = U_i + \varepsilon_i$, and $Y_i = V_i + \eta_i$. U_i and V_i have a joint normal distribution with variances σ_U^2 and σ_V^2 and correlation coefficient ρ_{UV} . In the observed variables X , Y , and Z , the observed errors ε , η , and τ are independent normal variables with zero means and variance σ_ε^2 , σ_η^2 , σ_τ^2 . X , Y , and Z have a multivariate normal distribution.

The asymptotic biases of $\hat{\beta}$ and $\hat{\gamma}$ can be seen from the following:

$$\text{plim} \hat{\beta} - \beta = \frac{\sigma_{VW} \sigma_\eta^2 - \beta (\sigma_U^2 \sigma_\eta^2 + \sigma_V^2 \sigma_\varepsilon^2 + \sigma_\varepsilon^2 \sigma_\eta^2)}{(\sigma_U^2 \sigma_V^2 - \sigma_{UV}^2) + \sigma_U^2 \sigma_\eta^2 + \sigma_V^2 \sigma_\varepsilon^2 + \sigma_\varepsilon^2 \sigma_\eta^2} \quad (4a)$$

$$\text{plim} \hat{\gamma} - \gamma = \frac{\sigma_{WV} \sigma_\varepsilon^2 - \gamma (\sigma_U^2 \sigma_\eta^2 + \sigma_V^2 \sigma_\varepsilon^2 + \sigma_\varepsilon^2 \sigma_\eta^2)}{(\sigma_U^2 \sigma_V^2 - \sigma_{UV}^2) + \sigma_U^2 \sigma_\eta^2 + \sigma_V^2 \sigma_\varepsilon^2 + \sigma_\varepsilon^2 \sigma_\eta^2} \quad (4b)$$

The direction of the biases of $\hat{\beta}$ and $\hat{\gamma}$ can be treated according to different assumptions.²

Concerning the coefficient of the reliability, Cochran (1970) shows that measurement errors of both explained and explanatory variables will reduce the multiple correlations and increase the residual variance, and the good prediction formula is more sensitive to measurement errors than the poor one. Moreover, from the analysis of the effects of measurement error on both the simple regression coefficient and residual variance, in general, we can conclude that the t statistic of the simple regression coefficient will be downward biased if variables are measured with errors.

²Please see Lee (1973) and Chen (2011) for detail.

100.3 Estimation Methods when Variables Are Subject to Error

In this section, we will discuss alternative EIV estimation methods, classical method, grouping method, instrumental variable method, mathematical method, maxima likelihood method, LISREL method, and the Bayesian approach.

100.3.1 Classical Estimation Method

100.3.1.1 The Classical Method to a Simple Regression Analysis

In general, the classical method considers three cases: (i) either σ_ε^2 or σ_η^2 is known; (ii) $\lambda = \frac{\sigma_\eta^2}{\sigma_\varepsilon^2}$ is known; and (iii) σ_ε^2 and σ_η^2 are known. We can obtain the estimate for β from Eq. (2) under every possible situation as:

$$(i) \quad \hat{\beta} = \frac{S_{XY}}{S_{XX} - \sigma_\varepsilon^2}, \text{ when } \sigma_\varepsilon^2 \text{ is known.} \quad (5)$$

$$\hat{\beta} = \frac{S_{YY} - \sigma_\eta^2}{S_{XY}}, \text{ when } \sigma_\eta^2 \text{ is known.} \quad (6)$$

$$(ii) \quad \hat{\beta} = \frac{(S_{YY} - \lambda S_{XX}) + \left\{ (S_{YY} - \lambda S_{XX})^2 + 4\lambda S_{XY} \right\}^{1/2}}{2S_{XY}}, \text{ when } \lambda = \frac{\sigma_\eta^2}{\sigma_\varepsilon^2} \text{ is known.} \quad (7)$$

(iii) When both σ_ε^2 and σ_η^2 are known, Kendall and Stuart (1961) regarded it as an overidentified situation unless a nonzero covariance between U_i and V_i is introduced. Barnett (1967) followed Kiefer's (1964) suggestion and derived a consistent estimator of $\hat{\beta}$ as one of the real roots of Eq. (19).

$$\begin{aligned} & \hat{\beta}^4 - \left(\frac{1}{b_2} - \frac{\lambda}{b_1} - 2\lambda b_2 \right) \hat{\beta}^3 - 3\lambda \left(1 - \lambda \frac{b_2}{b_1} \right) \hat{\beta}^2 + \lambda^2 \left(\lambda \frac{b_2}{b_1^2} - \frac{1}{b_1} - 2b_2 \right) \hat{\beta} \\ & - \lambda^3 \frac{b_2}{b_1} \\ & = 0, \end{aligned} \quad (8)$$

where $S_{XX} = \frac{\sum_{i=1}^n (X_i - \bar{X})^2}{n}$, $S_{YY} = \frac{\sum_{i=1}^n (Y_i - \bar{Y})^2}{n}$, $S_{XY} = \frac{\sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y})}{n}$, $m_{XX} = \text{Var}(X) = \sigma_U^2 + \sigma_\varepsilon^2$, $m_{YY} = \text{Var}(Y) = \beta^2 \sigma_U^2 + \sigma_\eta^2$, $m_{XY} = \text{Cov}(X, Y) = \beta \sigma_U^2$, $b_1 = \frac{m_{XY}}{m_{XX}}$, $b_2 = \frac{m_{XY}}{m_{YY}}$, and $\lambda = \frac{\sigma_\eta^2}{\sigma_\varepsilon^2}$.

The advantage of the knowledge of both σ_ε^2 and σ_η^2 is that one obtains a more efficient estimator of $\hat{\sigma}_\eta^2$.

The analysis of Eqs. (5), (6), (7), and (8) furnishes us two important implications. First, if only U or V is subject to measurement error, then we know that the maximum likelihood estimator of β is equivalent to fitting a least square line when using the error-free variable as a regressor. Second, if both U and V are measured with errors, then the estimate of β lies between the values estimated from Eqs. (5) and (6). This situation can be further analyzed. The quadratic equation for Eq. (7) is

$$\hat{\beta}^2 S_{XY} + \hat{\beta}(\lambda S_{XX} - S_{YY}) - \lambda S_{XY} = 0. \quad (9)$$

(a) When either $\sigma_\eta^2 \rightarrow 0$ or $\sigma_\varepsilon^2 \rightarrow \infty$, Eq. (6) shows $\hat{\beta} = \frac{S_{YV}}{S_{XV}}$.

(b) When $\sigma_\varepsilon^2 \rightarrow 0$ or $\sigma_\eta^2 \rightarrow \infty$, Eq. (5) shows $\hat{\beta} = \frac{S_{XV}}{S_{XX}}$.

100.3.1.2 The Classical Method to a Multiple Regression Analysis

It is clear that U is orthogonal to V if $\rho = 0$. It is well known that this multiple regression reduces to two simple regression relationships. If $\rho \neq 0$, to identify β and γ , we need to know either the actual values of σ_ε^2 , σ_η^2 , and σ_τ^2 or the relative ratios among σ_ε^2 , σ_η^2 , and σ_τ^2 . We will investigate the following cases:

- (i) $\sigma_\eta^2 = 0$, $\sigma_\varepsilon^2 > 0$, $\sigma_\tau^2 < 0$, and $\sigma_\varepsilon^2 = \lambda \sigma_\tau^2$
- (ii) $\sigma_\varepsilon^2 > 0$, $\sigma_\eta^2 > 0$, and $\sigma_\tau^2 > 0$
 - (a) σ_ε^2 and σ_η^2 are known
 - (b) $\sigma_\eta^2 = \lambda_1 \sigma_\varepsilon^2$ and $\sigma_\tau^2 = \lambda_2 \sigma_\varepsilon^2$

(Case i) Only Z and X are measured with errors.

The estimator of $\hat{\beta}$ can be one of real root of Eq. (10)

$$k_2 \hat{\beta}^2 + k_1 \hat{\beta} + k_0 = 0, \quad (10)$$

where

$$\begin{aligned} k_0 &= \left(S_{XZ} - \frac{S_{XY}S_{YZ}}{S_{YY}} \right), k_1 = - \left(S_{XX} - \frac{S_{XY}^2}{S_{YY}} \right) + \lambda \left(S_{ZZ} - \frac{S_{YZ}^2}{S_{YY}} \right), \text{ and } k_2 = -\lambda k_0 \\ &= -\lambda \left(S_{XZ} - \frac{S_{XY}S_{YZ}}{S_{YY}} \right). \end{aligned}$$

There are three cases to consider:

(a) $\lambda \rightarrow 0$ when $\sigma_\varepsilon^2 \rightarrow 0$, then in this case from Eq. (10), we know that

$$\hat{\beta} = \frac{-S_{XY}S_{YZ} + S_{XZ}S_{YY}}{S_{XX}S_{YY} - S_{XY}^2}. \quad (11)$$

(b) $\lambda \rightarrow \infty$ when $\sigma_\tau^2 \rightarrow 0$, in this case from Eq. (11), we know that

$$\hat{\beta} = \frac{-S_{ZZ}S_{YY} - S_{YZ}^2}{S_{XZ}S_{YY} + S_{XY}S_{YZ}}. \quad (12)$$

(c) When both $\sigma_\varepsilon^2 > 0$ and $\sigma_\tau^2 > 0$, then

$$\hat{\beta} = \frac{k_1 \pm \sqrt{k_1^2 + 4\lambda k_O}}{2\lambda k_O}. \quad (13)$$

When β is determined, γ can also be estimated. After both β and γ are estimated, then α can be estimated by

$$\hat{\alpha} = \bar{Z} - \hat{\beta}\bar{X} - \hat{\gamma}\bar{Y}. \quad (14)$$

(Case ii) When Z , X , and Y are all observed with errors

(a) Both σ_ε^2 and σ_η^2 are known.

We can obtain the two normal equations as follows:

$$S_{XZ} = \beta(S_{XX} - \hat{\sigma}_1^2) + \gamma S_{XY} \quad (15)$$

$$S_{YZ} = \beta S_{XZ} + \gamma(S_{YY} - \hat{\sigma}_\eta^2) \quad (16)$$

Solving Eqs. (15) and (16) by Cramer's rule we have

$$\hat{\beta} = \frac{S_{XZ}S_{YY} - S_{XY}S_{YZ} - S_{XZ}\hat{\sigma}_\eta^2}{S_{XX}S_{YY} - \hat{\sigma}_\varepsilon^2 S_{YY} - \hat{\sigma}_\eta^2 S_{XX} + \hat{\sigma}_\varepsilon^2 \hat{\sigma}_\eta^2 - (S_{XY})^2} \quad (17)$$

$$\hat{\gamma} = \frac{S_{YZ}S_{XX} - S_{XZ}S_{YY} - S_{YZ}\hat{\sigma}_\varepsilon^2}{S_{XX}S_{YY} - \hat{\sigma}_\varepsilon^2 S_{YY} - \hat{\sigma}_\eta^2 S_{XX} + \hat{\sigma}_\varepsilon^2 \hat{\sigma}_\eta^2 - (S_{XY})^2}.$$

(b) Both $\hat{\sigma}_\eta^2 = \lambda_1 \hat{\sigma}_\varepsilon^2$ and $\hat{\sigma}_\tau^2 = \lambda_2 \hat{\sigma}_\varepsilon^2$ are known.

We can obtain β estimator as one of real roots of the following cubic equation

$$\hat{\beta}^3 H_3 + \hat{\beta}^2 H_2 + \hat{\beta} H_1 + H_O = 0, \quad (18)$$

where

$$\begin{aligned}
 H_3 &= S_{XY}S_{YZ}^2 - MS_{XZ}S_{YZ} - \lambda_1 S_{XY}S_{XZ}^2 \\
 H_2 &= -S_{YZ}^2 + 2\lambda_2 S_{XY}^2 S_{YZ} + MTS_{YZ} - M\lambda_2 S_{XY}S_{YZ} - \lambda_1 S_{XZ}^2 S_{YZ} + 2\lambda_1 TS_{XZ}S_{XY} \\
 H_1 &= \lambda_2^2 S_{XY}^3 - 2\lambda_2 S_{XY}S_{YZ}^2 + MT\lambda_2 S_{XY} + \lambda_2 S_{XY}S_{YZ} + \lambda_2 MS_{YZ}S_{XZ} \\
 &\quad - \lambda_1 \lambda_2 S_{XZ}^2 S_{XY} + 2\lambda_1 S_{XY}S_{XZ}^2 - \lambda_1 T^2 S_{XY} \\
 H_0 &= \lambda_2^2 S_{YZ}S_{XY}^2 + \lambda_2^2 S_{XZ}S_{XY} + \lambda_1 \lambda_2 S_{XZ}^2 S_{YZ} + T\lambda_1 \lambda_2 S_{XZ}S_{YZ} - 2\lambda_1 \lambda_2 TS_{XZ}S_{XY}
 \end{aligned}$$

When $\lambda_2 = 0$, Eq. (18) will reduce to a quadratic equation in $\hat{\beta}$.

100.3.1.3 The Constrained Classical Method

Under the classical case (Case ii), if we only know $\hat{\sigma}_\eta = \hat{\sigma}_\epsilon \lambda$, then we can identify β and γ by imposing $\beta + \gamma = 1$.

We can obtain a quadratic equation in $\hat{\beta}$

$$\hat{\beta}^2(1 - \lambda)S_{XY} + \hat{\beta}(S_{YZ} - \lambda S_{XZ} + 2\lambda S_{XY} + S_{YY} - \lambda S_{XX}) + \lambda(S_{XZ} - S_{XY}) = 0. \quad (19)$$

When $\lambda = 0$, Eq. (19) will reduce to

$$\hat{\beta} = -\frac{S_{YZ} + S_{YY}}{S_{XY}}. \quad (20)$$

Imposing $\beta + \gamma = 1$, upon a multiple regression will help to identify the regression coefficients, but it should also be realized that the constrained regression technique will bias the estimates of the regression coefficients if the unrestricted estimator fails to satisfy the restriction $\beta + \gamma = 1$. The advantages and disadvantages of the constrained regression technique have been discussed by Theil (1971) in some detail.

100.3.2 Grouping Method

Following the structural relationship described in Eq. (1)

$$V_i = \alpha + \beta U_i. \quad (1)$$

Both V_i and U_i are unobserved, and only $Y_i = V_i + \eta_i$ and $X_i = U_i + \epsilon_i$ can be observed. There exists EIV bias when using Y_i and X_i , to investigate the relationship between V_i and U_i .

Wald (1940) proposes a two-portfolio grouping method in dealing with the EIV problem when both dependent and independent variables are subject to measurement errors. He suggests that the measurement error can be reduced by grouping

observations into portfolios. In Wald's two-portfolio grouping method, he groups the independent variable either in descending or ascending order, and divides the observations into two equal groups for both dependent and independent variables; therefore, the first-step estimator of the market model, estimated beta risk, can be written as:

$$\hat{\beta} = \frac{(\bar{Y}_1 - \bar{Y}_2)}{(\bar{X}_1 - \bar{X}_2)}, \quad (21)$$

where $\bar{X}_1$ and $\bar{X}_2$ are the arithmetic means of independent variables for the first and the second groups, respectively; and $\bar{Y}_1$ and $\bar{Y}_2$ are the arithmetic means of dependent variables for the first and the second groups, respectively.

Grouping method is widely used in finance-related research. For example, to minimize the EIV problem in testing the asset pricing model, Black et al. (1972), Blume and Friend (1973), Fama and MacBeth (1973), and Litzenberger and Ramaswamy (1979) use two-pass procedure and the k -portfolio grouping method to examine the capital asset pricing model. By combining securities into portfolios, most of the firm-specific component of the returns can be diversified away and the precision of the beta estimates will be enhanced. The grouping method can, therefore, mitigate the problem raised from measurement errors in estimated beta.

However, some limitations affect the grouping method. First, the grouping method shrinks the range of estimators in the first step and reduces statistical power. To mitigate this problem, in two-pass procedure, the grouping method suggests sorting securities on the first-pass estimator first. Then portfolios are formed by grouping securities with same level of first-pass estimators. This sorting procedure is now standard in empirical tests. Second, a trade-off exists between the bias and the variance of the first-pass estimator according to the number of portfolios. Shanken (1992) argues that the grouping method may cause a larger variation in the portfolio beta. As the number of portfolios (N) increases, the magnitude of the bias becomes greater while the variance of the estimator becomes smaller, and vice versa; therefore, an optimal number of portfolios might exist in which a minimum mean squared error can be obtained. More specifically, when risk premium is estimated by the time-series mean of the cross-sectional regression estimates in testing capital asset pricing model, the mean squared error of the risk premium estimate would be dominated by its bias because its variance would monotonically decrease as the testing period becomes longer. Third, the formation of portfolios for the second-pass estimation might cause a loss of valuable information about cross-sectional behavior among individual securities, because the cross-sectional variations would be smoothed out. Fourth, Ahn et al. (2009) argue that the grouping method, although mitigating measurement error, may yield different results by using different portfolio grouping methods.

Although the grouping method suffers from the limitations discussed above, it still has some clear advantages. With the cross-sectional regression in the second pass, interpreting the results in economic terms is straightforward. Examining model misspecification by testing whether firm characteristics, such as firm size and book-to-market ratio, can explain returns across firms is also convenient. Moreover, the

grouping method is intuitive and easy to implement with real data. The grouping method is therefore still preferred in many empirical studies.

100.3.3 Instrumental Variable Method

Durbin (1954) proposes an instrumental variable method to deal with the EIV problem in a regression model. In the instrumental variable method, the instrumental variable, T_i , is an observable variable known to correlate with V_i and U_i , but is independent of η_i and ε_i . Then β can be estimated by

$$\begin{aligned}\hat{\beta} &= \frac{\sum_{i=1}^n (T_i - \bar{T})(Y_i - \bar{Y})}{\sum_{i=1}^n (T_i - \bar{T})(X_i - \bar{X})} \\ &= \frac{\sum_{i=1}^n (T_i - \bar{T})(U_i - \bar{U}) + \sum_{i=1}^n (T_i - \bar{T})(\eta_i - \bar{\eta})}{\sum_{i=1}^n (T_i - \bar{T})(V_i - \bar{V}) + \sum_{i=1}^n (T_i - \bar{T})(\varepsilon_i - \bar{\varepsilon})}.\end{aligned}\quad (22)$$

If $\text{plim} \sum_{i=1}^n (T_i - \bar{T})(U_i - \bar{U})$ exists, then $\hat{\beta}$ is a consistent estimator of β because both ε_i and η_i are independent of T_i . Equation (22) can be written in matrix form as follows:

$$\begin{bmatrix} \hat{\alpha} \\ \hat{\beta} \end{bmatrix} = (\mathbf{T}'\mathbf{X})^{-1}\mathbf{T}'\mathbf{Y}, \quad (23)$$

$$\begin{aligned}\text{where, } \mathbf{T}' &= \begin{bmatrix} 1 & 1 & 1 & \cdots & 1 \\ T_1 & T_2 & T_3 & \cdots & T_n \end{bmatrix} \\ \mathbf{X}' &= \begin{bmatrix} 1 & 1 & 1 & \cdots & 1 \\ X_1 & X_2 & X_3 & \cdots & X_n \end{bmatrix}, \text{ and} \\ \mathbf{Y}' &= [Y_1 \ Y_2 \ Y_3 \ \cdots \ Y_n].\end{aligned}$$

However, finding an instrumental variable uncorrelated with η_i and ε_i while highly correlated with V_i and U_i is difficult. Durbin (1954) suggests that if the order of U_i is the same as the order of X_i , then a better instrumental variable would be $T_i = i$, where X_i are ordered by magnitude. That is, $T' = \begin{bmatrix} 1 & 1 & 1 & \cdots & 1 \\ 1 & 2 & 3 & \cdots & n \end{bmatrix}$ and $X' = \begin{bmatrix} 1 & 1 & 1 & \cdots & 1 \\ X_1 & X_2 & X_3 & \cdots & X_n \end{bmatrix}$. This variable will lead to a more efficient estimate than that of the method of grouping. If we let $T_i = 1$ for X_i greater than its median, $T_i = 0$ for X_i equal to its median, and $T_i = -1$ for X_i smaller than its median, then the

estimator of the instrumental variable method will be the same as the estimator of Wald's two-group grouping method. Therefore, Wald's two-group grouping method is a special case of the instrumental variable method. In other words, the instrumental variable method is more generalized than the grouping method.

Griliches and Hausman (1986) propose an instrumental variable approach to reduce the bias resulted from measurement error. In a panel data framework, they show that instrumental variables estimator is consistent if the measurement error $\varepsilon_{i,t}$ is *i.i.d* across i and t and unobserved independent variable is serially correlated. An instrumental variable using the lags or the difference of lags of the unobserved independent variable can result in a consistent estimator when T is finite and N approaches to infinite.

However, Griliches and Hausman's *i.i.d* assumption is too strong. Biorn (2000) further relaxes Griliches and Hausman's *i.i.d* assumption, and, instead, assumes that the regressor has τ period moving average process. Biorn (2000) shows that using the lags of the variables at least $\tau - 2$ periods as instruments can clear the memory of the moving average process and obtain the consistent estimator.

Lewbel (1997) show simple functions of the model data can be used as instruments for two-staged least squares (TSLS) estimation. Such instruments can be used for identification and estimation when no other instruments are available or improve efficiency.

Given the standard linear regression model with measurement error:

$$Y_i = a + b'W_i + cX_i + e_i, \text{ and} \quad (24)$$

$$Z_i = d + X_i + v_i, \quad (25)$$

in which Y_i , W_i , and Z_i are observable for $i = 1, \dots, n$, while X_i , e_i , and v_i are unobservable. Eqs. (24) and (25) imply that

$$Y_i = \alpha + b'W_i + cZ_i + \varepsilon_i. \quad (26)$$

However, since both Z_i and ε_i depend on v_i , estimators of b and c from OLS regression is inconsistent. Lewbel (1997) shows that the consistent estimators can be obtained by using TSLS with instruments 1 , W_i , and q_i , where q_i is some vector of instruments that are correlated with X_i but not correlated with e_i and v_i .

Lewbel (1997) further empirically applies the instrumental variable method to testing elasticity of patent applications with respect to research and development (R&D) expenditures. He finds, using the TSLS instrumental variable model, the estimated elasticity yields very close to one. Therefore, the TSLS instrumental variable model can mitigate the effects of measurement error and confirm the relationship between patent and R&D.

In addition, Erickson and Whited (2000, 2002) propose a two-step generalized method of moments (GMM) estimators that exploit over-identifying information contained in the high-order moments of residuals obtained from perfectly measured regressors. Basing GMM estimation on residual moments of more than second order requires that the GMM covariance matrix be explicitly adjusted to account for the fact that estimated residuals are used instead of true residuals defined by population

regressions. Erickson and Whited (2000) show that estimators obtained by using moments up to seventh order perform well in Monte Carlo simulations.

Almeida et al. (2010) use Monte Carlo simulations and empirically test investment models to compare the performance of the instrumental variables approach suggested by Biorn (2000) and generalized method of moments. They find that the instrumental variable method can obtain more consistent and efficient estimators than generalized method of moments when independent variables are subject to measurement error.

However, it is difficult to obtain appropriate instrument variables, resulting in weak evidence in empirical research. Lewbel (2012) proposes a new method to deal with measurement error problems in regression model when instrumental variables are not available. Under the assumption of heteroscedastic errors, Lewbel (2012) shows that the regression model with measurement regressors can be identified and estimated by TSLS or GMM.

100.3.4 Mathematical Method

100.3.4.1 Bivariate Case

Deming (1943), York (1966), and Clutton-Brock (1967) have developed a weighted-regression-method-under-iteration approach. Deming (1943) proposed that the best straight line of Eq. (1) can be obtained by minimizing the sum in the following equation:

$$S = \sum_i \left\{ w(X_i) (\hat{U}_i - X_i)^2 + w(Y_i) (\hat{V}_i - Y_i)^2 \right\} \quad (27)$$

$\hat{U}_i$ and $\hat{V}_i$ are the adjusted value of X_i and Y_i , which make the sum in Eq. (27) a minimum. Since we require $\hat{U}_i$ and $\hat{V}_i$ to lie on the best straight line, we must have

$$\hat{V}_i = \alpha + \beta \hat{U}_i, \quad (i = 1, \dots, n) \quad (28)$$

Both $w(X_i)$ and $w(Y_i)$ are the weights of various observations. They are reciprocally proportional to the variance of their measurement error, respectively.

If these values of $\hat{U}_i$, $\hat{V}_i$, α , and β make S a minimum, we have

$$\begin{aligned} & \beta^3 \sum_i \frac{k_i^2 x_i^2}{w(X_i)} - 2\beta^2 \sum_i \frac{k_i^2 x_i y_i}{w(X_i)} - \beta \left\{ \sum_i k_i x_i^2 - \sum_i \frac{k_i^2 y_i^2}{w(X_i)} \right\} + \sum_i k_i x_i y_i \\ & = 0, \end{aligned} \quad (29)$$

where $x_i = X_i - \bar{X}$, $y_i = Y_i - \bar{Y}$,

$$\bar{X} = \frac{\sum_i k_i X_i}{\sum_i k_i}, \quad \bar{Y} = \frac{\sum_i k_i Y_i}{\sum_i k_i}$$

and

$$k_i = \frac{w(X_i)w(Y_i)}{\beta^2 w(Y_i) + w(X_i)}.$$

Equation (29) is the least-square cubic derived by York (1966). To solve Eq. (29), an initial value is assigned to β to estimate k_i . After obtaining the roots of Eq. (29), one of the legitimate solutions is assigned to estimate k_i and obtain new solutions for β again. A similar procedure is employed iteratively until a convergent solution is obtained.

The mathematical approach involves the estimation of the parameters of a function conditional on the maximum likelihood function adjusted for the true values. This method is different from the classical method in three ways. First, variances of measurement errors for every observation are different. Second, a weighted regression method is applied. Third, the iteration procedure is used to obtain a consistent estimator.

It can be proved that the mathematical programming method reduces to the classical method under three certain conditions.

- (i) Only Y_i has an EIV problem

We can put more weight on X_i which has no EIV problem, $w(X_i) = \infty$, $k_i = w(Y_i)$. We can therefore solve the least square cubic

$$\beta = \frac{\sum_i w(Y_i) x_i y_i}{\sum_i w(Y_i) x_i^2}, \quad (30)$$

which is the estimated coefficient of weighted regression of Y_i on X_i .

- (ii) Only X_i has an EIV problem

In this case, we put more weight on Y_i which has no EIV problem, then $w(Y_i) = \infty$, $k_i = \frac{w(X_i)}{\beta^2}$. We can solve the least square cubic

$$\beta = \frac{\sum_i w(X_i) y_i^2}{\sum_i w(X_i) x_i y_i}, \quad (31)$$

which is the inverse estimated coefficient of weighted regression of Y_i on X_i .

- (iii) Both X_i and Y_i have EIV problem, and $w(X_i)/w(Y_i) = c$.

The least square cubic becomes

$$\beta^2 + \beta \frac{\{c \sum_i k_i x_i^2 - \sum_i k_i y_i^2\}}{\sum_i k_i x_i y_i} - c = 0 \quad (32)$$

100.3.4.2 Multivariate Case

Lee (1973) extends the bivariate mathematical programming method, which was developed by Deming (1943), York (1966), and Clutton-Brock (1967), to a trivariate

case. We define $w(Z_i)$, $w(X_i)$, and $w(Y_i)$ which are the weights of the various observations of Z_i , X_i , and Y_i . It is assumed W , U , and V are functionally rather than structurally related. The mathematical programming procedure begins by minimizing³

$$S = \sum_i \left\{ w(X_i)(x_i - X_i)^2 + w(Y_i)(y_i - Y_i)^2 + w(Z_i)(z_i - Z_i)^2 \right\} \quad (33)$$

s.t. $z_i = \alpha + \beta x_i + \gamma y_i$.

This extension will reduce to Deming's (1943) weighted regression results when the quadratic term of equations are omitted, while Lee's (1973) result is more general than Deming's weighted multiple regression analysis.

100.3.5 Maximum Likelihood Method

In testing capital asset pricing model with dividend and tax, Litzenberger and Ramaswamy (1979) use maximum likelihood method to reduce the effect of errors-in-variables. Litzenberger and Ramaswamy (1979) show that, assuming that the variance of the measurement error in beta is known, the cross-sectional variance of true betas can be replaced by the difference in the variation of the observed betas and the variance of the measurement error. Then the estimator in capital asset pricing model test, under such condition, is consistent by maximum likelihood method.

Kim (1995, 1997, 2010) further provides a maximum likelihood method to correct the EIV problem in testing the asset pricing model. Based upon two-pass capital asset pricing model, Kim (1995) shows that in a multifactor asset pricing model test the EIV leads to an underestimation of the independent variable with a measurement error and an overestimation of the independent variable without measurement error. To correct EIV biases, Kim (1995) extracts additional information about the relation between idiosyncratic error variance, which can be obtained from the first step and the measurement error variance, and incorporates such additional information into the second step of the capital asset pricing model test. Assuming the homoscedasticity of the disturbance term of the market model, Kim (1995) shows that the corrected factors for the traditional least squares estimators of the cross-sectional regression coefficients can be obtained by the maximum likelihood method. The closed form estimators of the multifactor asset pricing model test can therefore be obtained. Assuming the first and second steps of the multifactor asset pricing model are

$$R_{i,t} = \alpha_i + \beta_i R_{m,t} + e_{i,t}, \quad \text{and} \quad (34)$$

$$R_{i,t} = \gamma_{0,t} + \gamma_{1,t} \hat{\beta}_{i,t-1} + \gamma_{2,t} V_{i,t-1} + e_{i,t}, \quad (35)$$

³Please see Lee (1973) for the solution of Eq. (33).

where $\beta_{i,t-1}$ is the market risk factor with measurement error, and $V_{i,t-1}$ is a risk factor with no measurement error for security i at time $t-1$. The adjusted estimators in the second step can be written as follows:

$$\begin{aligned}\hat{\gamma}_{1t} &= \frac{M + \left[M^2 + 4\delta_t m_{R\beta}^2 \left(1 - \left(\hat{\rho}_{RV} \hat{\rho}_{\beta V} / \hat{\rho}_{R\beta} \right)^2 \right) \right]^{1/2}}{2m_{R\beta} \left(1 - \left(\hat{\rho}_{RV} \hat{\rho}_{\beta V} / \hat{\rho}_{R\beta} \right) \right)} \\ \hat{\gamma}_{2t} &= \left(m_{RV} - \hat{\gamma}_{1t} m_{\beta V} \right) / m_{VV} \\ \hat{\gamma}_{0t} &= \tilde{R}_t - \hat{\gamma}_{1t} \tilde{\beta}_{t-1} - \hat{\gamma}_{2t} \tilde{V}_{t-1}\end{aligned}\quad (36)$$

where $M = m_{RR} \left(1 - \hat{\rho}_{RV}^2 \right) - \delta_t m_{\beta\beta} \left(1 - \hat{\rho}_{\beta V}^2 \right)$,

$$\begin{aligned}m_{xy} &= (1/N) \sum_{i=1}^N \sum_{j=1}^N w_{ij} (x_i - \bar{x})(y_i - \bar{y}) / \sum_{i=1}^N \sum_{j=1}^N w_{ij}, \\ \bar{x} &= \sum_{i=1}^N \sum_{j=1}^N w_{ij} x_i / \sum_{i=1}^N \sum_{j=1}^N w_{ij}, \\ \bar{y} &= \sum_{i=1}^N \sum_{j=1}^N w_{ij} y_i / \sum_{i=1}^N \sum_{j=1}^N w_{ij},\end{aligned}$$

w_{ij} is the (i, j) element of inverse matrix of residual variance in the first step, $\hat{\Sigma}_e^{-1}$, and

$$\hat{\rho}_{xy}^2 = m_{xy} / (m_{xx} m_{yy})^{1/2}.$$

As a result, the maxima likelihood method can correct the problem on exaggerating the estimated coefficient associated to the variable without measurement error. Moreover, the absolute value of estimated intercept by maxima likelihood method is generally smaller than the absolute value of estimated intercept by traditional least squares.

100.3.6 LISREL and MIMIC Methods

Goldberger (1972) conceptually described the LISREL model as a combination of factor analysis and econometrics model. In addition, Anderson (1963) has shown that factor analysis is a generalized version of errors-in-variables (EIV) methods. In this section, we will review and discuss how LISREL and multiple indicators and multiple causes (MIMIC) methods can be used to deal with EIV in finance research.

The linear simultaneous equation system is widely used in finance and accounting-related research. However, a serious limitation of the simultaneous equation approach is an EIV problem. For example, the theoretical determinants of

capital structure in corporate finance can be attributed to unobservable constructs that are usually measured in empirical studies by a variety of observable indicators or proxies. These observable indicators or proxies can then be viewed as measures of latent variables with measurement errors. Maddala and Nimalendran (1996) show that the use of these indicators as theoretical explanatory variables may cause EIV problems. Bentler (1983) also emphasizes the estimated results of the traditional simultaneous equation model has no meaning when variables have measurement errors. Therefore, the latent variable covariance structure model is provided and applied in corporate finance. Titman and Wessels (1988), Chang et al. (2009), and Yang et al. (2009) mitigate the measurement problems of proxy variables, and apply structure equation models (e.g. LISREL model and MIMIC model) to determine capital structure decision. Maddala and Nimalendran (1996) use the structure equation model to examine the effect of earnings surprises on stock prices, trading volumes, and bid-ask spreads.

Goldberger (1972) and Jöreskog and Goldberger (1975) developed a structure equation model with multiple indicators and multiple causes of a single latent variable, MIMIC mode, and obtained maximum likelihood estimates of parameters. Figure 1 shows the path diagram that depicts a simplified MIMIC model in which variables in a rectangular box denote observable variables, while variables in an oval box are latent constructs. In this diagram, observable variables X_1 , X_2 , and X_3 are causes of the latent variable η , while Y_1 , Y_2 , and Y_3 are indicators of η . In our study, X s are determinants of capital structure (η), which are then measured by Y s.

Jöreskog and Sörbom (1989) show that the full structural equation (LIEREL model) can be restricted to a MIMIC model. We here discuss the structural model and show how structural model can be restricted to a MIMIC model.

100.3.6.1 Structural Model (LISEREL Model)

A structural equation model is composed of two sub-models – structural sub-model and measurement sub-model. The structural model can be defined as.

$$\eta = \Gamma X + \zeta, \quad (37)$$

$$Y = \Lambda_y \eta + \varepsilon, \quad (38)$$

Fig. 1 Path diagram of a simplified MIMIC model

where Y is a vector of indicators of the latent variable η , and X is a vector of causes of η .

The latent variable η is linearly determined by a set of observable exogenous causes, $X = (x_1, x_2, \dots, x_q)'$, and a disturbance ζ . The latent variable η , in turn, linearly determines a set of observable endogenous indicators, $Y = (y_1, y_2, \dots, y_p)'$ and a corresponding set of disturbance, $\varepsilon = (\varepsilon_1, \varepsilon_2, \dots, \varepsilon_p)'$.⁴

100.3.6.2 MIMIC Model

Substituting Eq. (38) into Eq. (39), we obtain a reduced form:

$$Y = \Lambda_y \eta + \varepsilon = \Lambda_y (\gamma' X + \zeta) + \varepsilon = \Pi' X + z \quad (39)$$

In structural equation modeling, the total effect of a cause variable on an indicator can be measured as the sum of the direct effect and the indirect effect. Since a MIMIC model is a reduced form of a structural equation model, the total effect of MIMIC model, denoted as Π' in Eq. (39), comes merely from the indirect effect.

Since the scale of the latent variable is unknown, the factor indeterminacy is a common problem in the MIMIC model, as in other structure equation models. We can obtain infinite parameter estimates from the reduced form by arbitrarily changing the scale of the latent variables. However, by fixing the scales of latent variables, one can solve the indeterminacy problem. Two methods are usually adopted to fix the scale of latent variables. One method is normalization in which a unit variance is assigned to each latent variable, while another method is to fix a nonzero coefficient at unity for each latent variable.

In terms of estimation of the parameters, Jöreskog and Goldberger (1975) adopt the normalization method to deal with the factor indeterminacy problem and use maximum likelihood estimation method in structural equation modeling to estimate parameters. The maximum likelihood estimates for the parameters of the model are obtained at the minimization of the fit function as follows:

$$F = \log \|\Sigma\| + \text{tr}(S\Sigma^{-1}) - \log \|S\| - (p-q), \quad (40)$$

where Σ is the population covariance matrix; S is the model-implied covariance matrix; p is the number of exogenous observable variables; and q is the number of endogenous observable variables. Minimization of the fit function can be done by the LISREL program provided by Jöreskog and Sörbom (1981).

100.3.7 Bayesian Approach

Zellner (1970) uses the Bayesian approach to deal with measurement problems in the estimation of regression relationships containing unobservable independent

⁴Stapleton (1978) further develops MIMIC with more latent variables.

variables. Zellner (1970) shows that the Bayesian approach can obtain optimal estimates under a finite sample. Several studies use Bayesian approaches to examine cost of capital (e.g., Lee and Wu 1989) and asset pricing models (e.g., Ang and Chen 2007; Davis 2010; Geweke and Zhou 1996; McCulloch and Rossi 1991).

Davis (2010) develops a Bayesian approach and uses US firm level data to reexamine the capital asset pricing model. The Bayesian approach can estimate all parameters simultaneously in one step and effectively avoid the errors-in-variables problem on the estimators induced from two-pass capital asset pricing test.

Davis (2010) uses a Bayesian approach to simultaneously estimate coefficients of the following three equation system.

$$r_{i,t,y} = \alpha_{i,y} + \gamma_{i,y}r_{m,t,y} + \delta_{i,y}r_{m,t-1,y} + \varepsilon_{i,t,y}, \text{ where } \varepsilon_{i,t,y} \sim N(0, \sigma_{r_{i,y}}^2); \quad (41)$$

$$\overline{r_{i,y}} - \overline{r_{f,y}} = c_{0,y} + c_{m,y}\beta_{i,y} + \eta_{i,y}, \quad (42)$$

where $\eta_{i,y} \sim N(0, \sigma_y^2)$ and $\beta_{i,y} \sim \gamma_{i,y} + \delta_{i,y}$;

$$\mathbf{c}_y = \begin{bmatrix} c_{0,y} \\ c_{m,y} \end{bmatrix} \tilde{N}(\mathbf{c}, \mathbf{V}_c), \text{ where } \mathbf{c} = \begin{bmatrix} c_0 \\ c_m \end{bmatrix} \text{ and } \mathbf{V}_c = \begin{bmatrix} \sigma_0^2 & \sigma_{0m}^2 \\ \sigma_{0m}^2 & \sigma_m^2 \end{bmatrix}; \quad (43)$$

where $r_{i,t,y}$ is firm i 's return in month t during the time period y , and $\overline{r_{i,y}} - \overline{r_{f,y}}$ denotes the average monthly excess return for firm i during the time period y . The model allows firm-level β s to vary over each time period, y . The model also assumes that the joint normality of stock returns and market returns, contemporaneously estimated β s, and average excess returns are statistically independent.

In addition to dealing with errors-in-variables problem, there are several advantages using the Bayesian approach to test the capital asset pricing model. First, the Bayesian approach allows β s to vary over time periods and firms and controls the inherent uncertainty associated with firm-level β s. Second, the Bayesian approach can modify the distribution assumptions in stock returns and market returns. Third, the Bayesian inference is free from the use of asymptotic approximations and therefore can be used under finite sample. Fourth, the Bayesian approach takes parameter uncertainty associated with all the model parameters into account.

100.4 Applications of Errors-in-Variables Models in Finance Research

For the last four and a half decades, EIV models have been used to correct estimation bias associated with empirical results in various finance-related research issues. We here review four kinds of research, cost of capital, asset pricing models, capital structure, and investment equation, and discuss how EIV models can remedy measurement error problems induced from finance-related research. It is therefore

useful to understand the statistical properties of these EIV models in situations resembling real research question.

The main focus of this section is to discuss the measurement error problems on various empirical studies related to finance research and investigate how EIV models can remedy such problems. However, in empirical studies, it is impossible to observe variables without measurement error. We cannot evaluate EIV models and suggest a best EIV model for a certain circumstance. Instead, we here provide Table 1 to summarize the application of EIV models in finance-related research. Research topics, EIV models, specialties of EIV model, and results for each study are included in Table 1.

100.4.1 Cost of Capital

Miller and Modigliani (1966) developed a theoretical expression for the value of a firm from which the firm's cost of capital could be derived. They assume a perpetual stream of earnings from real assets, and a constant capitalization rate (ρ), at which the market discounts the uncertain pure (unlevered) equity stream of earnings for some risk classes and perfect markets. It is thus possible to estimate the market capitalization rate (and thus the cost of capital) of a group of firms by performing a cross-sectional regression of the market value of the firm's equity on the expected average earnings of the firm, the market value of debt, and the growth resulting from the above-average investment opportunities. The above analysis suggests a cross-sectional regression:

$$(V - \tau_c D) = a_0 + a_1 \bar{X}(1 - \tau_c) + a_2(\text{growth potential}) + \varepsilon, \quad (44)$$

where V is sum of the market value of all securities issued by the firm, τ_c is the corporate tax rate, D is the market value of a firm's debt, and $\bar{X}$ is the expected level of average annual earnings generated by current assets.

To avoid heteroscedasticity of regression residuals, the equation must be adjusted to compensate for the dominance of the large companies. Miller and Modigliani (1966) use weighted least square to adjust the standard deviation of the error term to firm size (deflating each variable by the book value of total assets). Therefore Eq. (44) can be adjusted to:

$$\frac{(V - \tau_c D)}{A} = \frac{a_0}{A} + a_1 \bar{X} \frac{(1 - \tau_c)}{A} + a_2 \frac{\Delta \bar{A}}{A} + u, \quad (45)$$

where $u = \varepsilon / A$. With this reformulation, the regression equation is expected to be homogeneous, that is, to have no constant term, and the term A , total assets, is used to avoid heteroscedasticity.

An additional problem beyond that of heteroscedasticity is the possible error of measurement associated with the earnings term. Since anticipated average earnings are essentially unobservable, accounting-statement estimates of earnings must be

Table 1 Applications of errors-in-variables models in finance research

Study	Issue	Method	Specialties/ conditions	Results
Miller and Modigliani (1966)	Determinants of cost of capital	Instrumental variable method	Have to find exogenous variables	Measurement error problem matters
Black et al. (1972)	CAPM test	Grouping (10 groups)	Panel data; 2-pass estimation	Reject both the CAPM and the zero-beta CAPM
Blume and Friend (1973)	CAPM test	Grouping (12 groups)	Panel data; 2-pass estimation	Linear model is better than quadratic model in explaining expected return Reject both the CAPM and the zero-beta CAPM
Fama and MacBeth (1973)	CAPM test	Grouping (20 groups), period by period	Panel data; 2-pass estimation	Find a linear relationship between the expected return and beta risk, beta is the only risk measure in explaining expected return, and risk premium is greater than zero CAPM and efficient capital market hold
Higgins (1974)	Determinants of cost of capital	Smoothing procedure	Assume that measurement error has zero mean and serially uncorrelated	The extrapolation of historical population trends is superior to the conventional use of change of capital, and share prices are not a positive function of dividends as often suggested
Lee (1977)	CAPM test	Wald's grouping/ instrumental variable	Adjust for measurement error of market return in first-step	Estimated risk premium is larger than realized risk premium Reject CAPM
Litzenberger and Ramaswamy (1979)	CAPM test	MLE, OLS, GLS	For individual stocks	Before-tax expected rates of return are linearly related to systematic risk and dividend yield MLE can obtain consistent estimators without losing

(continued)

Table 1 (continued)

Study	Issue	Method	Specialties/ conditions	Results
				efficiency CAPM is rejected because of nonzero $\hat{\gamma}_0$
Cheng and Grauer (1980)	CAPM test	Grouping (20 groups)	Price-level testing (invariance law)	Neither framework of invariance law nor security market line can accommodate the possibility that the CAPM may hold for each period Reject CAPM
Gibbons (1982)	CAPM test	One-step Gauss- Norman procedure (40 groups)	One-step estimation	Gauss-Norman procedure can increase the precision of estimated risk premium Reject CAPM
Titman and Wessels (1988)	Determinants of capital structure	LISREL model	Deal with EIV problem due to the imperfect representation of proxy variables for interested attributes	Do not support for four of eight propositions on the determinants of capital structure A firm's capital structure is not significantly related to its non-debt tax shields, volatility of earnings, collateral value of assets, and future growth
Lee and Wu (1989)	Determinants of cost of capital	Zellner's EV method	Use sample information to estimate the ratio of error variances and construct an operational estimator	Obtain better cost of capital estimates
MacKinlay and Richardson (1991)	CAPM test	GMM	Release the assumption of the normality of asset returns	Conclusions of mean-variance efficiency vary by settings
Shanken (1992)	CAPM test	MLE	For individual stocks; deal with small-sample bias in the second-step	The adjustment does not have much effect on Fama and MacBeth's (1973)

(continued)

Table 1 (continued)

Study	Issue	Method	Specialties/ conditions	Results
			cross-sectional regression estimates	conclusion Support CAPM
Fama and French (1992)	CAPM test	2-way grouping (10 × 10 groups)	Take size and book-to-market ratio into account	The market capitalization and the book-to-market ratio can replace beta altogether Reject CAPM
Jagannathan and Wang (1996)	CAPM test	Multifactor Asset Pricing Model	Test conditional CAPM	Including human capital and business cycle can increase explanatory power of expected return Support CAPM
Kim (1995, 2010)	CAPM test	MLE	Closed form adjustment; for individual stocks or groups	MLE method can effectively adjust the errors-in-variables bias and CAPM holds Support CAPM
Kim (1997)	CAPM test	MLE	Closed form adjustment; for individual stocks or groups; for multifactor estimation	Linear relationship between beta and expected return Book-to-market ratio has significant explanatory power for expected return, but size has not
Lewbel (1997)	Elasticity of patent applications to R&D expenses	Instrumental variable method	Applicable if no outside data available for use as instruments	TSLS estimator can mitigate the effects of measurement error The estimated elasticity of patent applications with respect to R&D expenditures yields very close to one
Erickson and Whited (2000)	Test q theory	GMM	For balanced panel data	Cash flow does not affect firms' financial decision, even for financially constrained firms Support the q theory if measurement error is taken into account
Pastor et al. (2008)		Implied cost of capital	Use earnings forecasts to compute	The implied cost of capital can capture

Chen et al. (2019)	Determinants of capital structure	SEM with CFA approach	Jointly determine capital structure and return	SEM with CFA approach outperforms MIMIC model and 2SLS method in terms of the joint determinants of capital structure and stock return

used instead. Therefore, the true relation between value and anticipated earnings, when replaced by the observable estimates, implies a simultaneous system of relationships:

$$V_i^* = \alpha X_i^* + \sum_j \beta_j Z_{ij} + u_i, \quad (46)$$

$$X_i = X_i^* + v_i, \quad (47)$$

$$X_i^* = \sum_j \delta_j Z_{ij} + w_i, \quad (48)$$

where $V_i^* = \frac{V_i - \tau_c D_i}{A_i}$, $X_i^* = \frac{\bar{X}(1 - \tau_c)}{A_i}$ (the true anticipated earnings); v_i = measurement errors associated with current earnings; X_i = observable estimate of earnings derived from the accounting statements; and Z_{ij} = other relevant variables determining earnings. Equations (46), (47), and (48) are related to anticipated earnings and a set of explanatory variables, which may also be correlated with the firm's anticipated earnings.

In addition, the earnings variable used in the regression only approximates the true value of anticipated earnings, varying by the error of measurement, v_i . The system represents the simultaneous determination of two endogenous variables, V^* and X , by the Z_j exogenous variables. In regressing:

$$V_i^* = \alpha X_i + \sum_j \beta_j Z_{ij} + U' \quad (49)$$

the coefficients will be biased. The coefficient for earnings, α , will have a downward bias.

In an attempt to remedy the simultaneous-equation bias, Miller and Modigliani (1966) use an instrumental-variable approach. In this approach, the endogenous variable X is first regressed against all the instrumental variables, Z_j , to obtain estimates of the various coefficients. These estimates are then used to develop a new variable, $\hat{X}$, which is

$$\hat{X}_i^* = \sum_j \hat{\delta}_j Z_{ij} \quad (50)$$

Depending on the choice of Z_j , the new estimate of earnings, $\hat{X}_i^*$, should be relatively free of the error measurement. It can then be used in the second-stage regression as the earnings variable. The resulting estimates of α and β can be shown to be consistent.

Miller and Modigliani (1966) hypothesized that the constant term was really zero. The reduction of bias on the estimates through the use of the two-stage process also seems to support the hypothesis that the constant term is zero. Miller and Modigliani (1966) state that the reason the constant term was significantly different from zero for the direct least-squares cases was that the error of measurement for earnings was large. This error is reduced by the two-stage process.

Higgins (1974) derives and tests a finite-growth model for the estimation of the cost of capital and share price of electric utility industry between 1960 and 1968. He suggests that the market value of equity is related to the trend of earnings and the trend of population in utility's service area. Assuming that observations of a variable consist of a true component and a random element, if such random elements have zero mean and are serially uncorrelated, the smoothing procedure can reduce potential errors in measurement. Empirical results show that the extrapolation of historical population trends is superior to the conventional use of change of capital, and share prices are not a positive function of dividends as often suggested.

Zellner (1970) proposes a least squares regression method to deal with potential errors-in-variables problems. He shows that his methods utilize more information than traditional instrumental variables methods do in dealing with an errors-in-variables problem. Lee and Wu (1989) further apply Zellner's method to reexamine Miller and Modigliani's (1966) cost of capital estimation for utility industry and obtain better cost of capital estimates than OLS methods and instrumental variable method.

More recently, Pastor et al. (2008) propose an implied cost of capital, which is calculated by earnings forecasts, and argue that the implied cost of capital can capture time variation in expected stock returns. Ortiz-Molina and Phillips (2014) adopt Pastor et al. (2008) method to investigate the relationship between real asset liquidity and the cost of capital, and find the implied cost of capital can mitigate measurement error problem on determining the cost of capital. Guay et al. (2011) further propose the implied cost of capital corrected sluggish analyst forecast to improve the ability to explain cross-sectional variation in future stock returns.

100.4.2 Capital Asset Pricing Model

The capital asset pricing model (CAPM) developed by Sharpe (1964), Lintner (1965), and Mossin (1966) implies that the expected returns on securities and their market risks (β) are positively and linearly correlated and that market risks have sufficient power to explain expected returns of securities. Black et al. (1972), Fama and MacBeth's (1973), and others use the two-step method to test CAPM. In the first step, estimated betas are obtained by time-series market model for each security. In the second step, the estimated betas are used in testing the linear relationship between betas and expected returns on securities. Because estimated betas are subjected to a measurement error (estimation error) problem, there exists an EIV problem in the second step. The EIV problem will result in estimating the explanatory power of beta and the estimated rate of return on beta risk. More specifically, the EIV problem leads to an underestimation of the coefficient associated with beta risk. Although the EIV problem exists in the two-step method of the asset pricing test, most researchers do not carefully use sophisticated econometric and statistical methods to deal with this kind of problem. Roll (1969, 1977) shows that the testing asset pricing model suffers an EIV problem, concluding that (i) no correct and unambiguous test of the theory has appeared in the literature, and (ii) practically

no possibility exists that such a test can be accomplished in the future. Roll and Ross (1994) show that the measurement error problem of market rate of return can bias the empirical test of CAPM.

Several studies focus on beta estimation in the first step to solve the EIV problem in testing CAPM. Brennan (1970), Lee and Jen (1978), and Roll (1977) show that the possible measurement error in market beta risk is the unobserved market rate of return and risk-free rate of return.⁵ To improve the beta estimator, Fabozzi and Francis (1978) and Lee and Chen (1979) use the random coefficient procedure to estimate random coefficient betas. Brennan and Schwartz (1977), Brennan (1979), and Brown and Warner (1980) also provide different types of market models that can produce different results in predicting rates of return, testing efficient market hypotheses, and measuring security price performance.

To reduce the impact of the measurement error problem in the second step, Black et al. (1972) use the grouping method in the capital asset pricing model test. Although the results support the linear relationship between the systematic risk and expected return, CAPM cannot hold because of the nonzero intercept term and the lower market premium in the cross-sectional regression. Blume and Friend (1973) and Fama and MacBeth (1973) also use the grouping method in testing CAPM and show that the CAPM is valid. However, Jagannathan et al. (2009) show that the time series average of the cross-sectional estimators converges in probability to the true value of the estimator. Although their results support CAPM indicating a linear relationship between the systematic risk and the expected return, the lower value of time-series average of the market premium shows that the measurement error problem still exists after Fama and MacBeth's (1973) grouping method.

Considering the measurement errors of the market rate of return and risk-free rate of return, Lee (1977) uses two EIV estimation methods, Wald's two-group grouping method and Durbin's instrumental variable method, to adjust the estimated beta risk in the first step of the capital asset pricing test. Although correcting the measurement errors induced from the unobservable market rate of return, Lee (1977) finds that the predictive ability of the capital asset pricing model is still poor.

Litzenberger and Ramaswamy (1979) derive an after-tax version of CAPM and show that, in the equilibrium, the before-tax expected return on a security is linearly related to its systematic risk and its dividend yield. Litzenberger and Ramaswamy (1979) further empirically test both the before tax and the after-tax versions of

⁵Roll (1969, 1977), and Lee and Jen (1978) show that the observed market rate returns in terms of stock market index are measured with errors since the stock market index does not include all assets which investors can invest. Lee and Jen (1978) have theoretically shown how beta estimate and Jensen performance measures can be affected by both constant and random measurement errors of R_m and R_f .

Diacogiannis and Feldman (2011), Green (1986), Roll and Ross (1994), and Gibbons and Ferson (1985) have argued that market portfolio measure with errors is an inefficient portfolio and show how the inefficient benchmark can affect theoretical CAPM derivation. Diacogiannis and Feldman (2011) provide a pricing model that uses inefficient benchmarks, a two beta model, one induced by the benchmark, and one adjusting for its inefficiency.

CAPM. Instead of grouping method, Litzenberger and Ramaswamy (1979) use maximum likelihood estimation in the second-step regression to test the before-tax and the after-tax versions of capital asset pricing model. Although maximum likelihood estimators are consistent, the average risk premium is small and not significantly different from zero.

Given the EIV bias in the two-step CAPM test, Gibbons (1982) introduces a one-step Gauss-Newton procedure and uses the maximum likelihood method to obtain the estimated price of systematic risk. Because the one-step Gauss-Newton procedure does not use estimated beta as an explanatory variable in a regression model, the measurement errors problem of estimated beta can be avoided. Shanken (1992) shows that using generalized least square (GLS) on the second step of CAPM test can yield an estimator identical to the Gauss-Newton estimator obtained by Gibbons' (1982) maximum likelihood method. Gibbons (1982) shows that the Gauss-Newton procedure increases the precision of estimated risk premium, but rejects the mean-variance efficiency of the market portfolio.

Shanken (1992), who provides a modified version of the two-step estimator by using maximum likelihood estimation, finds that Fama and MacBeth's two-step procedure overstates the precision of the estimator in the second-step and therefore provides an adjusted standard error for the estimator in the second-step regression. Jagannathan and Wang (1998a, b) further release Shanken's assumption that asset returns are conditional homoscedasticity to derive a more general standard error for the second-step estimator by generalized least squares.

Fama and French (1992) use a two-way sort grouping method to control for size effect, and find a weak relationship between beta risk and expected return. Before reaching the conclusion that the capital asset pricing has not been valid in the recent years, one possible reason that may be considered is that the measurement error problem cannot be fully eliminated by the grouping method, and results of CAPM test may vary depending on the portfolio formation technique (e.g., Ahn et al. 2009).

To deal with the problem of EIV in testing CAPM, Kim (1995) provides a maximum likelihood method, extracting information associated with the relationship between the measurement error variance and idiosyncratic error variance and incorporating such information into the maximum likelihood estimation in the second step of the capital asset pricing model test. Given the assumption that the disturbance term of the market model is homoscedasticity, the corrected factors for the traditional least squares estimators of the cross-sectional regression coefficients can be obtained. Although Kim's (1995) maximum likelihood method can only deal with the EIV problem of the estimated beta in the first pass, the maximum likelihood method can test, besides the capital asset pricing model, the multifactor asset pricing models. Kim (1995) uses maxima likelihood method to reexamine CAPM and multifactor asset pricing model and finds more support for the role of market beta risk and less support for the role of firm size. His results show that the prominent risk factors (e.g., size, book-to-market ratio, and momentum factors) might result in a different explaining power for cross-sectional stock returns after correcting the EIV problem.

MacKinlay and Richardson (1991) use generalized method of moments (GMM) to test the mean-variance efficiency. They theoretically show that the estimator from GMM and the estimator from maximum likelihood method are equivalent when stock returns are conditionally homoscedasticity, but GMM can avoid the EIV problem by estimating coefficients in one step. Empirical and simulation results show that the conclusion mean-variance efficiency of market indexes is sensitive to the model settings.

Lee et al. (2019) show that, when applying the two-step regression method to test the asset pricing model, the errors-in-variables problem underestimates the market beta and overestimates other risk factors with no measurement error. They, therefore, provide three alternative errors-in-variable models in testing the capital asset pricing model, including the grouping method, the instrumental variable method, and the maximum likelihood method.⁶ Using the grouping method in both first step and second step to deal with measurement error of market return and estimated beta, Lee et al. (2019) show that only the two-group grouping method used in the second step can improve the price of the beta risk, which is market premium (see Table 2).

Table 3 presents results of the instrumental variable method for testing the capital asset pricing model. Uncorrected estimators, estimators corrected in the first step, estimators corrected in the second step, and estimators corrected in both first step and second step are presented in order. Results show that, after correcting by instrumental variables method in the second step, the corrected price of beta risk has been improved both in magnitude and significant level.

Table 4 presents the time series average of the cross-sectional regression estimators by the maximum likelihood method and by traditional ordinary least square method. After correcting the errors-in-variables problem by the maximum likelihood method, for the capital asset pricing model test, the estimated intercept decreases in both magnitude and significant level, and the estimated price of beta risk increases and turns to significant. For the multifactor asset pricing model, the estimated intercept and the estimated coefficient of the size factor decrease in both magnitude and significance level; and the estimated price of beta risk turns to significant. The results therefore show that the evidence of failure in the capital asset pricing model or the finding of new risk factors might occur because of the errors-in-variables problem rather than model misspecification.

Lee et al. (2019) shows that both potential measurement error problems of market return in the first pass and estimated beta in the second pass are corrected by either the grouping method or the instrumental variable method. In addition, the errors-in-variable model can improve the capital asset pricing model tests at the individual stock level. The empirical results support the role of market beta in the capital asset pricing model after correcting the EIV problem.

To deal with the measurement error problem associated with testing both CAPM and APT, Lee and Wei (1984) and Wei (1984) use the MIMC model to test whether

⁶Please check Chap. 8 of Lee et al. (2019) entitled “Three alternative methods in testing capital asset pricing model.”

Table 2 Grouping method in both first step and second step for testing capital asset pricing model This table provides the corrected estimators of the capital asset pricing test by using Wald’s grouping method in both first step and second step. In the first step, 60 time-series observations of each stock are divided into k groups based on their corresponding market returns ($k = 2, 10, 15, 20$, and 30). The market-adjusted preranking beta for each stock is estimated by the market model using k time-series observations. In the second step, based on each firm’s preranking beta, portfolios are formed into N ($N = 2, 10, 20, 50, 100$, and 200) beta-sorted portfolios in month t . Postranking beta of each beta-sorted portfolio in month t is the average of preranking betas of each portfolio. The monthly cross-sectional regression coefficients for each portfolio, $\hat{\gamma}_{0t}$ and $\hat{\gamma}_{1t}$, are estimated through the ordinary least square. Parameters, $\bar{\gamma}_0$ and $\bar{\gamma}_1$, are the time-series averages of the month-by-month cross-sectional regression coefficient estimates by using average beta as postranking portfolio beta. Coefficients are presented in percentages, and t -statistics are presented in the parentheses. The sample period is from January 1931 to December 2009

Portfolio Size (first step/second step)		$R_{it} = \gamma_{0t} + \gamma_{1t}\hat{\beta}_{it-1} + e_{it}$

Table 3 Instrumental variable method for testing capital asset pricing model This table provides corrected estimators of the capital asset pricing test by using Durbin's instrumental variable approach in both first step and second step. In the first step, the instrumental variables for 60 time-series observations of each stock are ranking orders of their corresponding market returns. Then the beta of each security can be estimated by the instrumental variable method. In the second step, the instrumental variables for cross-sectional observations in month t are the rank orders of the estimated betas of cross-sectional observations. The monthly cross-sectional regression coefficients in month t , $\hat{\gamma}_{0t}$ and $\hat{\gamma}_{1t}$, are estimated through the instrumental variable method. Parameters, $\bar{\gamma}_0$ and $\bar{\gamma}_1$, are the time-series averages of the month-by-month cross-sectional regression coefficient estimates. The t -statistics are provided under the null hypothesis that the estimator is different from zero. This table also presents the number of observations and the percentage of observations that are significant under the null hypothesis that the absolute value of corrected estimator is greater than the absolute value of the uncorrected estimator at 95% and 99% significance levels. Coefficients are presented in percentages, and t -statistics are presented in the parentheses. The sample period is from January 1931 to December 2009. Results of subperiods are also provided

	0.7095 (0.49)	1.5465 (1.04)	−0.0787 (−0.68)	3.2995 (1.44)	0.1733 (0.55)	−0.1951 (−1.17)

APT outperformed CAPM. Betas are obtained from simultaneous equation system, and a cross-sectional regression of the security return against its β will be used to test the CAPM. They conclude that the beta estimated from the MIMC model by allowing measurement error on the market portfolio does not significantly improve the OLS beta estimate, and MLE estimator does a better job than the OLS and GLS estimators in the cross-sectional regressions because the MLE estimator takes care of the measurement error in beta.

More recently, Jagannathan et al. (2010) and Da et al. (2012) use three-stage cross-sectional regression to correct the errors-in-variables problem from the rolling-window betas. Their empirical findings support CAPM in explaining option-adjusted stock returns at the individual stock level.

100.4.3 Capital Structure

Titman and Wessels (1988), Chang et al. (2009), and Yang et al. (2009) use structure equation models (e.g., LISREL model and MIMIC model) to mitigate the measurement problems of proxy variables when working on capital structure theory. Titman and Wessels (1998) use LISREL method to investigate determinants of capital structure. In the structure equation model, they use 15 indicators associated with 8 latent variables and set 105 restrictions on the coefficient matrix. Empirical results, however, do not support four of eight propositions on the determinants of capital structure. Specifically, their results show that a firm's capital structure is not significantly related to its non-debt tax shields, volatility of earnings, collateral value of assets, and future growth. One possible reason for the poor results is that the indicators used in the empirical study do not adequately reflect the nature of the attributes suggested by financial theory.

Chang et al. (2009) apply a Multiple Indicators and Multiple Causes model (MIMIC) with refined indicators to reexamine Titman and Wessels (1998) work on determinants of capital structure. Chang et al. (2009) examine the seven indicator factors as follows: growth, profitability, collateral value, volatility, non-debt tax shields, uniqueness, and industry. Their empirical results show that the growth is the most influential determinant on capital structure, followed by profitability, and then collateral value. Under a simultaneous cause-effect framework, their seven constructs as determinants of capital structure have significant effects on capital structure decision.

Yang et al. (2009) apply a LISREL model to find determinants of capital structure and stock returns, and estimate the impact of unobservable attributes on capital structure decisions and stock returns. Using leverage ratios and stock returns as two endogenous variables and 11 latent factors as exogenous variables, Yang et al. (2009) find that stock returns, expected growth, uniqueness, asset structure, profitability, and industry classification are the main determinants of capital structure, while leverage, expected growth, profitability, firm value, and liquidity can explain stock returns. In addition, the capital structure and stock return are mutually determined by each other.

Chen et al. (2019) develop a simultaneous determination model to identify the joint determinants of capital structure and stock returns. The structural equation model with confirmatory factor analysis shows that stock return, asset structure, growth rate, industry classification, uniqueness, volatility and financial rating, profitability, government financial policy, and managerial entrenchment are key factors in determining a firm's capital structure. Such results are robust in the MIMIC and two-stage least square methods.

100.4.4 Measurement Error in Investment Equation

Modern q theory, developed by Lucas and Prescott (1971) and Mussa (1977), shows that the shadow value of capital, marginal q , is the firm manager's expectation of the marginal contribution of new capital goods to future profits. Marginal q , therefore, should summarize the effects of all factors relevant to the investment decision. Lucas and Prescott (1971) and Hayashi (1982) show that the equality of marginal q with average q is under the assumptions of constant returns to scale and perfect competition. Because the marginal q is unobservable in the real world, most of empirical studies adopt Lucas and Prescott (1971) and Hayashi's (1982) assumption and use average q instead of marginal q to test q theory. In addition, if financial markets' valuation of the capital will be equal to the manager's valuation, average q should equal an observable value, Tobin's q , defined as the ratio of the market value to the replacement value. Most empirical studies use Tobin's q as a proxy for marginal q to test the q theory of investment. However, their empirical results are inconsistent to the q theory (e.g., Blundell et al. 1992; Fazzari et al. 1988; Gilchrist and Himmelberg 1995; Schaller 1990).⁷

The model introduced by Fazzari et al. (1988) is

$$I_{it}/K_{it} = \eta_i + \beta q_{it}^* + \alpha CF_{it}/K_{it} + u_{it}, \quad (51)$$

where I_{it} represents the investments of firm i at time t , K_{it} is capital stock of firm i at time t , q_{it}^* is the marginal q , CF_{it} is cash flow of firm i at time t , η_i is the firm-specific effect, and u_{it} is the innovation term.

Almeida et al. (2010) show that OLS estimated coefficient of independent variable with measurement error, q_{it}^* , will be biased downward, and OLS estimated coefficient of the independent variable without measurement error, CF_{it}/K_{it} , will be biased upward. Following Eq. (51), if one of independent variables has measurement error and the other independent variables has no measurement error, the asymptotic biases of estimated coefficients can be defined as:

⁷Empirical work in testing association between the investment decision and cash flow shows that cash flow has poor explanation in determining investment decision. In addition to cash flow, output, sales, and internal funds have significant explanation in determining investment decision.

$$\text{plim } \hat{\beta} - \beta = \frac{-\beta\sigma_e^2}{\sigma_{CF/K}^2 - b_{CF/K,q^*} + \sigma_e^2}, \text{ and} \quad (52)$$

$$\text{plim } \hat{\alpha} - \alpha = \beta b_{CF/K,q^*} \left(\frac{\sigma_e^2}{\sigma_e^2 + \sigma_{CF/K}^2 (1 - R_{CF/K,q^*}^2)} \right), \quad (53)$$

in which $\sigma_{CF/K}^2$ is the variance of CF/K , σ_e^2 is the variance of error term between unobserved marginal q and observable average q^* , $b_{CF/K,q^*}$ is the auxiliary regression coefficient of a regressing q^* on CF/K , and $R_{CF/K,q^*}^2$ is the correlation coefficient between q^* and CF/K . We know that $\sigma_{CF/K}^2 - b_{CF/K,q^*} + \sigma_e^2$ is generally positive, so the estimated coefficient of q^* is downward biased. In addition, the direction of bias of estimated coefficient of CF/K will depend on the signs of β and $b_{CF/K,q^*}$. Given that q and cash flow are positively correlated, we can get the conclusion of Almeida et al. (2010) that $\hat{\beta}$ is downward biased and $\hat{\alpha}$ is upward biased.

Erickson and Whited (2000) argue that the measurement error of marginal q can result in different implications in empirical q models. They incorporate an EIV model to reexamine the empirical work done by Fazzari et al. (1988). By using generalized method of moments (GMM), Erickson and Whited (2000) obtain consistent estimators that use the information contained in the third- and higher-order moments of the joint distribution of the observed regression variables. The estimator precision and consistency can be increased by exploiting the information afforded by an excess of moment equations over parameters. Results show that cash flow does not affect a firms' financial decision, even for financially constrained firms, and the q theory is held if measurement error is taken into account.

Almeida et al. (2010) use Monte Carlo simulations and real data to compare the performance of generalized method of moments and instrumental variables approach dealing with measurement error problems in investment equations. In Monte Carlo simulations, they find estimators of GMM proposed by Erickson and Whited (2000) are biased for both mismeasured and well-measured regressors when the data have individual-fixed effects, heteroscedasticity, or no high degree of skewness. In contrast, the instrumental variable method results in fairly unbiased estimators under those same conditions. Almeida et al. (2010) further empirically examine the investment equation introduced by Fazzari et al. (1988) by using GMM and instrumental variable method. Almeida et al. (2010) adopt Biorn's (2000) method using the lags of the variable as instruments in testing the investment equation. Empirical results show that estimators from generalized method of moments are unstable across different specifications and not economically meaningful, while estimators from a simple instrumental method are robust and conform to q theory. Almeida et al. (2010) conclude that instrumental method yields more consistent estimators and support the q theory in the investment equation.

In contrast, Erickson and Whited (2012) compare the ability of three errors-in-variables models, instrumental variables, dynamic panel estimators, and the high-order moment estimators in investment equation. They conclude that all of three

models can perform well under correct specification, while the high-order moment estimators often outperform the instrumental variables and dynamic panel estimators in terms of bias and dispersion. Erickson and Whited (2012) also demonstrate a minimum distance technique to extend the high-order moment estimators used on unbalanced panel data.

100.5 Conclusion

In this chapter, we investigate theoretical issues related to errors-in-variables (EIV) problem, and review how existing EIV estimation methods deal with measurement error problem. We first show how EIV problems affect the coefficients of independent variables in the regression model. We then discuss how classical method, mathematical programming method, grouping method, instrumental variable method, maximum likelihood method, and LISREL method deal with EIV problems. We further investigate how alternative EIV models have been used in empirical finance research. We find that the empirical research of cost of capital, asset pricing, capital structure, and investment equation have used alternative EIV methods to improve the empirical results. Not only can the reader of this chapter understand the important research topics in finance, but also can realize how measurement error problems affect the results of empirical work in such research topics. Finally, we suggest that future empirical studies on finance-related issues should pay more efforts to deal with EIV problems and obtain more robust empirical results.

Optimal Payout Ratio under Uncertainty and the Flexibility Hypothesis: Theory and Empirical Evidence

101

Cheng-Few Lee, Manak C. Gupta, Hong-Yi Chen, and Alice C. Lee

Abstract

Following the dividend flexibility hypothesis used by DeAngelo and DeAngelo (J Financ Econ 81, 227–254, 2006), Blau and Fuller (J Corp Financ 14:133–152, 2008), and others, we theoretically extend the proposition of DeAngelo and DeAngelo's (J Financ Econ 81, 227–254, 2006) optimal payout policy in terms of the flexibility dividend hypothesis. We also introduce growth rate, systematic risk, and total risk variables into the theoretical model. In addition, based upon Lee and Lee (2021), we discuss the implication of the existence of optimal payout ratio in financial analysis and decision for a company.

To test the theoretical results derived in this chapter, we use data collected in the USA from 1969 to 2009 to investigate the impact of growth rate, systematic risk, and total risk on the optimal payout ratio in terms of the fixed-effect model. We find that based on flexibility considerations, a company will reduce its payout when the growth rate increases. In addition, we find that a nonlinear relationship exists between the payout ratio and the risk. In other words, the relationship between the payout ratio and risk is negative (or positive) when the growth rate is higher (or lower) than the rate of return on total assets. Our theoretical model and

101.1 Introduction

Corporate dividend policy has long engaged the attention of financial economists, dating back to the irrelevance theorem of Miller and Modigliani (1961; M&M hereafter), in which they state that a rational and perfect economic environment is free of illusion. Since then, their rather controversial findings have been challenged and tested by weakening the assumptions or introducing imperfections into the analysis. For example, the signaling models developed by Bhattacharya (1979), Miller and Rock (1985), and John and Williams (1985), and the free cash flow hypothesis proposed by Easterbrook (1984) and Jensen (1986) are the two well-known propositions challenging M&M's dividend irrelevance theorem; however, empirical studies examining signaling and free cash flow hypotheses have yielded mixed results.

DeAngelo and DeAngelo (2006) reexamine the irrelevance of the M&M dividend irrelevance theorem by allowing partial dividend payout. They argue that the original M&M (1961) irrelevance result is due to the fact that they consider either paying out all earnings or not paying any of them at all. Therefore, payout policy might be relevant if partial payout is allowed. In other words, DeAngelo and DeAngelo (2006) use dividend flexibility hypothesis to show their dividend relevance results. Underlying the flexibility hypothesis, the current chapter (1) develops a theoretical model to support the proposition of DeAngelo and DeAngelo's (2006) optimal payout policy when the partial payout is allowed; (2) reconciles the dispute between free cash flow hypothesis and flexibility hypothesis in dividend policy literature; and (3) performs empirical tests in terms of theoretical results derived in this chapter.

First of all, following DeAngelo and DeAngelo (2006), we develop a dynamic model allowing firms to hold some amount of cash into a positive NPV project for the reason of financial flexibility. Under the assumption of stochastic rate of return and the dividend flexibility hypothesis, we carry out the optimization procedure to maximize firm value, and the final expression of the optimal dividend policy of the firm is thus derived. The model is comprehensive and allows structural analysis of different variables that could be relevant for corporate dividend policy. For example, the model incorporates the rate of return on assets, growth rate, and risk (systematic, firm-specific, and total risk) to name a few variables that could affect corporate dividend decisions. Comparative statics provide insights into the effect of each of these parameters on corporate dividend policy, and this is followed by an analysis of the interaction effects of these variables on corporate dividend policy.

Second, the implications of the optimization results are explained. Our results show that the relationship between the optimal payout ratio and the growth rate is negative in general. We investigate the separate and then the combined effects of market-dependent and market-independent components of risk on the optimal dividend policy. We perform comparative static analyses of the relationships between the payout ratio and (1) change in total risk, (2) change in systematic risk, (3) simultaneous changes in both total risk and systematic risk, and (4) no change in risk. We examine in detail the effects of variations in the profitability rate, its distribution parameters, and their dynamic behavior on the optimal dividend policy of the firm. The theoretical relationship between the payout ratio and the growth ratio implies that high growth firms need to reduce the payout ratio and retain more earnings to build up “precautionary reserves” for flexibility considerations, but low growth firms are likely to be more mature and already build up their reserves. More importantly, the relationship between the payout ratio and the risks reflects different dividend policies at high growth firms and low growth firms. With higher risk, the costs of external funds increase; therefore, to optimize shareholders’ wealth, high growth firms tend to reduce their payouts and keep more relatively low-cost funds to sustain their high growth, whereas low growth firms tend to pay more dividends and reduce the risk for shareholders.

Third, our theoretical model and its implications lead us to three testable hypotheses. Although a large and growing body of empirical research on the optimal dividend payout policy has emerged, none of it has a solid theoretical model to support findings or introduces a nonlinear structured model on payout policy.¹ We here try to empirically examine three hypotheses derived from our theoretical optimal payout model. Using data collected in the USA from 1969 to 2009, we analyze 28,333 dividend-paying firm-years. Our empirical results show that firms’ payout ratios are negatively related to firms’ growth and a negative (or positive) relationship exists between firms’ risks and the dividend payout ratios among firms with higher (or lower) growth rates relative to their rate of return on assets. Our empirical results are consistent with our theoretical model under the dividend flexibility hypothesis. We also find that growth and risk interact in explaining the payout ratio, indicating that the payout ratio is not linearly related to the growth rate or to the risk of the firm. Furthermore, we implement the moving estimates process to find the empirical breakpoint of the structural change for the relationship between the payout ratio and risks and confirm that the empirical breakpoint is not different from our theoretical breakpoint.

The primary contributions of this chapter are our theoretical derivation of an optimal payout ratio under the dividend flexibility hypothesis and our demonstration

¹For example, Rozeff (1982), Jagannathan et al. (2000), Grullon et al. (2002), Aivazian et al. (2003), and Blau and Fuller (2008).

of a negative but nonlinear relationship between the payout ratio and the growth rate. More importantly, we theoretically and empirically locate a structural change point for the relationship between the payout ratio and the growth rate. Rozeff (1982), Aivazian et al. (2003), Blau and Fuller (2008), and others conclude that a firm's risk and optimal payout are negatively related. Contrary to these conclusions and generally held beliefs, the dynamic optimization model developed here shows that the optimal payout is not necessarily negatively related to risk but implies that payout policies differ in high growth firms and low growth firms. High growth firms pay out their dividends for flexibility considerations, but low growth firms pay out their dividends to reduce their free cash flow problem. In addition, this chapter also shows that the relationship between firms' payouts and their growth rates (or risks) can be affected by their risks (or growth rates). Contrary to earlier studies, the theoretical model developed here shows that the optimal payout ratio is not linearly related to the growth rate or to the risk of the firm, and whether the rate of return on assets is higher or lower than the growth rate has significant effect on the relationships between these variables. The results are borne out by rather extensive empirical research done in this chapter based on 40 years of data collected in the USA from 1969 to 2009.

The stochastic dynamic optimization model developed here challenges many commonly held beliefs and results obtained from earlier studies. It provides more meaningful relationships among total risk and its separate components (systematic and firm-specific), growth rate, rate of return on assets, and optimal dividend policy. Our results represent an advance in corporate finance literature because all the important variables included in this study were never simultaneously included in those earlier studies, and more importantly, the interaction effects among these variables were neither recognized nor fully appreciated. We believe that this study is the first of its kind to provide a theoretical basis for relating dividend policies with firm risks, growth rates, and return on assets (ROAs) in an interrelated fashion.

The remainder of this chapter is organized as follows. Section 101.2 contains a review of the literature on dividend-relevant theories and the findings of empirical work on dividend policy. In Sect. 101.3, we lay out a dynamic model used in subsequent sections to examine the existence, or nonexistence, of an optimal dividend policy. Section 101.4 provides the final expression of the optimal dividend policy of the firm derived from the optimization procedure to maximize firm value. In Sect. 101.5, we present both a detailed form and an approximated form of the relationship between the optimal dividend payout ratio and the growth rate. Section 101.6 includes a discussion of the effects of market-dependent and market-independent components of risk on the optimal dividend policy; Section 101.7 includes empirical evidence supporting the model and implications in previous sections; Sect. 101.9 discusses the potential interaction among dividend, investment, financing, and production policies, and the conclusion appears in Sect. 101.10.

101.2 Review of the Literature

Corporate dividend policy has puzzled financial economists, dating back to the dividend irrelevance theorem proposed by M&M (1961). Since then, their controversial findings have been challenged and tested by weakening the assumptions or introducing imperfections into the analysis. The signaling models developed by Bhattacharya (1979), Miller and Rock (1985), and John and Williams (1985) suggest that because of the asymmetric information between managers and shareholders, managers use dividends as a signal to release private information to the market; however, empirical studies examining the signaling hypothesis have yielded mixed results. Nissim and Ziv (2001), Brook et al. (1998), Bernheim and Wantz (1995), Kao and Wu (1994), and Healy and Palepu (1988) support the signaling (asymmetric information) hypothesis by finding a positive association between dividend increases and future profitability. Kalay and Lowenstein (1986) and Asquith and Mullins (1983) find that dividend changes are positively associated with stock returns in the days surrounding dividend announcements, and Sasson and Kolodny (1976) identify that a positive association between the payout ratio and average rates of return. Studies by Benartzi et al. (1997), DeAngelo et al. (1996), and Grullon et al. (2002), however, reveal no support for the hypothesized relationship between dividend changes and future profitability.

Using agency cost theory, Easterbrook (1984) and Jensen (1986) propose the free cash flow hypothesis, arguing that because managers cannot credibly pre-commit to shareholders, they will not invest excess cash in negative-NPV projects. Dividend changes may convey information about how the firm will use future cash flow. Again, the results of empirical studies have been mixed at best. Several researchers, including Agrawal and Jayaraman (1994), Jensen et al. (1992), and Lang and Litzenberger (1989) find positive supports for the agency cost hypothesis, but others find no support for this hypothesis, for example, Howe et al. (1992), Denis et al. (1994), and Yoon and Starks (1995).

DeAngelo and DeAngelo (2006) argue that M&M's (1961) dividend irrelevance occurs because they consider either paying out all earnings or not paying any of them at all; therefore, payout policy might have impact on firm value if partial payout is allowed. In other words, DeAngelo and DeAngelo (2006) use the dividend flexibility hypothesis to show their dividend relevance results. Blau and Fuller (2008) have theoretically and empirically shown that the dividend flexibility hypothesis is indeed a reasonable dividend policy. In addition, several empirical studies show evidence of firms preferring financial flexibility, for example, Lie (2005), DeAngelo et al. (2006), Denis and Osobov, (2008), and Gabudean (2007).

Besides focusing on the relevance of dividend policy, a growing body of literature deals with the determinants of optimal dividend payout policy. For example, Rozeff (1982) shows that the optimal dividend payout is related to the fraction of insider holdings, the growth of the firm, and the firm's beta coefficient. He also finds evidence that the optimal dividend payout is negatively correlated to

beta risk, and supporting that beta risk reflects the leverage level of a firm. Jagannathan et al. (2000) empirically show that operation risk is negatively related to the propensity to increase payouts. Grullon et al. (2002) show that dividend changes are related to the change in the growth rate and the change in the rate of return on assets. They also find that dividend increases should be associated with subsequent declines in profitability and risk. Aivazian et al. (2003) examine eight emerging markets and show that, similar to the US firms, dividend policies in emerging markets can also be explained by profitability, debt, and the market-to-book ratio. None of the foregoing scholars, however, has a solid theoretical model to support their finding.

We use these authors' works as a springboard to deal with the flexibility hypothesis and develop the theoretical underpinnings and a stochastic dynamic optimization model determining the conditions for an optimal dividend policy. We believe that ours is the first attempt ever made to include growth rate, risks, and more importantly, the rate of return and its distribution parameters in a single model deriving the conditions for an optimal dividend policy; furthermore, this chapter empirically tests the findings and conclusions of the theoretical model developed here, using an extensive data set involving 28,333 dividend-paying firm-years from 1969 to 2009. The results of the empirical tests confirm and validate the findings of the theoretical model and provide new insights in the determination of optimal dividend policy, the influence of each explanatory variable listed above, and more importantly, their interaction effects on the corporate dividend policy. Notably, some of these results run counter to categorically stated conclusions reached in earlier studies.

101.3 The Model

We develop the dividend policy model under the assumptions that the capital markets represent the closest approximation to the economists' ideal of a perfect market – zero transaction costs, rational behavior on the part of investors, and the absence of tax differentials between dividends and capital gains. It is assumed that the firm is not restricted to financing its growth only by retained earnings, and that its rate of return, $\tilde{r}(t)$, is a nonstationary random variable, normally distributed with mean, μ , and variance, $\sigma(t)^2$.

Let $A(0)$ represent the initial assets of the firm and h be the growth rate. Then the earnings of this firm are given by Eq. (1), which is

$$\tilde{x}(t) = \tilde{r}(t)A(0)e^{ht}, \quad (1)$$

where $\tilde{x}(t)$ represents the earnings of the firm, and the tilde ($\sim$) denotes its random character.

Based upon DeAngelo and DeAngelo's (2006) assumption, we here allow that the firm partially pay out its earnings and retain a certain amount of earnings in

support of its growth.² The retained earnings of the firm, $y(t)$, can therefore be expressed as follows:

$$y(t) = \tilde{x}(t) - m(t)\tilde{d}(t), \quad (2)$$

where $\tilde{d}(t)$ is the dividends per share, and $m(t)$ is the total number of shares outstanding at time t .

Equation (2) further indicates that the focus of the firm's decision-making is on retained earnings, which implies that dividend $\tilde{d}(t)$ also becomes a random variable. The growth of a firm can be financed by retained earnings or by issuing new equity.

The new equity raised by the firm at time t can be defined as follows:

$$e(t) = \delta p(t)\dot{m}(t), \quad (3)$$

where

$p(t)$ = price per share

$\dot{m}(t) = dm(t)/dt$

δ = degree of market perfection, $0 < \delta \leq 1$

The value of δ equal to one indicates that new shares can be sold by the firm at current market prices.

From Eqs. (1, 2, and 3) investment in period t is the sum of retained earnings and funds raised by new equity, so the investment in period t can be written as follows:

$$hA(0)e^{ht} = \tilde{x}(t) - m(t)\tilde{d}(t) + \delta\dot{m}(t)p(t). \quad (4)$$

This implies that

$$\tilde{d}(t) = \{[\tilde{r}(t) - h]A(0)e^{ht} + \delta\dot{m}(t)p(t)\}/m(t), \quad (5)$$

and the mean and variance of the dividends per share can be expressed as follows:

$$\begin{aligned} E[\tilde{d}(t)] &= \{[\mu - h]A(0)e^{ht} + \delta\dot{m}(t)p(t)\}/m(t) \\ Var[\tilde{d}(t)] &= A(0)^2\sigma(t)^2e^{2ht}/m^2(t) \end{aligned} \quad (6)$$

²DeAngelo and DeAngelo (2006) carefully explain why partial payout is important to obtain an optimal ratio under perfect markets. In addition, they also argue that partial payout is important to avoid the suboptimal solution for optimal dividend policy.

Also, let us postulate an exponential utility function of the following form³:

$$U[\tilde{d}(t)] = -e^{-\alpha \tilde{d}(t)}, \quad (7)$$

where $\alpha > 0$

Following the moment generating function, we have

$$E\left(-e^{-\alpha \tilde{d}(t)}\right) = -e^{-\alpha E[\tilde{d}(t)] + \frac{\alpha^2}{2} \text{Var}[\tilde{d}(t)]}, \quad (8)$$

where $\tilde{d}(t)$ is the certainty equivalent value of $\tilde{d}(t)$.⁴

From Eqs. (6) and (8), the certainty equivalent dividend stream can be written as

$$\bar{d}(t) = \frac{(\mu - h)A(0)e^{th} + \delta \dot{m}(t)p(t)}{m(t)} - \frac{\alpha' A(0)^2 \sigma(t)^2 e^{2th}}{m(t)^2}, \quad (9)$$

where $\alpha' = \alpha/2$. Therefore, taking advantage of exponential utility, we can obtain a risk adjusted dividend stream. Furthermore, $\bar{d}(t)$ will reduce to the certainty case, if we assume $\sigma(t)^2 = 0$.

In accordance with the capital asset pricing theory developed by Sharpe (1964), Lintner (1963), and Mossin (1966), the total risk can be decomposed into systematic risk and unsystematic risk; that is, $\tilde{r}(t)$ can be defined as follows:

$$\tilde{r}(t) = a + b\tilde{I}(t) + \tilde{\varepsilon}(t), \quad (10)$$

where $\tilde{I}(t)$ is the market index; $\tilde{\varepsilon}(t) \sim N(0, \sigma_\varepsilon^2)$; a and b are regression parameters; and $\text{Var}(b\tilde{I}(t))$ and $\text{Var}(\tilde{\varepsilon}(t))$ represent the systematic and unsystematic risk, respectively.

Following Eq. (10), Eq. (6) can be rewritten as

$$\begin{aligned} E[\tilde{d}(t)] &= [(a + b\tilde{I} - h)A(0)e^{ht} + \delta \dot{m}(t)p(t)]/m(t) \\ \text{Var}[\tilde{d}(t)] &= A(0)^2 [b^2 \text{Var}(\tilde{I}(t)) + \text{Var}(\varepsilon(t))] e^{2th}/m(t)^2, \\ &= A(0)^2 [\rho(t)^2 \sigma(t)^2 + (1 - \rho(t)^2) \sigma(t)^2] e^{2th}/m(t)^2 \end{aligned} \quad (11)$$

³Pratt (1964) provides a detailed analysis of the various utility functions. Exponential, hyperbolic, and quadratic forms have been variously used in the literature; but the first two seem to have preference over the quadratic form because the latter has the undesirable property that it ultimately turns downwards.

⁴From the moment generating function discussed in Hogg and Craig (2004), we know that $E(-e^{ty}) = -e^{tE(y) + \frac{1}{2}t^2 \text{Var}(y)}$. Let $t = -\alpha$, then the right hand side of (8) is easily obtained.

where

$\rho(t)$ = the correlation coefficient between $\tilde{r}(t)$ and $\tilde{I}$
 a = market-independent component of the firm's rate of return
 $b\tilde{I}$ = market-dependent component of the firm's rate of return
 $\rho(t)^2\sigma(t)^2$ = nondiversifiable risk
 $(1 - \rho(t)^2)\sigma(t)^2$ = diversifiable risk

The unsystematic risk usually can be diversified away by the investors,⁵ so the certainty equivalent value in Eq. (9) should be revised as

$$\hat{d}'(t) = \frac{(a + b\tilde{I} - h)A(o)e^{th} + \delta\dot{m}(t)p(t)}{m(t)} - \frac{\alpha'A(o)^2\rho(t)^2\sigma(t)^2e^{2th}}{m(t)^2}. \quad (12)$$

Following Lintner (1962), we observe that the stock price should equal the present value of this certainty equivalent dividend stream discounted at a riskless rate of return. Therefore,

$$p(0) = \int_0^T \hat{d}'(t)e^{-kt} dt, \quad (13)$$

where

$p(0)$ = the stock price at $t = 0$
 k = the risk free rate of return
 T = the planning horizon

This model will be used in subsequent sections to find the functional form of $m(t)$ and optimize the payout ratio. The formulation of our model is different from that of M&M (1961), Gordon (1962), Lerner and Carleton (1966a), and Lintner (1964). For example, in contrast to our model, M&M consider neither the non-stationarity of the firm's rate of return in their model nor explicitly incorporated uncertainty in their valuation model. Their models are also essentially static and would not permit an extensive analysis of the dynamic process of moving from one equilibrium state to another; furthermore, the formulation of our model is different from those who propose to capitalize the market-dependent and market-independent components of the uncertain stream of earnings at the risky and riskless rates, respectively.⁶ Instead, we view the market value of a firm as the present value of certainty equivalents of random future receipts. In the next section,

⁵See Lintner (1965), Mossin (1966), and Sharpe (1964).

⁶See Brennan (1973).

we carry out the optimization of Eq. (13) and derive the final expression for the optimal payout ratio.⁷

101.4 Optimum Dividend Policy

Based upon the evaluation model developed in the previous section, in this section we will derive an optimal dividend payout ratio.

Substituting Eq. (12) into Eq. (13), we obtain

$$p(0) = \int_0^T \left[\frac{(A + b\bar{I} - h)A(0)e^{th} + \delta\dot{m}(t)p(t)}{m(t)} - \frac{\alpha'A(0)^2\rho(t)^2\sigma(t)^2e^{2th}}{m(t)^2} \right] e^{-kt} dt. \quad (14)$$

To maximize Eq. (14), we observe that

$$p(t) = \int_t^T \hat{d}'(s)e^{-k(s-t)} ds = e^{kt} \int_t^T \hat{d}'(s)e^{-ks} ds, \quad (15)$$

where s = the proxy of time in the integration

From Eq. (15), we can formulate a differential equation as

$$\frac{dp(t)}{d(t)} = \dot{p}(t) = kp(t) - \hat{d}'(t). \quad (16)$$

Substituting Eq. (12) into Eq. (16), we obtain the differential equation

$$\dot{p}(t) + \left[\frac{\delta\dot{m}(t)}{m(t)} - k \right] p(t) = -G(t), \quad (17)$$

where

$$G(t) = \frac{(a + b\bar{I} - h)A(0)e^{th}}{m(t)} - \frac{\alpha'A(o)^2\rho(t)^2\sigma(t)^2e^{2th}}{m(t)^2}. \quad (18)$$

Following Kreyszig (2010) and Lee and Shi (2010), we solve the differential Eq. (17) and obtain the solution as indicated in Eq. (19).

⁷For further explanation of the optimization of the deterministic and stochastic control models and their applications to economic problems, please see Aoki (1967), Bellman (1990 and 2003), and Intriligator (2002).

$$p(t) = \frac{e^{kt}}{m(t)^\delta} \int_t^T G(s) m(s)^\delta e^{-ks} ds. \quad (19)$$

Then, Eq. (20) can be obtained from Eq. (18) and Eq. (19), implying that the initial value of a stock can be expressed as the summation of present values of its earnings stream adjusted by the risk taken by the firm.

$$p(0) = \frac{1}{m(0)^\delta} \int_0^T \left\{ (a + b\bar{l} - h) A(0) e^{th} m(t)^{\delta-1} - \alpha' A(0)^2 \rho(t)^2 \sigma(t)^2 e^{2th} m(t)^{\delta-2} \right\} e^{-kt} dt. \quad (20)$$

To maximize firm value, the Euler-Lagrange condition for the optimization of $p(o)$ is given by Eq. (21),⁸

$$(\delta - 1) (a + b\bar{l} - h) A(0) e^{th} m(t)^{\delta-2} - \alpha' A(0)^2 \rho(t)^2 \sigma(t)^2 e^{2th} m(t)^{\delta-3} (\delta - 2) = 0. \quad (21)$$

Therefore, the optimal shares outstanding at time t can be derived.

$$m(t) = \frac{(2 - \delta) \alpha' A(0) e^{th} \rho(t)^2 \sigma(t)^2}{(1 - \delta) (a + b\bar{l} - h)}. \quad (22)$$

From Eqs. (18), (19), and (22), we can obtain the maximized stock value

$$p(t) = \frac{(a + b\bar{l} - h)^2 (1 - \delta) e^{kt - th\delta} \int_t^T e^{\delta hs - ks} (\rho(s) \sigma(s))^{2\delta-2} ds}{\alpha' (2 - \delta)^2 \rho(t)^{2\delta} \sigma(t)^{2\delta}}. \quad (23)$$

From Eq. (22), we also obtain the optimal number of shares of new equity issued at time t

$$\dot{m}(t) = \frac{\left\{ h(2 - \delta) \alpha' A(0) e^{th} \rho(t)^2 \sigma(t)^2 + (2 - \delta) \alpha' A(0) e^{th} \left[\rho(t)^2 \dot{\sigma}(t)^2 + \sigma(t)^2 \dot{\rho}(t)^2 \right] \right\}}{(1 - \delta) (a + b\bar{l} - h)}. \quad (24)$$

From Eq. (23) and Eq. (24), we have the amount generated from issuing new equity

⁸For the derivation of Eq. (21), please refer to the [Appendix B](#).

$$\dot{m}(t)p(t) = \frac{(a + b\bar{l} - h)e^{kt - (\delta-1)th}A(0) \left(h\rho(t)^2\sigma(t)^2 + \rho(t)^2\dot{\sigma}(t)^2 + \sigma(t)^2\dot{\rho}(t)^2 \right) \int_t^T e^{s(\delta h - k)} (\rho(s)\sigma(s))^{2\delta-2} ds}{(2 - \delta)\rho(t)^{2\delta}\sigma(t)^{2\delta}}. \quad (25)$$

From Eq. (5) and Eq. (25), we can obtain $\bar{D}(t) = m(t)\bar{d}(t)$. From Eq. (1) and Eq. (10), we can obtain $\bar{x}(t) = (a + b\bar{l})A(0)e^{ht}$. When δ approaches unity, we can derive the optimal payout ratio as

$$\frac{\bar{D}(t)}{\bar{x}(t)} = \frac{(a + b\bar{l} - h)}{(a + b\bar{l})} \left\{ 1 + \frac{[e^{(h-k)(T-t)} - 1]}{(h - k)} \left(h + \frac{\dot{\sigma}(t)^2}{\sigma(t)^2} + \frac{\dot{\rho}(t)^2}{\rho(t)^2} \right) \right\}. \quad (26)$$

Eq. (26) implies an optimal payout ratio when we use an exponential utility function to derive the stochastic dynamic dividend policy model. This result does not necessarily imply that the dividend policy results derived by M&M (1961) are false because we allowed free cash flow to be paid out partially as assumed by DeAngelo and DeAngelo (2006) instead of paying out all free cash flows as assumed by M&M (1961).

In the following section, we use Eq. (26) to explore the implications of the stochasticity, the stationarity (in the strict sense), and the nonstationarity of the firm's rate of return for its dividend policy.⁹ We also investigate in detail the differential effects of variations in the systematic and unsystematic risk components of the firm's stream of earnings on the dynamics of its dividend policy.

101.5 Relationship Between the Optimal Payout Ratio and the Growth Rate

In this section, we investigate the relationship between the optimal payout ratio and the growth rate in terms of both exact and approximate approaches. Taking the partial derivative of Eq. (26) with respect to the growth rate, we obtain

$$\begin{aligned} \frac{\partial [\bar{D}(t)/\bar{x}(t)]}{\partial h} &= \left(-\frac{1}{a + b\bar{l}} \right) \left[\frac{-k + he^{(h-k)(T-t)}}{h - k} \right] + \left(1 - \frac{h}{a + b\bar{l}} \right) \\ &\quad \times \left[\frac{[(-k) + h(h - k)(T - t)]e^{(h-k)(T-t)} + k}{(h - k)^2} \right]. \end{aligned} \quad (27)$$

⁹See Hamilton (1994), pp. 45–46.

The sign of Eq. (27) is not only affected by the growth rate (h) but also by the expected rate of return on assets ($a + b\bar{l}$), the duration of future dividend payments ($T - t$), and the cost of capital (k).

Since the sign of Eq. (27) cannot be analytically determined, we use a sensitivity analysis approach to investigate the sign of Eq. (27). Table 1 shows the sign of partial derivatives of Eq. (27) under different values of the growth rate and the rate of return on assets as well as duration ($T - t$). We find that the relationship between the optimal payout ratio and the growth rate is always negative when the growth rate is higher than the rate of return on assets. If the growth rate is lower than the rate of return on asset, the direction of relationship essentially depends on the duration of the dividend payment ($T - t$). We find that the sign of Eq. (27) is negative if the duration ($T - t$) is small and the growth rate and rate of return on assets are within a reasonable range. In addition, the curved lines in Table 1 also indicate a nonlinear relationship between the growth rate and the optimal payout ratio. We can therefore conclude that the relationship between the optimal payout ratio and the growth rate is nonlinear and generally negative.

Table 1 shows the sensitivity analysis of the relationship between the optimal payout and the growth rate. Panel A presents, when the duration of dividend payments ($T - t$) is equal to 3 years and the cost of capital is equal to 7%, the values of Eq. (32) under different settings of the rate of return on assets and the growth rate. Similar to Panel A, Panel B and Panel C present the values of Eq. (32) when the duration of dividend payments is equal to 3 years and 5 years and the cost of capital is equal to 7%.

Based upon Eq. (27), Fig. 1 plots the change in the optimal payout ratio with respect to the growth rate in different durations of dividend payments and costs of capital. We find a negative relationship between the optimal payout ratio and the growth rate, indicating that a firm with a higher rate of return on assets tends to pay out less when its growth opportunities increase. Moreover, a firm with a lower growth rate and higher expected rate of return will not decrease its payout when its growth opportunities increase, but a firm with a lower growth and a higher expected rate of return on asset is not a general case in the real world. We also find that the duration of future dividend payments is an important determinant of the dividend payout decision, but the effect on the cost of capital is relatively minor.

In the finite growth case, if $(h - k)(T - t) < 1$, then following the MacLaurin expansion, the optimal payout ratio under no change in risk defined in Eq. (26) can be written as

$$[\bar{D}(t)/\bar{x}(t)] \approx \left(1 - \frac{h}{a + b\bar{l}}\right)(1 + h(T - t)) \quad (28)$$

The partial derivative of Eq. (28) with respect to the growth rate is

$$\frac{\partial [\bar{D}(t)/\bar{x}(t)]}{\partial h} \approx \left(\frac{[(a + b\bar{l}) - h](T - t) - h(T - t) - 1}{a + b\bar{l}} \right) \quad (29)$$

Fig. 1 Sensitivity analysis of the relationship between the optimal payout and the growth rate. The figures show the sensitivity analysis of the relationship between the optimal payout and the growth rate. In each figure, each line shows the percentage change of the optimal dividend payout with a 1% change in the growth rate. The various lines represent different levels of the rate of return on assets. The figures present different durations of dividend payments (T - t) and costs of capital

Equation (29) indicates that the relationship between the optimal dividend payout and the growth rate depends on firm’s level of growth, the rate of return on assets, and the duration of future dividend payment.¹⁰ Eq. (29) is negative when the rate of return on assets is lower than the growth rate. This implies that the firm will reduce its payout when its growth rate increases. The higher growth rate (h) and the lower rate of return on assets ($a + b\bar{l}$) will lead to a more negative relationship between dividend payout ratio and growth rate. More specifically, the condition of Eq. (29) will lead to a negative relationship between the optimal payout ratio and the growth rate.

$$h > \frac{1}{2} \left[(a + b\bar{l}) - \frac{1}{(T - t)} \right] \tag{30}$$

Consistent with the sensitivity analysis of Eq. (27), when a firm with a high growth rate or a low rate of return on assets faces a growth opportunity, it will decrease its dividend payout to generate more cash to meet such a new investment.

¹⁰Please see the Appendix C for the derivation of Eq. (28) and Eq. (29).

A possible explanation is that high growth firms need more retained earnings to meet their future growth opportunities because the growth rate is the main determinant of value in the case of such companies, but low growth firms do not need more earnings to maintain their low growth perspective and can afford to increase their payouts. Based on the flexibility concerns, the relationship between firms' payout ratios and their growth rates is therefore negative.

101.6 Relationship Between Optimal Payout Ratio and Risks

Equation (26) implies that the optimal payout ratio is a function of the expected profitability rate ($a + b\bar{l}$), growth rate (h), cost of capital (k), age ($T-t$), total risk ($\sigma(t)^2$), and the correlation coefficient between profit and market rate of return ($\rho(t)^2$). In addition, Eq. (26) is also a function of two dynamic variables – the relative time rate of change in the total risk of the firm, $[\dot{\sigma}(t)^2/\sigma(t)^2]$, and the relative time rate of change in the covariability of the firm's earnings with the market, $[\dot{\rho}(t)^2/\rho(t)^2]$. This theoretical dynamic relationship between the optimal payout ratio and other determinants can be used to do empirical studies to determine dividend policy. The dynamic effects of variations in $[\dot{\sigma}(t)^2/\sigma(t)^2]$ and $[\dot{\rho}(t)^2/\rho(t)^2]$ on the time path of optimal payout ratio can be investigated under the following four cases: (1) changes in total risk, (2) changes in correlation between profit and the market rate of return (i.e., systematic risk), (3) changes in total risk and systematic risk, and (4) no changes in risk.

101.6.1 Case 1: Total Risk

First, we examine the effect of $[\dot{\sigma}(t)^2/\sigma(t)^2]$ on the optimal payout ratio. By differentiating Eq. (26) with respect to $[\dot{\sigma}(t)^2/\sigma(t)^2]$, we obtain

$$\frac{\partial [\bar{D}(t)/\bar{x}(t)]}{\partial [\dot{\sigma}(t)^2/\sigma(t)^2]} = \left(1 - \frac{h}{a + b\bar{l}}\right) \left[\frac{e^{(h-k)(T-t)} - 1}{h - k}\right]. \quad (31)$$

In Eq. (31) the cost of capital, k , can be either larger or smaller than the growth rate h . We can show that $\frac{e^{(h-k)(T-t)} - 1}{h - k}$ is always larger than 0, regardless of whether k is larger or smaller than h .¹¹ Thus, the sign of Eq. (31) depends on the sign of $\left(1 - \frac{h}{a + b\bar{l}}\right)$, which depends on the growth rate h relative to $(a + b\bar{l})$.

¹¹If $h > k$, then $e^{(h-k)(T-t)} > 1$, and both the numerator and denominator are greater than zero, resulting in a positive value; if $h < k$, then $e^{(h-k)(T-t)} < 1$, and both the numerator and denominator are less than zero, resulting in a positive value. Thus, $\frac{e^{(h-k)(T-t)} - 1}{h - k}$ is always larger than 0, regardless of whether k is larger or smaller than h .

If the growth rate h is equal to $(a + b\bar{l})$, then $\left(1 - \frac{h}{a+b\bar{l}}\right)$ is equal to zero. Eq. (31) is thus zero, and the change in total risk will not affect the payout ratio because the first derivative of the optimized payout ratio, Eq. (26), with respect to $\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]$ is always zero.

If growth rate h is larger than $(a + b\bar{l})$, then the entire first derivative of Eq. (26) with respect to $\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]$ is negative (i.e., Eq. (31) is negative); furthermore, $h > (a + b\bar{l})$ implies that the growth rate of a firm is larger than its expected profitability rate. An alternative case is $h < (a + b\bar{l})$, which implies that the growth rate of a firm is less than its expected profitability rate. This situation can occur when a company is either in a low growth, no growth, or negative growth stage. Under this situation, a company will increase its payout ratio as shown in Eq. (31). If $h < (a + b\bar{l})$, then Eq. (31) is positive, indicating that a relative increase in the risk of the firm would increase its optimal payout ratio. This implies that a relative increase in the total risk of the firm would decrease its optimal payout ratio. Lintner (1965) and Blau and Fuller (2008) have found this kind of relationship, yet they did not theoretically show how it can be derived.

Jagannathan et al. (2000) empirically show that operation risk is negatively related to the propensity to increase payouts in general and dividends in particular. Our theoretical analysis in terms of Eq. (31) shows that the change in total risk is negatively or positively related to the payout ratio, conditional on the higher growth rate relative to the expected profitability rate. We find negative relationships between payout and the change in total risk for high growth firms ($h > (a + b\bar{l})$). A possible explanation is that in the case of high growth firms, a firm must reduce the payout ratio and retain more earnings to build up “precautionary reserves,” which become all the more important for a firm with volatile earnings over time. High growth firms thus tend to retain more earnings when they face higher risk. By contrast, in the case of established low growth firms ($h < (a + b\bar{l})$), low growth firms are likely to be more mature and have most likely already built such reserves over time. They probably do not need more earnings to maintain their low growth perspective and can afford to increase the payout; consequently, when facing higher risk on their earnings, low growth firms can reduce their shareholders’ risk by paying more dividends to their shareholders.

The age of the firm ($T-t$), which is one of the variables in Eq. (31), becomes an important factor because the very high growth firms are also the newer firms with very little built-up precautionary reserves.

Under more dynamic conditions, we provide further evidence of the validity of Lintner’s (1965) observations that, *ceteris paribus*, optimal dividend payout ratios vary directly with the variance of the firm’s profitability rates. The rationale for such relationships, even when the systematic risk concept is incorporated into the analysis, is obvious; that is, holding $\rho(t)^2$ constant and letting the $\sigma(t)^2$ increase imply that the covariance of the firm’s earnings with the market does not change though its relative proportion to the total risk increases.

101.6.2 Case 2: Systematic Risk

To examine the effect of a relative change in $\left[\dot{\rho}(t)^2/\rho(t)^2\right]$ (i.e., systematic risk) on the dynamic behavior of the optimal payout ratio, we differentiate Eq. (26) to obtain

$$\frac{\partial [\bar{D}(t)/\bar{x}(t)]}{\partial [\dot{\rho}^2(t)/\rho^2(t)]} = \left(1 - \frac{h}{a + b\bar{l}}\right) \left[\frac{e^{(h-k)(T-t)} - 1}{h - k}\right]. \quad (32)$$

The sign of Eq. (32) can be analyzed as with Eq. (31), so the conclusions of Eq. (32) are similar to those of Eq. (31). A relative change in $\rho(t)^2$ can either decrease or increase the optimal payout ratio, all things being equal. The effect of non-stationarity in the firm's nondiversifiable risk would tend to be obliterated should both the systematic and the unsystematic components of total risk not be clearly identified in the expression for optimal payout ratio. Although the total risk of the firm is stationary (i.e., $[\dot{\sigma}(t)^2/\sigma(t)^2]$ is equal to zero) a change in the total risk complexion of the firm could still conceivably, occur because of an increase or decrease in the covariability of its earnings with the market. Eq. (26) and Eq. (32) clearly identify the effect of such a change in the risk complexion of the firm on its optimal payout ratio.

An examination of Eq. (26) indicates that only when the firm's earnings are perfectly correlated with the market (i.e., $\rho^2 = 1$), whether the management arrives at its optimal payout ratio using the total variance concept of risk or the market concept of risk does not matter. For every other case, the optimal payout ratio followed by management using the total variance concept of risk would be an overestimate of the true optimal payout ratio for the firm based on the market concept of risk underlying the capital asset pricing theory.

Management may decide not to use the truly dynamic model and instead substitute an average of the long run systematic risk of the firm, but for $\dot{\rho}^2(t) > 0$, because the initial average is higher than the true $\rho^2(t)$, the management would pay out less or more in the form of dividends than is optimal. In other words, the payout ratio followed in the initial part of the planning horizon would be an overestimate or an underestimate of the optimal payout under truly dynamic specifications.

Rozeff (1982) empirically shows a negative relationship between the β coefficient (systematic risk) and the payout level. The theoretical analysis in terms of Eq. (32) provides a more detailed analytical interpretation of his findings. The explanations of these results are similar to those discussed for findings in previous sections.

101.6.3 Case 3: Total Risk and Systematic Risk

In our third case, we attempt to investigate the compounded effect of a simultaneous change in the total risk of the firm and also a change in its decomposition into the

market-dependent and market-independent components. Taking the total differential of Eq. (26) with respect to $\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]$ and $\left[\dot{\rho}(t)^2/\rho(t)^2\right]$, we obtain

$$d[\overline{D}(t)/\overline{x}(t)] = \gamma d\left(\frac{\dot{\sigma}(t)^2}{\sigma(t)^2}\right) + \gamma d\left(\frac{\dot{\rho}(t)^2}{\rho(t)^2}\right), \quad (33)$$

where $\gamma = \left(1 - \frac{h}{a+b\bar{l}}\right) \left[\frac{e^{(h-k)(T-t)} - 1}{h-k}\right]$. Also, γ can be either negative or positive, as shown above.

Now from Eq. (33), the greatest decrease or increase in the optimal payout ratio would obviously occur when both $\dot{\sigma}(t)^2$ and $\dot{\rho}(t)^2$ are positive. This implies that the total risk of the firm increases, and in addition, its relative decomposition into systematic and unsystematic components also changes, making the firm's earnings still more correlated with the market. Under this circumstance, the decrease or increase in the optimal payout would now represent the compounded effect of both these changes; however, it is conceivable that although $\dot{\sigma}(t)^2$ is positive, $\dot{\rho}(t)^2$ is negative, tending to offset the decrease or increase in the optimal payout ratio resulting from the former. Alternatively, $\dot{\sigma}(t)^2$ could be negative, indicating a reduction in the total risk of the firm and may offset the increase in the optimal payout ratio resulting from a positive $\dot{\rho}(t)^2$.

To what extent the inverse variations in the total risk and the risk complexion of the firm will offset each other's effects on the optimal payout ratio for the firm would, of course, be dependent upon the relative magnitudes of $\dot{\rho}(t)^2$ and $\dot{\sigma}(t)^2$. To see the precise trade-off between the two dynamic effects of $\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]$ and $\left[\dot{\rho}(t)^2/\rho(t)^2\right]$ on the optimal payout ratio, let the total differential of (26), given in Eq. (33), be set equal to zero, yielding

$$d\left[\dot{\sigma}(t)^2/\sigma(t)^2\right] = -d\left[\dot{\rho}(t)^2/\rho(t)^2\right] \quad (34)$$

Equation (34) implies that the relative increase (or decrease) in $\sigma(t)^2$ has a one-to-one correspondence with the relative decrease (or increase) in $\rho(t)^2$, so in Eq. (34) conditions are established for relative changes in $\rho(t)^2$ and $\sigma(t)^2$, which lead to a null effect on the optimal dividend payout ratio.

101.6.4 Case 4: No Change in Risk

Now we consider the least dynamic situation, in which no changes exist in total risk or systematic risk, assuming $\dot{\sigma}(t)^2 = 0$ and $\dot{\rho}(t)^2 = 0$. Under this circumstance, Eq. (26) reduces to

$$[\overline{D}(t)/\overline{x}(t)] = \left(1 - \frac{h}{a+b\bar{l}}\right) \left[\frac{-k + he^{(h-k)(T-t)}}{h-k}\right]. \quad (35)$$

Thus, when the firm's total risk and covariability of its earnings with the market are assumed stationary, Eq. (35) indicates that a firm's optimal payout ratio is independent of its risk. Notice that neither $\sigma(t)^2$ nor $\rho(t)^2$ now appear in the expression for the optimal payout ratio given in Eq. (35). These conclusions, like those of Wallingford (1972a, b) for example, run counter to the intuitively appealing and well-accepted theory of finance emphasizing the relevance of risk for financial decision-making.¹² Our model clearly shows that the explanation for such unacceptable implications of the firm's total risk and its market-dependent and market-independent components for the firm's optimal payout policy lies, of course, in the totally unrealistic assumptions of stationarity underlying the derivation of such results as illustrated in Eq. (35).

101.7 Empirical Evidence

A growing body of literature focuses on the determinants of optimal dividend payout policy. Rozeff (1982), Jagannathan et al. (2000), Grullon et al. (2002), Aivazian et al. (2003), Blau and Fuller (2008), and others empirically investigate the determination of dividend policy, but none of them has a solid theoretical model to support their findings. Based upon our theoretical model and its implications discussed in the foregoing sections, we develop the three testable hypotheses that follow.

Hypothesis 1: Firms generally reduce their dividend payouts when their growth rates increase.

The negative relationship between the payout ratio and the growth ratio in our theoretical model implies that high growth firms need to reduce the payout ratio and retain more earnings to build up "precautionary reserves," but low growth firms are likely to be more mature and already build up their reserves for flexibility considerations. Rozeff (1982), Fama and French (2001), Blau and Fuller (2008), and others argue that high growth firms will have higher investment opportunities and tend to pay out less in dividends. Based upon flexibility concerns, we predict that high growth firms pay higher dividends. This result is obtained when risk factor is not explicitly considered.

Following Eqs. (31) and (32), we theoretically find that the relationship between the payout ratio and the risk can be either negative or positive, depending upon whether the growth rate is higher or lower than the rate of return on total assets. Based upon this finding, we develop two other hypotheses.

Hypothesis 2: The relationship between the firms' dividend payouts and their risks is negative when their growth rates are higher than their rates of return on asset.

High growth firms need to reduce the payout ratio and retain more earnings to build up "precautionary reserves," which become more important for a firm with volatile earnings over time. For flexibility considerations, high growth firms tend to

¹²For example, Lintner (1963).

retain more earnings when they face higher risk. This theoretical result is consistent with the flexibility hypothesis.

Hypothesis 3: The relationship between the firms' dividend payouts and their risks is positive when their growth rates are lower than their rates of return on asset.

Low growth firms are likely to be more mature and have most likely already built such reserves over time, and they probably do not need more earnings to maintain their low growth perspective and can afford to increase the payout (see Grullon et al. 2002). Because the higher risk may involve higher cost of capital and make the free cash flow problem worse, for free cash flow considerations, low growth firms tend to pay more dividends when they face higher risk. This theoretical result is consistent with the free cash flow hypothesis.

101.7.1 Sample Description

We collect the firm information, including total asset, sales, net income, and dividends payout, from Compustat. Stock price, stock returns, share codes, and exchange codes are retrieved from the Center for Research in Security Prices (CRSP) files. The sample period is from 1969 to 2009. Only common stocks (SHRCD = 10, 11) and firms listed on NYSE, AMEX, or NASDAQ (EXCE = 1, 2, 3, 31, 32, 33) are included in our sample. We exclude utility services (SICH = 4900–4999) and financial institutions (SICH = 6000–6999).¹³ The sample includes those firm-years with at least 5 years of data available to compute average payout ratios, growth rate, return on assets, beta, total risk, size, and book-to-market ratios. The payout ratio is measured as the ratio of the dividend payout to the net income. The growth rate is the sustainable growth rate proposed by Higgins (1977). The beta coefficient and total risk are estimated by the market model over the previous 60 months. For the purpose of estimating their betas, firm-years in our sample should have at least 60 consecutive previous monthly returns. To examine the optimal payout policy, only firm-years with five consecutive dividend payouts are included in our sample.¹⁴ Considering the fact that firm-years with no dividend

¹³We filter out those financial institutions and utility firms based on the historical Standard Industrial Code (SIC) available from COMPUSTAT. When a firm's historical SIC is unavailable for a particular year, the next available historical SIC is applied instead. When a firm's historical SIC is unavailable for a particular year and all the years after, we use the current SIC from COMPUSTAT as a substitute.

¹⁴To avoid creating a large difference in dividend policy, on one hand managers partially adjust firms' payout by several years to reduce the sudden impacts of the changes in dividend policy. On the other hand, they use not only 1-year firm conditions but also multiyear firm conditions to decide how much they will pay out. In examining the optimal payout policy, we use the 5-year rolling averages for all variables.

payout 1 year before (or after) might not start (or stop) their dividend payouts in the first (fourth) quarter of the year, we exclude from our sample firm-years with no dividend payouts 1 year before or after to ensure the dividend payout policy reflects the firm's full-year condition.

Table 2 shows the summary statistics for 2,645 sample firms during the period from 1969 to 2009. Panel A of Table 2 lists the number of firm-year observations for all sample high growth firms and low growth firms, respectively. High growth firm-years are those firm-years that have 5-year average sustainable growth rates higher than their 5-year average rate of return on assets. Low growth firm-years are those firms with 5-year average sustainable growth lower than their 5-year average rate of return on assets. The sample size increases from 345 firms in 1969 to 1,203 firms in 1982, while declining to 610 firms by 2009. A total of 28,333 dividend paying firm-years are included in the sample. When classifying high growth firms and low growth firms relative to their return on assets, the proportion of high growth firms increases over time. The proportion of firm-years with a growth rate higher than return on assets increases from less than 50% during the late 1960s and early 1970s to 80% in 2008. Panel B of Table 2 shows the 5-year moving averages of mean, median, and standard deviation values for the measures of payout ratio, growth rate, rate of return, beta coefficient, total risk, market capitalization, and market-to-book ratio across all firm-years in the sample. Among high growth firms, the average growth rate is 12.33%, and the average payout ratio is 31.80%; but for low growth firms, the average growth rate is 4.13%, and the average payout ratio is 57.62%. High growth firms undertake more beta risk and total risk, indicating that high growth firms undertake both more systematic risk and unsystematic risk to pursue a higher rate of return.

Table 2 presents the descriptive statistics for those major characteristics of our sample firms. Sample includes those firms listed on NYSE, AMEX, and NASDAQ with at least 5 years of data available to compute average payout ratios, growth rate, return on assets, beta, total risk, size, and book-to-market ratios. All financial service operations and utility companies are excluded. Panel A lists the numbers of firm-years observations for all sample firms, high growth firms, and low growth firms, respectively, during the period between year 1969 and year 2009. High growth firm-years are defined as firm-years with sustainable growth rates higher than their rates of return on assets. Low growth firm-years are defined as firm-years with sustainable growth rates lower than their rate of return on assets. Panel B lists the mean, median, and standard deviation values of the 5-year average of the payout ratio, growth rate, rate of return on assets, beta risk, total risk, size, and book-to-market ratio. The payout ratio is measured as the ratio of the dividend payout to the earnings. Growth rate is the sustainable growth rate proposed by Higgins (1977). The beta coefficient and total risk are estimated by the market model over the previous 60 months. Size is defined as market capitalization calculated by the closing price of the last trading day of June of that year times the outstanding shares at the end of June of that year.

101.8 Univariate Analysis

To examine Hypothesis 1, we divide our sample into five groups by growth rate. As Table 3 Panel A indicates, the average (median) payout ratio is 48.64% (48.35%) for the lowest growth group and is 22.13% (19.67%) for the highest growth group. The argument of “precautionary reserves” for flexibility concerns and Hypothesis 1 can therefore be confirmed. We further divide our sample into 5 groups by beta risk and total risk indicated in Panel B and Panel C of Table 3. We can observe a monotonic decrease in payout ratios when the beta risk or the total risk increases, which is consistent with the findings of Rozeff (1982), Fenn and Liang (2001), Grullon et al. (2002), Aivazian et al. (2003), and Blau and Fuller (2008), but they do not consider the relationship between the payout ratio and the risk may alter by the growth. To examine the Hypothesis 2 and Hypothesis 3, we further divide our sample by two-way sorts on the growth rate and risks. High growth groups are firm-years with sustainable growth rates higher than their rate of return on total assets. Low growth groups are firm-years with sustainable growth rates lower than their rate of return on total assets. In Table 3 Panel B, among high growth firms, the average (median) payout ratio decreases from 31.73% (30.10%) to 28.86% (25.88%) when

the beta risk increases. Among low growth firms, however, the average (median) payout ratio increases from 61.15% (58.64%) to 62.92% (60.90%) when the beta risk increases. Similar to Panel B, Panel C also shows a negative relationship between the payout ratio and the total risk among high growth firms and a positive relationship between the payout ratio and the total risk among low growth firms. Above all, the static analysis results of Panel B and Panel C support Hypotheses 2 and 3 that the relationship between the payout ratio and the risk depends upon the growth rate of a firm.

Table 3 presents the average and the median payout ratios in difference groups partitioned by growth rate, beta risk, or total risk during the sample period from 1969 to 2009. Panel A reports the average and the median payout ratios by one-way sort on the growth rate. Panel B reports the average and the median payout ratios by independent two-way sort on the growth rate and the beta. Panel C reports the average and the median payout ratios by independent two-way sort on the growth rate and the total risk. High growth firm-years are defined as firm-years with sustainable growth rates higher than their rates of return on assets. Low growth firm-years are defined as firm-years with sustainable growth rates lower than their rate of return on assets.

101.8.1 Multivariate Analysis

To examine the relationship between the payout ratio and other financial variables, we propose fixed-effects models of the payout ratio as follows¹⁵:

$$\ln \left(\frac{\text{payout ratio}_{i,t}}{1 - (\text{payout ratio}_{i,t})} \right) = \alpha + \beta_1 \text{Risk}_{i,t} + \beta_2 D_{i,t}(g_{i,t} < c \cdot ROA_{i,t}) \cdot \text{Risk}_{i,t} + \beta_3 \text{Growth}_{i,t} + \beta_4 \text{Risk}_{i,t} \times \text{Growth}_{i,t} + \beta_5 \ln(\text{Size})_{i,t} + \beta_6 ROA_{i,t} + e_{i,t}. \quad (36)$$

In the regression, the dependent variable is the logistic transformation of the payout ratio. Independent variables include risk measure (beta coefficient or total risk), the interaction of dummy variable and risk measure, growth rate, the interaction of risk measure and growth rate, log of size, and rate of return on total assets.¹⁶ Based upon the theoretical model and its implications from Sect. 101.6, we assume

¹⁵ The dummy variable $D_{i,t}(g_{i,t} < c \cdot ROA_{i,t})$ used in Eq. (36) implies that the relationship between the payout ratio and risks is nonlinear (piecewise regression). In other words, the breakpoint of the structural change is at $g_{i,t} = c \cdot ROA_{i,t}$. Based upon our theoretical model, we assume that c is equal to 1 in our empirical work.

¹⁶ Besides merely adding an interaction dummy as indicated in Eq. (36), we include an intercept dummy to take care of the individual effect of two groups. We also run regressions for high growth firms and low growth firms separately. Results from both models are qualitatively the same as those from Eq. (36) and also support Hypotheses 1 to 3.

that c is equal to 1. The dummy variable (D_i) is equal to 1 if a firm's 5-year average growth rate is less than its 5-year average rate of return on assets and 0 otherwise. Such structure allows us to analyze the relationship between payout ratio and growth rate and the relationship between payout ratio and risk under different growth rate levels.

Thompson (2011), Peterson (2009), and Cameron et al. (2006) have pointed out that standard errors of two-way fixed-effects estimates can be biased if 2-dimensional clustering (clustering in the cross-sectional errors and clustering in time-series errors) is not controlled for. Thompson (2011) and Boehmer et al. (2010) have empirically found that these clustering effects are not important for large samples.

The robust standard errors are very similar to standard errors for ordinary least square (OLS), suggesting that the fixed effects and control variables are removing most of the correlation that is present across observations. In addition, our dataset cannot be meaningfully applied to the clustering effect model¹⁷; therefore, statistical inferences in this chapter are conducted using fixed-effects standard errors.

Table 4 provides the results of fixed-effects regressions for 2,645 firms during the period 1969 to 2009. *Model (1)* and *Model (2)* show that the estimated coefficients of the growth rate are -0.03 with a t -statistics of -4.85 and -0.03 with a t -statistics of -4.85 , respectively. Such significantly negative coefficients confirm Hypothesis 1, which states that high growth firms will pay less in dividends for the consideration of flexibility. We also include an interaction term of risk and growth rate into *Model (3)* and *Model (4)*. The results in *Model (3)* and *Model (4)* also support Hypothesis 1.

Table 4 presents results from fixed-effects regressions of dividend payout ratios on firm characteristics for 2,645 firms during the period from 1969 to 2009. The regressions are as follows:

$$\ln \left(\frac{\text{payout ratio}_{i,t}}{1 - (\text{payout ratio}_{i,t})} \right) = \alpha + \beta_1 \text{Risk}_{i,t} + \beta_2 D(g_{i,t} < c \cdot ROA_{i,t}) \cdot \text{Risk}_i \\ + \beta_3 \text{Growth}_{i,t} + \beta_4 \text{Risk}_{i,t} \times \text{Growth}_{i,t} \\ + \beta_5 \ln(\text{Size})_{i,t} + \beta_6 ROA_{i,t} + e_{i,t}.$$

The dependent variable is the payout ratio with a logistic transformation. Following the theoretical model, we assume c is equal to 1. The dummy variable is equal to 1 if a firm's 5-year average growth rate is less than its 5-year average ROA, and 0 otherwise. The independent variables are beta risk (total risk), dummy times beta risk (total risk), interaction between growth rate and beta risk (total risk), growth rate, log of size, and the rate of return on assets. t -statistics are presented in

¹⁷Because our sample is an unbalanced panel data, the clustering computer program cannot meaningfully estimate the variance components, variance of firm ($\hat{V}_{firm}$), variance of time ($\hat{V}_{time}$), and heteroskedasticity-robust OLS variance ($\hat{V}_{white}$).

parentheses, and the last column presents p -values of the F -test on the null hypothesis that the restricted *Models (1) to (4)* are not different from the restricted *-Models (5) to (8)*.

Models (1) to (4) show that the relationship between the payout ratio and the risk is significantly negative. The results are similar to the findings of Rozeff (1982), Jagannathan et al. (2000), and Grullon et al. (2002), indicating that dividend payouts are negatively correlated to firm risks; but our theoretical model shows that if firms follow their optimal dividend payout policy, the relationship between dividend payouts and firm risks depends on their growth rates relative to their rate of return on total assets as our theoretical analysis presented in Sect. 101.6. In Table 2, we find the number of firms with a higher growth rate with respect to their rate of return on assets is greater than the number of firms with a lower growth rate with respect to their rates of return on assets. When pooling high growth firms and low growth firms together, the negative risk effect of high growth firms will dominate the positive risk effect of low growth firms due to the larger proportion of high growth firms in the observations. The results of the negative relationship between the payout ratio and the risk shown in *Models (1) to (4)* may therefore result from the greater proportion of high growth firms. Based on our subsequent analysis, the effect of growth rates on dividend payout policies can be more accurately found when firms are separated into high growth firms and low growth firms relative to their rates of return on total assets of return on assets.

To test Hypotheses 2 and 3, we introduce an interaction term of the dummy variable and the risk. In *Model (5)* and *Model (6)*, the estimated coefficients of risk are -0.23 with a t -statistics of -13.88 and -0.22 with a t -statistics of -12.69 , respectively. The significantly negative coefficients support the hypothesis 2 that, because of the consideration of flexibility, the payout ratio and the risk are negatively correlated for firms with a higher growth rate relative to their rate of return on assets. In addition, significant and positive coefficients of the interaction term of the dummy variable and the risk indicate that, when the risk changes, the dividend policy for low growth firms is different from that of high growth firms. By summing the coefficient of risk and the coefficient of interaction term, we can obtain coefficients of 0.48 and 35.54 for beta and total risk, respectively, indicating the relationship between the payout ratio and the risk for low growth firms is positive. That is, when the risk increases, low growth firms will follow their optimal payout policies to increase their dividend payouts. Hypothesis 3 is thus confirmed in our empirical work. Blau and Fuller (2008) find that the flexibility hypothesis is more suitable than the free cash flow hypothesis to explain the dividend policy, but their method cannot separate the dividend policy decisions between high growth firms and low growth firms. Consequently, the model used in this chapter can be regarded as a generalization of their results.

In *Model (7)* and *Model (8)* in Table 4, we further include the interaction term of the risk and the growth rate into the regressions. The results still support our hypotheses that the relationship between the payout ratio (Hypothesis 1) and the growth rate is negative and the relationship between the payout ratio and the risk depends on firm's growth rate with respect to its rate of return on total assets

(Hypotheses 2 and 3). In addition, we find that the interaction terms of the risk and the growth rate are significantly different from zero. We also find that the adjusted R-squares for *Models (5) to (8)* are higher than those for models without dummies. *F* tests also reject the null hypothesis that the regression with the interaction of the dummy variable and the risk is not different from the regression without the interaction of the dummy and the risk. We can thus conclude that the payout ratio is not linearly related to the growth rate or to the risk, and previous empirical studies on dividend policy using linear model may suffer from model misspecification.

101.8.2 Moving Estimates Process for Structural Change Model

In Eqs. (31) and (32) in Sect. 101.6, we theoretically show that the structural change breakpoint for the relationship between the payout ratio and risks is at $g_{i,t} = ROA_{i,t}$. In empirical works, we use dummy variable approach to separate the sample into a high growth ($g_{i,t} > c \cdot ROA_{i,t}$) group and a low growth ($g_{i,t} < c \cdot ROA_{i,t}$) group, assuming c is equal to 1, and empirically test the relationship between the payout ratio and risks for high growth firms and low growth firms. Based on the moving estimates process developed by Chow (1960), Hansen (1996, 1999, and 2000), and Zeileis et al. (2002), we here try to estimate the empirical breakpoint of the structural change and examine whether the empirical breakpoint is different from our theoretical breakpoint or not.

By using the moving estimates process, we can obtain an empirical estimate of $c = 0.93$ when using beta risk and $c = 0.97$ when using total risk.¹⁸ That is, the breakpoint of the structural change is at $g_{i,t} = 0.93 \times ROA_{i,t}$ or $g_{i,t} = 0.97 \times ROA_{i,t}$. Then we redo *Model (5) to Model (8)* of Table 4 by using the empirical structural change point instead of the theoretical structural change point. In Table 5, we compare to the theoretical model and find that the estimates and significances using the empirical breakpoint of the structural change are almost same as those using the theoretical breakpoint indicated in Table 4. Results obtained from the moving estimates process show the existence of an empirical breakpoint for the relationship between the payout ratio and risks and also confirm that the dummy variable used in Eq. (36) is both theoretically and empirically acceptable.

Table 5 presents results from fixed-effects regressions of dividend payout ratios on firm characteristics for 2,645 firms during the period from 1969 to 2009. The regressions are as follows:

¹⁸ Gujarati (2009) shows that this kind of problem can be regarded as piecewise regression by using moving estimates processes. Please see the Appendix D for the details of the moving estimates process.

Table 5 Fixed-effects regressions using empirical structural change point

Model	Intercept	Beta	D*beta	Growth* beta	Total risk	D*total risk	Growth* total risk	Growth	ln (Size)	ROA	Adj- R2	F-test (p-value)
(1) $c = 0.93$ 0.931	0.29*** (2.58)	-0.21*** (-12.57)	0.77*** (58.41)					-0.02*** (-3.46)	0.005 (0.55)	-11.63*** (-58.46)	0.2891	<0.01

*, **, and *** indicate significance at the 10%, 5%, and 1% levels, respectively

$$\ln \left(\frac{\text{payout ratio}_{i,t}}{1 - (\text{payout ratio}_{i,t})} \right) = \alpha + \beta_1 \text{Risk}_{i,t} + \beta_2 D(g_{i,t} < c \cdot \text{ROA}_{i,t}) \cdot \text{Risk}_i \\ + \beta_3 \text{Growth}_{i,t} + \beta_4 \text{Risk}_{i,t} \times \text{Growth}_{i,t} \\ + \beta_5 \ln(\text{Size})_{i,t} + \beta_6 \text{ROA}_{i,t} + e_{i,t}.$$

The dependent variable is the payout ratio with a logistic transformation. Based upon results from the moving estimates process, c is equal to 0.93 when using beta risk and 0.97 when using total risk. The dummy variable is equal to 1 if a firm's 5-year average growth rate is less than its 5-year average ROA, and 0 otherwise. The independent variables are beta risk (total risk), dummy times beta risk (total risk), interaction between growth rate and beta risk (total risk), growth rate, log of size, and the rate of return on assets. t -statistics are presented in parentheses, and the last column presents p -values of the F -test on the null hypothesis that the restricted *Models (1)–(4)* in Table 4 are not different from the restricted *Models (1)–(4)* in Table 5.

101.9 Interaction Among Investment, Financing, and Dividend Policies

In previous sections, we have theoretically and empirically shown that dividend policy decision will affect the value of a firm. Fama (1974) investigated the relationship between investment and dividend policy and Fama and French (2002) investigated the relationship between dividend policy and financing policy. By updating and generalizing Fama and Fama and French's models, Lee et al. (2016) investigated the relationship among investment, dividend, and financing policy.

Using the data from 1965 to 2019, we update Lee et al. (2016) paper. The main empirical results in terms of updated data are presented in Table 6. We use a three-equation system, which is presented in Eqs. 37, 38, and 39, to perform the empirical study. The empirical results of their equation system is presented in Table 6. The exogenous variables used in Table 6 are now discussed in some detail. In addition to lag-terms of the three policies, they follow Fama (1974) to respectively incorporate sales plus change in inventories (Q_{it}) and net income minus preferred dividends (P_{it}) into investment and dividend decisions. Moreover, Lee et al. (2016) follow Fama and French (2002) to add natural logarithm of lagged total assets ($\ln A_{i,t-1}$) and the lag of earnings before interest and taxes divided by total assets ($E_{i,t-1}/A_{i,t-1}$) as the determinants of leverage. Finally, Leary and Roberts (2014) argue that the characteristic of peer firms is important to influence firms' capital structure and thus they also follow them to consider lagged industry averages book leverage ($\text{Industry}_{i,t-1}$) into their leverage decision.

$$\text{Inv}_{it} = \alpha_{1i} + \alpha_{2i} \text{Div}_{it} + \alpha_{3i} \text{Leverage}_{it} + \alpha_{4i} \text{Inv}_{i,t-1} + \alpha_{5i} Q_{it} + \epsilon_{it}, \quad (37)$$

Table 6 shows 2SLS regression results for simultaneous-equations model. Averages of individual firms' coefficient estimates of the investment, dividend, and debt financing regressions are presented. The results of relations among these three financial decisions could be directly obtained in this method. First, the positive coefficient of $Leverage_{it}$ (which is marginally significant in investment decision), and Inv_{it} (in debt financing decision) imply that firms with higher investment have higher debt financing and vice versa. Ross (1977) and Myers and Majluf (1984)

suggest that debt is preferred to equity for managers to signal the optimistic investment opportunity to investors because firms are expected to have higher future cash flows to repay the debt. Harris and Raviv (1990) argue that debt is a device to solve the asymmetric information for the investors, because it helps to monitor managers and force the firm to liquidation. In addition, our finding that increases in debt financing enhance the funds available to outlays for investment is consistent with McDonald et al. (1975), McCabe (1979), Peterson and Benesh (1983), John and Nachman (1985), and Froot et al. (1993). Thus, our optimal debt ratio may be the result of a trade-off between the value of information (from more debt) and the cost of monitor.

Second, the significant coefficients of Div_{it} and Inv_{it} imply that dividend outlays influence investment decisions and vice versa. This finding implies that the firms may use dividend payout to signal the growth opportunity and then these firms increase their investment. The firm with higher investment input may experience the higher earnings and thus could increase the dividend payout. Such finding, that dividend payout responds to investment, confirms the model prediction of Lambrecht and Myers (2012). The relationship between dividend payout and investment is also consistent with the signaling cash flow hypothesis of dividend payout in Yoon and Starks (1995).

Third, the impact of debt financing on dividend is significantly negative, showing that firms pay more dividend when they have lower leverage level. The pecking order hypothesis of Myers and Majluf (1984) implies that firms with less leverage level have more internal funds and thus these firms tend to have capability to pay dividend. Thus, our finding seems to support the concept of Myers and Majluf (1984) and is also consistent with Jensen et al. (1992) and Fama and French (2002).

Table 6 presents the 2SLS regression results of a simultaneous equation system model for investment, dividend, and debt financing.

The coefficients are shown in averages across the 563 firms. Regressions are based on non-missing observations and winsorization at the 1st and 99th percentiles. The three endogenous variables are Inv_{it} , Div_{it} , and $Leverage_{it}$, which are net plant and equipment, dividends, and book leverage ratio, respectively. The independent variables in the investment regression are lagged investment ($Inv_{i,t-1}$), and sales plus change in inventories (Q_{it}). The independent variables in the dividend regression are lagged dividends ($Div_{i,t-1}$), and net income minus preferred dividends (P_{it}). All the variables in both of investment and dividend equations are measured on a per share basis. The independent variables in the debt financing regression are lagged book leverage ($Leverage_{i,t-1}$), natural logarithm of lagged total assets ($\ln A_{i,t-1}$), the lag of earnings before interest and taxes divided by total assets ($E_{i,t-1}/A_{i,t-1}$), and lagged industry averages book leverage ($Industry_{i,t-1}$). Numbers in the parentheses are t-statistics. The sign in bracket is the expected sign of each variable of regressions.

101.10 Summary and Concluding Remarks

In this chapter, we extend the model developed in earlier studies and improve upon the results obtained in those studies on optimal dividend payout. By allowing partial dividend payout for the consideration of flexibility, we theoretically show the

existence of the optimal dividend payout. The results obtained in this chapter are different from those of M&M (1961) because, contrary to their model, the model developed here is dynamic, is under uncertainty, and allows the firm to retain some earnings for positive NPV projects, following DeAngelo and DeAngelo (2006) and Blau and Fuller (2008). The dynamic stochastic model developed and empirically tested here is comprehensive and for the very first time includes several variables simultaneously that have not been included in any of the earlier studies. More specifically, the optimization model developed here includes, among other things, a stochastic rate of return on assets, corporate growth rate, and total risk (broken down into its systematic and firm-specific components).

We further analyze the effects of different parameters on the optimal payout ratio. A sensitivity analysis and an approximation form show a negative but nonlinear relationship between the optimal dividend payout ratio and the growth rate. We also explicitly derive the theoretical relationship between the optimal payout ratio and risks. Results of the comparative static analyses cast a different light on the relationship between corporate dividend policy and risk. That the risk and dividend payout are negatively related is generally believed. On the contrary, the relationship between risk and dividend payout is positive when the growth rate is less than the company's rate of return on assets. Only when the growth rate exceeds the rate of return on assets does the relationship between dividend payout and risk turns negative. In sum, this chapter shows for the first time that the relationship between growth and dividend payout is nonlinear. In addition, no research has ever shown that the relationship between risk rates and the dividend payout is nonlinear and influenced by other important variables, those of the company's rate of return on assets and growth rate.

Based upon our theoretical model, we develop three testable hypotheses and try to reconcile conflicts between the flexibility hypothesis and the free cash flow hypothesis in existing literature. The empirical research covers 40 years of the US data from 1969 to 2009 for 28,333 dividend-paying firm-years. Our empirical results show that the optimal dividend payout ratio is negatively, but not linearly, related to the growth rate. In addition, the optimal dividend payout ratio is negatively (positively) related to both total risk and systematic risk when the growth rate is higher (lower) than the rate of return on assets. Such results also confirm the argument that high growth firms pay dividends due to flexibility considerations and low growth firms pay dividends due to the consideration of the free cash flow problem. This result implies that dividend policy affects the value of a firm. Based upon this result, we empirically analyze interaction among investment, financing, and dividend policy.

In sum, this chapter develops a dynamic stochastic model deriving relationships between corporate dividend payout and several important financial variables. The relationships derived from the model are then tested by extensive empirical research. The relationships found between dividend payout and the growth rate and between dividend payout and risk run counter to those observed in earlier studies and also counter to generally held beliefs. Extensive empirical research validated the conclusions derived from the dynamic stochastic optimization model developed in this chapter. For the first time we report here in the literature that these relationships are

nonlinear and not solely negative as found in other studies. Thus this chapter extends the model developed in earlier studies and improves upon the results obtained in those studies on optimal dividend payout. We believe that this chapter has shown that dividend policy is relevant instead of irrelevant in terms of affecting the value of a firm.

Appendix A. Derivation of Eq. (19)

This appendix presents a detailed derivation of the solution to the variable partial differential equation, Eq. (17), which is similar to Gould's (1968) Eq. (9) in investigation the adjustment cost. Following Gould's (1968) approach, we first derive a general solution for a standard variable partial differential equation. Then we apply this general equation to solve Eq. (17). The standard variable partial differential equation can be defined as

$$\dot{p}(t) + g(t)p(t) = q(t). \quad (40)$$

As a particular case of Eq. (40), the equation

$$\dot{p}(t) + g(t)p(t) = 0 \text{ or } \frac{\dot{p}(t)}{p(t)} = -g(t) \quad (41)$$

has a solution

$$p(t) = c \cdot \exp\left(-\int g(t)dt\right). \quad (42)$$

By substituting constant c with function $c(t)$, we have the potential solution to Eq. (40)

$$p(t) = c(t) \cdot \exp\left(-\int g(t)dt\right). \quad (43)$$

Taking a differential with respect to t , we obtain

$$\begin{aligned} \dot{p}(t) &= \dot{c}(t) \cdot \exp\left(-\int g(t)dt\right) - c(t) \cdot \exp\left(-\int g(t)dt\right)g(t) \\ &= \dot{c}(t) \cdot \exp\left(-\int g(t)dt\right) - p(t)g(t). \end{aligned} \quad (44)$$

Therefore,

$$\dot{p}(t) + p(t)g(t) = \dot{c}(t) \cdot \exp\left(-\int g(t)dt\right). \quad (45)$$

From Eq. (40) and Eq. (45), we have

$$\dot{c}(t) \cdot \exp \left(- \int g(t) dt \right) = q(t). \quad (46)$$

Equivalently,

$$\dot{c}(t) = q(t) \cdot \exp \left(\int g(t) dt \right). \quad (47)$$

Therefore,

$$c(t) = \int q(t) \cdot \exp \left(\int g(t) dt \right) dt. \quad (48)$$

Substituting Eq. (48) into Eq. (42), we have the general solution of Eq. (40),

$$p(t) = \exp \left(- \int g(t) dt \right) \cdot \left[\int q(t) \exp \left(\int g(t) dt \right) dt \right]. \quad (49)$$

To solve Eq. (17), we will apply the above result. Let $g(t) = \delta \frac{\dot{m}(t)}{m(t)} - k$ and $q(t) = -G(t)$.

Because

$$\begin{aligned} \exp \left(\int g(t) dt \right) &= \exp \left(\int \left(\delta \frac{\dot{m}(t)}{m(t)} - k \right) dt \right) \\ &= \exp \left(\delta \int \frac{\dot{m}(t)}{m(t)} dt - kt \right) \\ &= \exp \left(\delta \ln(m(t)) - kt + c \right) \\ &= c_1 \cdot m(t)^\delta \exp(-kt), \end{aligned} \quad (50)$$

where $c_1 > 0$,

then we have

$$P(t) = c_2 \cdot m(t)^{-\delta} \exp(kt) \cdot \left[\int q(t) c_3 \cdot m(t)^\delta \exp(-kt) dt \right], \quad (51)$$

where $c_2 > 0$, and $c_3 > 0$

or equivalently,

$$P(t) = c_4 \cdot \frac{e^{kt}}{m(t)^\delta} \cdot \left[\int -G(t) \frac{m(t)^\delta}{e^{kt}} dt \right], \quad (52)$$

where $c_4 > 0$.

Finally, we have

$$P(t) = c \frac{e^{kt}}{m(t)^k} \cdot \int G(t)m(t)^\delta e^{-kt} dt. \quad (53)$$

Changing from an indefinite integral to a definite integral, Eq. (52) can be shown as

$$p(t) = \frac{e^{kt}}{m(t)^\delta} \int_t^T G(s)m(s)^\delta e^{-ks} ds,$$

which is Eq. (19).

Appendix B. Derivation of Eq. (21)

This appendix presents a detailed derivation of Eq. (21). In Eq. (20), the initial value of the firm can be expressed as

$$p(0) = \frac{1}{m(0)^\delta} \int_0^T \left\{ (a + b\bar{l} - h)A(0)e^{th}m(t)^{\delta-1} - \alpha'A(0)^2\rho(t)^2\sigma(t)^2e^{2th}m(t)^{\delta-2} \right\} e^{-kt} dt. \quad (20)$$

To maximize firm value, the number of shares outstanding at each point of time should be determined; therefore, the objective function can be written as follows:

$$\max_{\{m(t)\}_{t=0}^T} p(0). \quad (54)$$

Following the Euler-Lagrange condition (see Chiang 1984), we take first order conditions on the objective function with respect to $m(t)$, where $t \in [0, T]$ and let such first order conditions be equal to zero.

$$\frac{1}{m(0)^\delta} \left\{ (\delta - 1)(a + b\bar{l} - h)A(0)e^{th}m(t)^{\delta-2} - \alpha'A(0)^2\rho(t)^2\sigma(t)^2e^{2th}m(t)^{\delta-3}(\delta - 2) \right\} e^{-kt} dt = 0, \quad (55)$$

where $t \in [0, T]$.

To simplify Eq. (55),

$$\begin{aligned} & (\delta - 1)(a + b\bar{l} - h)A(0)e^{th}m(t)^{\delta-2} - \alpha'A(0)^2\rho(t)^2\sigma(t)^2e^{2th}m(t)^{\delta-3}(\delta - 2) \\ & = 0, \end{aligned} \quad (56)$$

where $t \in [0, T]$, which is Eq. (21).

Appendix C. Derivation of Eqs. (28) and (29)

This appendix presents a detailed derivation of both Eq. (28) and Eq. (29). In Eq. (35), the optimal payout ratio with no changes in total risk or systematic risk is

$$[\overline{D}(t)/\overline{x}(t)] = \left(1 - \frac{h}{a + b\overline{l}}\right) \left[\frac{-k + he^{(h-k)(T-t)}}{h-k}\right]. \quad (35)$$

Considering the finite growth case, if $(h-k)(T-t) < 1$, then following MacLaurin expansion, the $e^{(h-k)(T-t)}$ can be expressed as

$$\begin{aligned} e^{(h-k)(T-t)} &= 1 + (h-k)(T-t) + \frac{(h-k)^2(T-t)^2}{2!} + \frac{(h-k)^3(T-t)^3}{3!} \\ &\approx 1 + (h-k)(T-t) \end{aligned} \quad (57)$$

Therefore, Eq. (31) can be approximately written as

$$[\overline{D}(t)/\overline{x}(t)] \approx \left(1 - \frac{h}{a + b\overline{l}}\right) (1 + h(T-t)),$$

which is Eq. (38).

We further take the partial derivative of Eq. (33) with respect to the growth rate. Then the partial derivative of optimal payout ratio with respect to the growth rate can be approximately written as

$$\frac{\partial [\overline{D}(t)/\overline{x}(t)]}{\partial h} \approx \left(\frac{(a + b\overline{l})(T-t) - 2h(T-t) - 1}{a + b\overline{l}}\right),$$

which is Eq. (29).

Appendix D. Using Moving Estimates Process to Find the Structural Change Point in Eq. (36)

To estimate the empirical breakpoint, we first assume the dummy variable associated with risk as $D(g_{i,t} < c \cdot ROA_{i,t})$. We introduce a no structural change model, Eq. (58), and a structural change model, Eq. (59). In Eq. (59), c is a continuous constant variable, ranging from 0.2 to 1.8 ($c \in [0.2, 1.8]$). The breakpoint of structural change is at $g_{i,t} = c \cdot ROA_{i,t}$.

$$\begin{aligned} \ln \left(\frac{\text{payout ratio}_{i,t}}{1 - (\text{payout ratio}_{i,t})} \right) &= \alpha + \beta_1 \text{Risk}_{i,t} + \beta_2 \text{Growth}_{i,t} + \beta_3 \ln(\text{Size})_{i,t} \\ &\quad + \beta_4 ROA_{i,t} + e_{i,t} \end{aligned} \quad (58)$$

$$\ln \left(\frac{\text{payout ratio}_{i,t}}{1 - (\text{payout ratio}_{i,t})} \right) = \alpha + \beta'_1 \text{Risk}_{i,t} + \beta'_2 D(g_{i,t} < c \cdot ROA_{i,t}) \cdot \text{Risk}_i + \beta'_3 \text{Growth}_{i,t} + \beta'_4 \ln(\text{Size})_{i,t} + \beta'_5 ROA_{i,t} + e_{i,t} \tag{59}$$

By using the moving estimates process, we calculate the F statistics for all potential structural change points between $g_{i,t} = 0.2 \times ROA_{i,t}$ and $g_{i,t} = 1.8 \times ROA_{i,t}$. The F test is under the null hypothesis that no structural change on the relationship between the payout ratio and the risk. That is, Eq. (58) is identical to Eq. (59). Finally, we can locate the breakpoint of the structural change at the point with highest value of F -statistics.

From Table 7, the process has a clear peak at $c = 0.93$ when using the beta risk as the independent variable and $c = 0.96$ when using the total risk as the independent variable. Figure 2 also graphically presents a peak F -statistics point at $c = 0.93$

Table 7 Moving estimates process for testing the break point of structural change

F-statistics			F-statistics		
c	Beta risk	Total risk	c	Beta risk	Total risk
0.20	120.38	92.78	1.01	658.58	533.26

1.00	622.77	545.64			

(0.96) in terms of beta risk (total risk). Results from the moving estimates process indicate that a structural change on the relationship exists between the payout ratio and risks. The breakpoint of the structural change is at $g_{i,t} = 0.93 \times ROA_{i,t}$ or $g_{i,t} = 0.97 \times ROA_{i,t}$.

Table 7 shows the F -statistics of moving estimates processes. The nonstructural change regression and structural change regression are as follows:

$$\ln \left(\frac{\text{payout ratio}_{i,t}}{1 - (\text{payout ratio}_{i,t})} \right) = \alpha + \beta_1 \text{Risk}_{i,t} + \beta_2 \text{Growth}_{i,t} + \beta_3 \ln (\text{Size})_{i,t} + \beta_4 ROA_{i,t} + e_{i,t}$$

$$\ln \left(\frac{\text{payout ratio}_{i,t}}{1 - (\text{payout ratio}_{i,t})} \right) = \alpha + \beta'_1 \text{Risk}_{i,t} + \beta'_2 D(g_{i,t} < c \cdot ROA_{i,t}) \cdot \text{Risk}_{i,t} + \beta'_3 \text{Growth}_{i,t} + \beta'_5 \ln (\text{Size})_{i,t} + \beta'_6 ROA_{i,t} + e_{i,t}.$$

The dependent variable is the payout ratio with a logistic transformation. The breakpoint, c , is between 0.2 times and 1.8 times the rate of return on total assets. The dummy variable is equal to 1 if a firm's 5-year average growth rate is less than c times its 5-year average ROA, and 0 otherwise. The independent variables are beta risk (total risk), dummy times beta risk (total risk), growth rate, log of size, and the rate of return on assets. F -statistics are under the null hypothesis that the relationship between the payout ratio and the risk does not depend on the growth rate of a firm.

Figure 2 shows the F -statistics of moving estimates processes. The nonstructural change regression and structural change regression are as follows.

$$\ln \left(\frac{\text{payout ratio}_{i,t}}{1 - (\text{payout ratio}_{i,t})} \right) = \alpha + \beta_1 \text{Risk}_{i,t} + \beta_2 \text{Growth}_{i,t} + \beta_3 \ln (\text{Size})_{i,t} + \beta_4 ROA_{i,t} + e_{i,t}$$

$$\ln \left(\frac{\text{payout ratio}_{i,t}}{1 - (\text{payout ratio}_{i,t})} \right) = \alpha + \beta'_1 \text{Risk}_{i,t} + \beta'_2 D(g_{i,t} < c \cdot ROA_{i,t}) \cdot \text{Risk}_{i,t} + \beta'_3 \text{Growth}_{i,t} + \beta'_5 \ln (\text{Size})_{i,t} + \beta'_6 ROA_{i,t} + e_{i,t}$$

The dependent variable is the payout ratio with a logistic transformation. The breakpoint, c , is between 0.2 times and 1.8 times rate of return on total assets. The dummy variable is equal to 1 if a firm's 5-year average growth rate is less than c times its 5-year average ROA, and 0 otherwise. The independent variables are beta risk (total risk), dummy times beta risk (total risk), growth rate, log of size, and the rate of return on assets. F -statistics is under the null hypothesis that the relationship between the payout ratio and the risk does not depend on the growth rate of a firm. The risk used in Fig. 1 is the beta, and the risk used in Fig. 2 is the total risk.

Mergers and Acquisitions: Principles and Practices

102

Harvey A. Poniachek

Abstract

Mergers and acquisitions (M&As) have been part of the corporate experience for over a century and most successful companies rely heavily on them to attain their strategic goals faster, cheaper, and less risky than through organic expansion (Poniachek, Harvey A., ed. 2019. *Mergers and acquisitions: A practitioner's guide to successful deals*. World Scientific; Bruner, Robert F. 2004. *Applied mergers and acquisitions*. University edition. Wiley Finance). M&As cover a wide range of transaction types that are complex and risky, are subject to intensive regulations related to securities issuing, antitrust, and corporate governance that often require the services of various professionals, which are predominantly procured from outside the corporation. Post-merger integration is vital, and its efficient application could assure successful deals.

The M&A market has globalized, and cross-border business have become quite significant. Covid-19 medical crisis promoted alternative deals that could achieve the same objectives with limited upfront investment and risk. M&A transactions are expected to yield synergies from reduction in cost, and expansion of sales and earnings. Expected synergies could affect the valuation, which is an art and science that applies primarily through the income and market approaches.

This chapter surveys the main theories and forms of M&As, and addresses the principles and analytical methods for decision-making. We discuss the legal framework, including issues relating to antitrust, corporate governance, and anti-takeover defenses, accounting, leverage buyouts (LBOs), payment methods and their implications, valuation, and cross-border deals.

102.1 Introduction

Mergers and acquisitions (M&As) have been part of the corporate experience for over a century and virtually every company has undertaken major deals with significantly business implications. Build versus buy analysis assists firms to determine whether to pursue organic development or M&A deals. The world's most successful companies rely heavily on mergers and acquisitions to attain their strategic goals faster, cheaper, and less risky than through organic expansion (Bruner 2004). Investments via mergers and acquisitions have become essential for corporations seeking to enhance competitiveness, achieve diversification, access emerging technologies, take advantage of favorable changes in economic and the regulatory environment, and promote supply chain participation in globalization. Expansionary investment decisions via M&As involve acquisition of other firms through traditional methods, including mergers, consolidation, and purchase of assets (Poniachek 2019).

M&As are important corporate events that allow companies to achieve a wide variety of strategic goals, including expansion into new markets (horizontal integration), build a more efficient supply chain (vertical integration), mollify competition, achieve operational efficiencies, or diversify business-portfolio risk (Schill and Loutskina 2017). External investment through M&A and internal development are complementary and facilitate entry into new markets and businesses (Weston et al. 2004). Post-merger integration (PMI) could affect the merger process success or failure.

The M&A market has globalized, and cross-border business have become quite significant. Covid-19 crisis disrupted global supply chains (EY 2020) and reduced M&As deals, but an expected upturn in economic growth coupled with significant cash balances held by the US corporate sector and private equity (PE) firms could provide a strong impetus for deal activities going forward. Over 60% of corporate executives surveyed by Deloitte in August 2020 expect M&A activity to return to pre-Covid-19 levels within a year. However, past M&A experience (PWC 2020) might not be fully applicable in the future because deals will be smaller, more deals will include earnout provisions that could help reconcile valuation differences, and dealmakers will need to incorporate a higher risk premium into the discount rate.

The challenging business circumstances due to Covid-19 medical crisis promoted alternative deals, including joint ventures, alliances, and partnerships as alternatives to traditional investment approaches (Elie et al. 2016). Alternative deals could be used to achieve the same strategic objectives as traditional M&As by offering access to resources and markets that are otherwise unavailable with limited upfront investment, risk mitigation through partnership, and accelerated time to market. In alternative deals companies acquire minority stakes or establish cooperative arrangements (Kengelbach et al. 2020) as an effective approach to pursue strategic goals at reduced risk. Alternative deals and classic M&A represent significantly different deal structures, but have similar success rates, with approximately 40% of alternative deals failing to achieve their stated financial and/or strategic goals, and 60% were successful (Kengelbach et al. 2020). In 2019, there were 11,000 joint ventures and business alliances driven largely by software and IT services, commercial and professional services in the Asia-Pacific and in North America.

Special Purpose Acquisition Companies (SPACs), also referred to as “blank check,” are shell corporations that raise funds from sponsors and investors, go public through a simplified IPO process, and then merge with target firms (Surance et al. 2021; Layne et al. 2018). SPACs like entities existed for decades in various forms (Malmberg et al. 2020), but their numbers have increased steadily from 2013 and reached a record in 2020, and 200 SPACs have raised \$80 billion and accounted for 50% of the IPO during that year (Harroch et al. 2020). Their growth is attributed to competitive IPO pricing and a record influx of high-profile investors and management teams, which turned SPACs into significant players for potential sponsors, investors, and target operating companies. Foreign businesses deem publicly listed SPACs attractive merger partners.

A SPAC’s life begins with its initial formation, followed by an IPO, search for an acquisition target, and finally closing of an acquisition. The funds raised in the IPO are placed in a trust account while the SPAC seeks to acquire an existing operating company within 18–24 months, but if no acquisition occurs in the above timeframe, the cash is returned to its investors. The SPAC sponsor usually purchases founder shares prior to the SPAC IPO filing that comprise of one share of common stock, plus a warrant to acquire common stock at a price of \$10 and following a merger their shares are converted into public shares. If the SPAC successfully completes an acquisition, the target becomes a public company, otherwise the cash held in its trust account is returned to its investors, unless if the SPAC extends its timeline via a proxy process.

M&A transactions require a multitude of participants with different specialization and responsibilities, including the corporate executives and board, investment bankers, accountants, tax specialists, and attorneys. The merger process commonly commences with the formulation of the investment objectives, followed by identification of the target, negotiations, due diligence, valuation, reaching an agreement, address funding and taxation implications, determine the transaction structure, and protect against various risks. The transactors need to obtain antitrust approval, assure shareholders’ approval, and apply effective post-merger integration.

M&As need to meet intensive regulations by the US Federal Government (SEC, FTC/DOJ) and States' corporation laws, and transactions are subject to hostile deals against which companies have developed effective defenses. Corporate governance, specifically the role of the board and the duties of directors are well established by case laws and States' corporation laws.

Divestitures remain an important feature of M&A and driven both by organizations seeking to cash in on high valuations and those aiming to reposition assets in advance of a downturn (Deloitte 2020). Valuation is an art and science and applied primarily through the income (DCF) and market (ratios/multiples) approaches that often yield results that requires investment bankers' fairness opinions to support the outcomes.

M&A transactions are complex and risky, and are affected by the state of the business cycle, financial conditions, and are legally intensive and subject to various laws and regulations, various taxation laws and accounting requirements. External investment through M&As are expected to yield synergies from reduction in cost, and lower taxes and cost of capital, and expansion of sales and earnings. In evaluating a proposed M&A, the question is whether merging parties be worth more together than separately and would their shareholders be better off in the post-merger than before? We note that a high share of M&A deals fails, but more effective management could lead to greater success.

This chapter surveys the main theories and forms of M&As, and addresses the principles and analytical methods for decision-making. We discuss the legal framework, including issues relating to antitrust, corporate governance, and anti-takeover defenses, accounting, leverage buyouts (LBOs), and payment methods and their implications.

102.2 Process and Theories, Data and Trends

Mergers and acquisitions comprise a wide range of transaction types as shown in Figure 1. Acquisitions include merger or consolidation, acquisition of stock, or acquisition of assets. Merger refers to the absorption of one firm by another where the acquired firm ceases to exist as a separate entity. A consolidation is a merger of two companies where a new entity is created and both firms cease to exist as legal entities. In an acquisition of assets, one firm acquires all or part of the assets of another firm.

A variety of mergers waves occurred since the late 1800s, shown in Table 1, that were driven primarily by favorable economic and financial conditions, deregulations of industries and favorable regulatory changes, technological innovations, favorable infrastructural changes, globalization, and the search for economies of scale and scope (Table 2).

Acquisitions are classified into three types, including

- Horizontal mergers involving two firms operating in the same or similar business activity that could provide economies of scale and scope.
- Vertical mergers between firms in different businesses, or different value-added functions, designed to internalize transactions and benefits by lowering

Fig. 1 Mergers and acquisitions

transaction cost through more efficient contracting, reduced or eliminated bargaining cost, harmonization of corporate objectives, reduced risk thanks to greater information availability, and adaptations to cope with regulations.

Table 1 Seven US merger waves

- Conglomerate mergers involve firms in unrelated types of business activity that could include product extension or geographic market extension.

In 2019, mergers deals reached 49,327 valued at \$3.27 trillion as shown in Fig. 2a and b. North America (predominantly the USA) accounted for 32% of the worldwide deals and 60% of total value. The year 2020 reflected the global Covid-19 health crisis and recession, with the number of deals and their value declined to 43, 252 and \$2.6 trillion (annualized data).

102.2.1 M&A Theories/Models

Companies could invest internally or externally through mergers and acquisitions. The advantages and disadvantages of mergers versus internal development are addressed in Table 3 that favors external investment through M&As. The primary goals of M&A are to increase growth, enter a new market, gain new products and technologies, and maximize shareholder value. Several synergies, shown in Table 4, could arise from M&As that could be generated from operating and/or financial sources, and provide additional value to the combined firms (Bruner 2004; Damodaran 2001). Synergy is a major attraction of mergers, and it is defined as $2 + 2 = 5$. If an acquirer is valued at V_a and the target value is V_b , then the value of the combined firm following the merger is V_{ab} (Brealey et al. 2020):

Fig. 2 (a) Mergers and acquisitions worldwide. (b) Mergers and acquisitions North America. <https://imaa-institute.org/mergers-and-acquisitions-statistics/>

$$\text{Synergy or gain } \Delta V_{ab} = V_{ab} - (V_a + V_b)$$

A merger adds value only if the two companies are worth more together than apart, that is, when synergy is positive. Synergy is attributed to higher sales, lower

Table 3 M&A versus internal development

	Mergers and acquisitions	Internal development
Lower cost	+	
Acquire know-how	+	
Quicker	+	
Higher risk		+
Acquire new markets	+	
Acquire new products	+	
Synergy	+	

Source: Harvey Poniachek

Table 4 Sources of synergy

Synergy is attributed to the expansion of output and revenue, or *a reduction of cost thanks to avoidance of duplications*, such as administrative costs and overhead costs *and/or* economies of scale

Increase in revenue is often related to expansion of the customer base and cross selling.

Financial synergies related to decreased costs of capital through lowered risks, better cash flows, and increased financial margins

Source: Damodaran (2001) and Bruner (2004)

cost thanks to removal of duplications in the post-merger and economies of scale and scope, lower taxes, and lower cost of capital. If the transaction is in terms of cash for stock, cost is defined as follows:

$$\text{Cost} = \text{Cash paid} - V_b$$

The net present value (NPV) of the transaction is as follows:

$$\text{NPV} + \text{Gain} - \text{Cost} = \Delta V_{ab} - (\text{Cash paid} - V_b)$$

There are various theories of mergers and acquisitions (Weston et al. 2004), but practitioners formulated models in terms of several variables. For instance, Bain & Company (2014), M&A model consists of five stages, as follows:

- M&A strategy – make you M&A an extension of your growth strategy, identify the target, and formulate how will M&A create value
- Deal thesis – examine how each deal creates value, apply existing capabilities to enhance value to the target
- Due diligence and valuation – test the deal rational, set a walk away price, determine where you can add value
- Merger integration planning – plan your post-merger integration and determine what is needed to integrate, and integrate where it makes sense
- Merger integration execution

McKinsey & Company (Goedhart et al. 2010) identify the strategic rationale for an acquisition that creates value as follows:

- Improving the performance of the target company
- Removing excess capacity from an industry
- Creating market access products
- Acquiring skills, or market technology more quickly or at a lower cost than they could build in-house
- Picking winners early and help them develop their businesses

Reasons for mergers include:

- The prospects for synergy where $2 + 2 = 5$ that arise from lower cost, higher revenues, and higher profit.
- It may be cheaper to acquire another company than to invest internally, or the target company may be undervalued and it represents a good investment.
- Diversification – It may be necessary to smooth-out earnings and achieve more consistent long-term growth and profitability.
- Short-term growth management may be under pressure to turnaround sluggish growth and profitability.
- Some mergers are executed for “financial” reasons and not strategic reasons.

The world’s most successful companies rely heavily on acquisitions to achieve their strategic goals faster, cheaper, and less risky than organic expansion (Notop 2007). For instance, Pitney Bowes achieved great success by developing and applying a merger process with more than 70 acquisitions that increased the company’s revenue by more than 25% and made a significant contribution to net income and cash flow. The following five rules had been critical in the acquisitions process that could be effective for meeting strategic objectives if executed properly.

- Rule 1, stick to adjacent fields of your business.
- Rule 2, manage acquisitions as you would a portfolio of investments.
- Rule 3, the leaders of business units are in the best position to gauge potential acquisitions and need to be the sources and owners of acquisition proposals, whereas the corporate development group’s role should be to facilitate and execute the details of the transaction.
- Rule 4, be clear on how acquisitions should be assessed in terms of various criteria, including expected synergy and what integration to expect.
- Rule 5, avoid impulsive purchasing.

The merger process could be described in terms of an input-output flow chart as shown in Table 5 and Fig. 3.

102.2.1.1 Takeover Tactics

Hostile takeovers have declined from 14% of total deals in the 1980s to 4% in the 1990s. The main tactics for hostile bidders are:

Table 5 The mergers process and decision-making

1. What to acquire? ID target
2. Where to acquire? Location decision
3. What price? Valuation process
4. Considerations (means of payments)
5. Expected benefits/synergies?
6. Environmental constraints: legal, tax, accounting, operational/competition
7. Proposed structure
8. Post-merger integration
9. Approach the target, convene preliminary discussions, propose the deal structure, and formulate a letter of intent
10. Conduct due diligence and verify the facts and data
11. Analysis – expected benefits/synergies? $1 + 1 = 3$ or $= 4$
12. Assessed benefit and price
13. Is it an attractive target?
14. Consideration (=means of payment): cash, stock swap, other securities, or a mix of the above
15. Environmental constraints
16. Legal (state corporation law, corporate bylaws, securities laws, fiduciary responsibilities)
17. Antitrust (DOJ and FTC)
18. Tax (tax deferred or taxable?)
19. Accounting (purchase methods – newly issued requirements)
20. Operational implications
21. Complete negotiations, sign the agreement, make the announcement, and close the deal
22. Begin or continue the merger integration
23. The mergers process is assisted by <i>investment bankers</i> , attorneys, accountants, tax specialists, and others
24. Some large firms, however, conduct most of the M&A process internally (e.g., GE, Intel, Cisco Systems)

Source: Harvey Poniachek

- A bear hug – Exert pressure on target's management before launching a hostile bid by contacting the BODs with an expression of interest in acquiring the target that could sometime follow by a public announcement on the intent to acquire the target or by mailing a summary of the offer to the Wall Street Journal.
- In a friendly transaction, the tender offer will be made pursuant to a negotiated merger agreement with the target company and its board of directors. A friendly merger that is funded by cash requires the acquirer to file a proxy statement with the SEC and issue to shareholders and to be approved at a shareholders meeting and closed. A friendly merger funded with stock requires the issuing of a proxy statement with the SEC and the securities offered in exchange for the target shares need to be registered with the SEC. Upon completion of the proxy statement and share registration, both documents are mailed to shareholder + a proxy card to be filled out by the shareholders. The deal is voted on the shareholders meeting.

Fig. 3 The merger process. (Source: Harvey Ponichcek)

- A hostile bid is usually structured as a tender offer to the target shareholders. A hostile deal funded with cash requires the acquirer to issue a tender offer to the target shareholders consistent with the William Act requirement. Due to the short timetable, the SEC does not have the opportunity to review and comment on the materials, but it might do so subsequently. Hostile deal funded with stock for stock requires filing a registration statement with the SEC by the bidder prior to launching the tender offer. The statement needs to be cleared by the SEC prior to its dissemination to shareholders.

- A tender offer issued to the target's shareholders skips the BODs and management. The tender offer is in compliance with the Williams Act. The hostile tender offer is a two-step process: in the first step, the hostile bidder acquires control of the target by securing sufficient shares (in Delaware it is 85%), and in the second step, which is known as a back-end or close out transaction, the remaining share are purchased. If the buyer acquires a very large percent of the shares, it could freeze out or close out the remaining shareholders via a short-form merger.
- A proxy fight is an attempt by a single shareholder or a group of shareholders to take control or bring about changes in a company's conduct through a proxy mechanism of corporate voting. A bidder is attempting to use his voting rights and obtain support from other shareholders to oust the incumbent bod and/or management. The SEC regulates proxy contests and proxy solicitation, which are subject to section 14(a) and requires public disclosure within 10 days on schedule 14a. There has been a sharp increase in proxy fights that is partially explained by aggressive activity of hedge funds to enhance shareholders value. The two main types of proxy contests include contests for seats on the board of directors, and contest relating to management proposals.

102.2.2 M&A Transactional Forms

Mergers commonly commence with direct discussion and negotiations between the acquirer and the target company or through investment bank intermediation. If negotiations are successful, the acquirer and the target company enter into an agreement that sets the terms and conditions of the acquisition and the structure of the transaction. Companies involved in M&A negotiate confidentiality agreements or letters of intent that are referred to as a "Non-Disclosure Agreement" or "NDA." A letter of intent sometimes referred to as a "memorandum of understanding" or "MOU" is more common in private transactions than in public company deals. The transaction structure has important implications for the tax treatment of the transaction and the speed at which the transaction will be completed.

In a merger, two or more corporations are merged into one of the entities, which is the surviving entity of the merger. In a consolidation, the entities are consolidated to form a new entity and the stock of the non-surviving entity or entities are exchanged into stock of the surviving or resulting entity, cash, or some other consideration. Acquisition of a US public company could utilize state merger statutes, where the parties enter into a merger agreement that requires the approval of the board of directors and the shareholders of the target company (Hall 2014; Lathan and Watkins 2020).

There are several versions of statutory mergers, including

- In a statutory merger, the target company is merged into a newly formed subsidiary of the acquirer – through a forward triangular merger structure – and the surviving entity becomes a wholly owned subsidiary of acquirer. The target's stockholders receive stock, cash, debt, or a combination thereof from the acquirer.
- In a reverse triangular merger, a newly created subsidiary is formed by the acquirer that is merged into the target, and target's stockholders receive stock, cash, debt, or

a combination thereof, of acquirer in exchange of their shares. The target becomes wholly owned subsidiary of acquirer and its corporate identity is preserved.

- In an asset purchase, the acquirer may purchase either all or part of the assets of a corporate target in return various consideration, and joint venture.

The merger and acquisition of a US company can be made on a friendly basis, pursuant to negotiation with the target's board of directors, or through a hostile approach, without the involvement or approval of the target's board of directors. A friendly transaction affords due diligence on the target, cooperation of the target's management, faster closing and lower costs. A hostile transaction involves considerable complexity and risk, and it is suitable when negotiating fail, and most often hostile offers serve as a means to bring a target to the bargaining table, rather than as the ultimate means of acquiring a target company.

M&As are motivated by several factor, including:

1. Interest in to exploiting "synergies" that could reduce cost, expand output and efficiency.
2. Reduction of cost through economics of scale and scope.
3. To acquire work forces with particular skills.
4. Obtain know-how.
5. Benefit from lower taxes.
6. To diversify or expand markets.
7. *Acquire an undervalued at "bargain" price, and*
8. *Managers interest in "empire-building."*

In a one-step statutory merger, the acquirer negotiates a merger agreement with the target's board of directors, which then needs to be approved by a majority of the target's shareholders. The merger transaction is usually structured in the form of a "reverse triangular merger." If the consideration includes securities, those securities need to be registered with the SEC, and the acquirer needs to file a registration statement with the SEC.

In a two-step acquisition, an acquirer pursues a hostile takeover by issuing a tender offer (to acquire the shares of the target subject to the Williams Act) directly to the target shareholders, in exchange for the cash or the acquirer's securities. Following the purchase of the tendered shares, the acquirer and the target will complete a back-end statutory merger (most often via a reverse triangular merger structure). The vast majority of US public company are one-step mergers involving consideration consisting in whole or in part of stock.

102.3 M&A Financing

Two of the most common forms of financing for acquisitions are the use of debt or the issuance of equity. Issuing debt has tax benefits because the interest payments are tax deductible. Another benefit of issuing debt is that no additional shares are issued and so there is no dilution of ownership. However, issuance of excessive debt could

hurt the company's credit rating which would hinder its ability to borrow money in the future and would lead to an increase in the company's cost of debt and debt issuance may be limited by existing lender covenants that set restrictions on the amount of debt the firm can assume.

Despite the higher cost of equity, it is quite commonly used in M&A transactions because of the flexibility it provides the issuers. Some of the benefits of equity include (i) no mandatory interest payments, (ii) no principal that must be repaid, and (iii) no restrictive covenants related to its issuance. Financing an M&A transaction with equity has no impact on a company's credit rating therefore allowing the company to issue debt in the future if needed. However, equity issuing could hurt a firm's earnings per share and return on equity as it becomes less leveraged. Frequently, public companies use equity financing as their preferred form of payment in M&A transactions, but debt still plays an important role because of its cost effectiveness and the advantages of leverage.

In 1988, nearly 60% of all large deals (of over \$100 million) was paid for in cash and less than 2% was paid for in stock; in 1998, 50% of all large deals was paid for in stock (Rappaport and Sirower 1999); in 2010, the cash and stock were approximately 50/50 (Malmendier et al. 2015); whereas in 2016, 33% of all deals was paid in stock and 17% in cash. In a cash deal, the acquirer takes the entire risk that the acquisition will fail, while in stock transactions, risk is shared proportionately with the ownership of the target company between the two parties. Paying with stock preserves cash and avoids the need to borrow to fund the deal and provides the seller the opportunity to share in the future growth of the business and defer taxes on capital gains associated with the sale.

A stock-for-stock offer could be structured as a fixed number of shares or a fixed value of shares. In a fixed exchange ratio, share price between the announcement date and the closing date could change but the exchange ratio will stay fixed, thus the total deal value is not actually defined until closing. Sometimes the exchange ratio floats to ensure a fixed transaction value. Table 6 provides a numerical illustration.

Table 6 Cost of acquisition: cash versus stock

	Firm A	Firm B	Cash	Shares	Shares, amended
Market value (V_a , V_b)	2000	200	550	2530	2530
Number of shares	100	20	25	115	113.64
Price per share	20	10	22	22	22.263

Notes

1. Firm B, the target, requested a 50% premium or \$300 and the value of both firms is assumed at $(2000 + 200) \times 1.15 = \2530 . Synergy equals $\$2530 / (2000 + 200) = 15\%$ or \$330
2. The acquisition NPV = Synergy - Cost = $\$330 - \$100 = \$230$
The value of Firm A share following the merger is $2530 / (100 + 15) = \$22$
3. Amended shares offer for Firm B = $2.530 \times R = 300$, $R = 0.12$
4. $0.12 = \text{New shares issued} / (100 + \text{New shares issued})$, New shares issued = 13.64
The price per share = $2530 / (100 + 13.64) = 22.263$

102.4 Restructuring and Divestitures

The primary restructuring approaches are conducted through the following functions:

- Sell offs or divestitures.
- Equity carve outs.
- Spin offs.
- Split offs.
- Split ups.
- Tracking stock (targeted stocks).
- Other strategies (JVS, ESOPS, LBOs), and
- Financial reorganization (debt-equity exchange offers, leverage recapitalizations, financial reorganization under Ch. 11).

A divestiture is the sale of a portion of the firm (assets, product line, sub) to an outside party for cash and/or securities or a mix of both. Some 40–50% of all M&As are divestitures by other firms. Equity carve outs involve the sale of an equity interest in a subsidiary to the public via an IPO. It begins with the creation of a new legal entity with its own management and board. Spin offs sometimes follow as the second stage of an equity carve out, in which some of the subs' shares are IPOed (less than 20%) and then spun off to shareholders of the parent on a pro rata basis. The parent often maintains 10–20% shareholding in the new entity.

Examples: In 1999, GM has done an equity carve out of Delphi via an IPO (17.7%), followed by a spin off (80.1%); GM kept 2.2%. The spun off entity becomes a separate legal entity, which is independently managed with its own management and board of directors. AT&T spun off NCR. In the basic spin off, controlled subsidiary's shares are distributed on a pro rata basis to the company's existing shareholders. Kraft Foods spun off Altria Group, Inc. planed on spinning off 88.5% of Kraft Food, Inc. (1/26/07, WSJ), Philip Morris Co (which became Altria) IPOed Kraft in 2001 by selling 280 million shares to the public. Altria shareholders were expected to receive 0.69 Kraft share for each share of Altria. Following the divestiture, Altria would become three distinct companies (1) Altria, (2) Phillip Morris Int'l, and (3) Kraft Foods.

Spin Offs Tax Effects. To qualify for a tax-free spinoff, the parent must own 80% of the sub's voting shares and 80% of the sub's shares need to be distributed. In cases where the spinoff is the second stage of an equity carve out, 80% of the shares in the second stage need to be distributed to qualify for a tax-free reorganization. Companies sometimes employ a two-stage spin off: the first stage IPOing by selling nonvoting shares, and in the second stage spinning off, the voting shares in tax-free transaction.

- Split offs.
- A new legal entity is created with its own management and board. Some of the shareholders exchange their shares for new shares in a division or subsidiary that is split off the parent company.

- There is a need to apply valuation and the exchange ratio to facilitate the exchange of shares.
- Example: In 1999, Dupont IPOed Conoco, which then followed by a split off. AT&T 1984 antitrust agreement with DOJ split up the corporation via spin offs into seven regional baby bells.
- Split ups.
- Split ups are usually accomplished by spin offs. In a split up, the entire firm is broken up through a series of carve outs and spin-offs with the parent ultimately ceasing to exist. Example: In 1999, Hewlett-Packard split into two firms, IPOed 15% of Agilent followed by spin off.
- AT&T restructured in 1995 by splitting into three public companies, where lucent was IPOed and then spun off.
- Divestiture/spin-off process.
- Decision to divest/spin-off relies on financial analysis (like an acquisition) by utilizing the DFC approach (WACC-NPV, APV ON FTE).
- Restructuring plan and agreement between the parent and subsidiary relating to assets, liabilities, equity, and operating relations require a proxy statement, voting, and approval by shareholders.
- Shares issued in an equity carve out or spin-off must be registered with the SEC.
- Tracking stock.
- First issued in 1984 when GM acquired EDS and issued GM class E shares. By 1992, there were four tracking shares, including GM E, GM H (Hughes Electronics), and two USX issues (Marathon – oil, US Steel group). By 2000, there were more than 44 issues.
- A company splits its operation into two or more entities or segments and issues tracking shares for one or several segments. The segments remain wholly owned by the parent company which itself might be publicly traded.
- Targeted stock is issued via an IPO and/or to existing shareholders afforded some rights in the segments relating to dividends, but no other rights are afforded in the parent firm. The benefits of targeted stocks: the capital market is provided with pure play and values the different businesses based on their own performance. Enhance flexibility to raise funds; provide opportunities in acquisitions; management incentives are more properly reflecting performance.

102.5 Leveraged Buyouts (LBOs)

LBOs are financial techniques that utilize substantial debt to acquire a target company by management or an outside company that are affected by the level of interest and availability of debt financing. These transactions increased dramatically in the 1980s, with a most notable LBO by KKR acquisition of RJR Nabisco \$32.5 billion in 1988. Sources of LBO gains are attributed to higher growth and enhanced efficiency. Asset-based lending of senior debt usually accounts for 50–60% of the deal, subordinated debt for 10–20% of the deal, and equity for 20–30%. High-yield bonds or junk bonds provided a major source for LBO funding.

In a leveraged buyout an acquirer takes control of a target firm by borrowing against its assets and/or cash flows. LBOs grew dramatically in the USA during the 1980s, declined in the 1990s, and reemerged in the 2000s fueled by cheap debt in the CDO markets (Renneboog et al. 2017), and it came to a halt with the demise of the securitized debt markets at the end of 2007. Tax advantages and the expropriation of non-equity stakeholders are the main sources of wealth gains from going private. Other potential sources of wealth gains are stronger performance and value, the reduction in wasting corporate resources, and improved monitoring capabilities embedded in the governance structure of an LBO.

In a leveraged buyout an investor acquires a target company using mainly borrowed funds. The debt is serviced either by the acquired target's operating cash flows, or from the sale of a portion of the company, or from the refinancing of the acquisition by collateralizing the target company. The debt used to finance an LBO ranges from 50% to 80% of the purchase price and may be as high as 95%. LBOs typically reduce a company's tax payments (and hence increase the returns available to its equity investors), primarily due to the tax shield from interest expense, increased depreciation and amortization expense following the write-up of a company's assets upon its LBO.

The leveraged buyout boom of the 1980s was spearheaded by KKR, The Carlyle Group, Blackstone, and Apollo (Shleifer et al. 1987) who created limited partnership (LP) that raised funding from large pension funds, insurance companies, financial institutions, and high net worth individuals, to finance the equity portion of the acquisitions. Management buyout transactions led by the existing management are more common in Europe and Asia than the USA. Drexel Burnham Lambert and its head of the high-yield bond business, Michael Milken developed the high-yield bond market⁴ which provided significant sources of funds for LBOs. Bank loans were another source of funds for LBOs, where lead banks commonly reduced their exposure by syndicating the loans to other banks. In the mid-2000s, a combination of lower interest rates, loosening lending standards, and creation of loan funds known as Collateral Loan Obligations (CLOs) – induced an LBO boom.

A successful LBO execution needs the cooperation of a private equity firm, a commercial or investment bank to provide the acquisition loans, and an investment bank that underwrites the bond debt. A shell company is typically created to serve as the vehicle for the acquisition that then bids for all the shares of the target company. If it is successful in acquiring a majority of the shares, it merges with the target company to create the surviving entity, which will be responsible for servicing the acquisition debt.

102.6 Joint Ventures and Strategic Alliances

Joint ventures (JVs) and strategic alliances could provide alternatives to M&As. In a joint venture, two or more companies combine certain assets and work toward achieving specified business objectives, while the companies maintain their own

business independent of the JV. JVs are subject to the antitrust laws as administered by the DOJ and FTC.

JVs are created for specific objectives and are of short duration. The objectives include conduct R&D, gain access to key supplies, enhance distribution systems, gain access to foreign market, and an interim step to enter an unfamiliar market. Strategic alliances are less formal associations between companies than JVs and could be defined as a collaboration by two or more firms to achieve specific goals.

A joint venture represents a combination of subsets contributed by two or more business entities for a specific business purpose and a limited duration. JV participants continue to exist as separate firms and the JP representing a newly created business enterprise. The JP can be organized as a partnership, a corporation, or any other form of business organization.

102.7 Anti-takeover Defenses

A corporation can adopt preventive anti-takeover defense measures against unknown threats or take reactive action in response to a potential or actual threat. Effective anti-takeover defenses enable management to resist unsolicited takeover bids, protect the corporation's long-term policy, search for a better offer to maximize shareholders wealth, and stand against shareholders who challenge their decisions to merge (Klausner 2013). The common preventive takeover defenses that are applied by most Fortune 500 companies include (Gaughan 2015):

1. The shareholder rights plans, also known as poison pill
2. Corporate charter amendments

Following the global financial crisis of 2007–2008, an increasing number of US public companies adopted or renewed their shareholder rights plans after years of decline in the use of this defense mechanism (Klausner 2003). In the post-financial crisis, unsolicited and hostile transactions constituted over 22% of all deal volume in the USA, compared with 12.1% for 2007 (Reuters 2008). In 2008, a total of 127 companies adopted rights plans and 182 companies allowed their existing rights plans to expire.

102.7.1 Anti-takeover Defense Measures

Pursuant to Delaware General Corporation Law (DGCL), the board of directors holds exclusive power to manage the corporation and has ultimate control of the corporation's business decisions, including business decisions associated with takeover activity. Shareholders have three basic rights as owners of the corporation that enable them to monitor managers (Thompson 1999) the right to sell their shares freely to third parties; the right to sue on behalf of the corporation, which can also be used as a tool to monitor managers; and the right to vote on significant corporate

matters that affect the corporation's destiny, including annually voting for the election of the board of directors. Thus, managers who do not perform in line with the expectations of their shareholders will be replaced by them, either by the shareholders tendering their shares to an acquirer who will replace the management or by the shareholders replacing the management at the annual meeting. The shareholders select the board of directors at the shareholders' annual meeting for a 1-year term, and if they are not satisfied with the board's performance or disagree with their decision-making, they can replace the entire board, a majority of the board, or those directors which they wish to replace at the annual meeting.

102.7.2 Shareholder's Rights Plan or the Poison Pill

The shareholders' rights plan, also known as the poison pill, is the most effective defense measure against a hostile takeover.¹ Since its inception, the poison pill was triggered in a very small number of occasions (The Delaware Chancery Court 2009). The strong anti-takeover effect of the pill either forced bidders to negotiate a friendly deal with the board or took corporations out of the takeover market. In 2011, the poison pill was challenged in the Delaware Supreme Court's *Airgas Poison Pill* case, but the court upheld its legitimacy.

Hostile bidders can go directly to the target shareholders with a tender offer to acquire their shares. The poison pill disables this possibility by making the takeover too expensive and economically unviable. This feature of the defense measure forces the hostile bidder to negotiate with the board a "friendly" deal (Lipton 1987).

The poison pill can be structured as a (i) the flip-in right or (ii) the flip-over right. Under the flip in, the board issues a right in the form of a special dividend to shareholders for each of their common share that entitles them to purchase common stock in the target at a 50% discount when a hostile acquirer (or group of acquirers) crosses a certain ownership threshold. Following the exercise of the rights, all shareholders increase their holdings in the target, except for the hostile bidder whose rights are void (Lipton and Steinberger 2015). The excluding of the hostile bidder from the shareholders rights plan results in a substantial dilution in the shareholdings of the hostile bidder. The flip-over right is intended to protect shareholders against a squeeze out that might follow by a merger. The triggering event for the exercise of the flip-over right is the acquisition of 50% or more of the corporation's assets. Upon the triggering event, the shareholders receive a right to buy shares in the surviving corporation or the acquirer. The board has the exclusive power to install a poison pill and redeem it. If the board decides to redeem the pill, the

¹The poison pill was invented in the 1980s by Martin Lipton, one of the founding partners of Wachtell, Lipton, Rosen & Katz, a distinguished Corporate and M&A law firm based in New York. In the mid-1980s, poison pills were challenged at the Delaware Supreme Court and their validity was upheld.

Table 7 The effect of a poison pill on a hostile takeover party

<i>Pre-poison pill</i>	
Target's shares outstanding	100,000
Price per share	\$10
Hostile party acquires % of total shares	10%
Hostile party's shares	10,000
Cost	\$ 100,000
Outstanding shares held by others	90,000
Hostile party seeks to acquire 50%	50,000
Hostile party needs additional shares	40,000
Total hostile acquisition cost	\$ 500,000
<i>Post-poison pill effect</i>	
Double outstanding shares	180,000
Outstanding shares	190,000
Doubles 90,000 + 10,000 held by hostile party	
% of hostile shares after PP	5.3%
Post-PP cost for hostile to reach 50% control	\$ 850,000
Initial cost pre-PP	\$100,000
Total cost to hostile	\$950,000
Post-PP cost/pre-PP cost	190%

Source: Harvey Poniachek

Notes: PP = poison pill

Price per share is assumed to stay unchanged under the various scenarios

If the hostile party does not obtain the rights to acquire shares at a discount, the acquisition cost is approximately 190% of the cost without the pill. However, if the hostile party gets the pill, the cost with and without the pill is the same

redemption is made for a nominal amount. See Table 7 on the effect of the pill on a hostile takeover party.

Bidders could avoid the poison pill by negotiating a friendly deal with the board or launch a proxy contest to replace the board with members that will redeem the poison pill. A poison pill can be easily adopted by the board, harder for the shareholders to dissemble, and more difficult for a bidder to overcome. There is a decrease in the number of rights plans due to rising influence from activist shareholder who oppose the poison pills because it makes a hostile takeover almost impossible. The Institutional Shareholder Services (ISS), a proxy advisory firms that advises on shareholders voting matters, typically support pro-takeover corporate governance. Their guidelines usually recommend either the redemption of poison pills or adoption of a short-term poison pill, the renewal of which will be subject to shareholders approval.

102.7.3 Charter and Bylaws Provisions

A vast majority of corporations with IPO's include staggered board provisions in their certificate of incorporation at the time of the IPO. A staggered board makes it

more difficult for a hostile takeover party to control the board because a shareholder or a group of shareholders would have to win two consecutive elections to replace a majority of the board (Coffee and Palia 2014). Anti-takeover defenses are usually perceived as impairing shareholder power and increasing the board's governing power in the corporation.

The poison pill and staggered board are widely recognized as the most effective anti-takeover defense measures, but there are other measures that a corporation can adopt as part of its defense profile. A provision in the corporation organizational documents that prevents shareholders from packing the board. Pursuant to the DGCL, all matters other than election of directors require majority of the shareholder vote. A supermajority vote requirement, typically 75% of the shares entitled to vote, limits the rights of stockholders to amend certain charter and bylaws provisions to facilitate takeovers. Certain business decisions that require shareholders vote, such as a sale of the corporation, would require a higher percentage of shares to approve, making it more difficult for the hostile bidder to receive the approval of the shareholders and complete the takeover.

102.7.4 Reaction (Economic Defense)

Another type of defense measure is financial defenses that would usually be used once an actual takeover activity is pursued or if the corporation feels vulnerable and become subject to a hostile activity.

102.7.5 Pac-Man

Pursuant to this tactic the target becomes an acquirer. Instead of defending against a hostile takeover, a target that has enough resources may seek to acquire the hostile bidder to eliminate the takeover threat.

Pac-Man tactics are not widely spread nowadays, although we did recently see an example of a successful Pac-Man tactic by Men's Wearhouse against Jos. A. Bank, two strong men's apparel companies. The takeover actions between the two began when Jos A. Bank launched its initial bid to acquire Men's Wearhouse. The bid was rejected by the latter and eventually Men's Wearhouse gave Jos. A. Bank's shareholders an offer that they accepted. The company that was first a target saw the opportunity in the combination transaction and became an acquirer (Solomon 2013).

102.7.6 Golden Parachutes

Golden parachutes are rewards set in employment agreements of senior executives to compensate them, among other things, upon the occurrence of a change of control event. Unlike most defense measures that we have included in this part of the chapter, a golden parachute would usually be implemented in the executive's

employment agreement when such executive joins the corporations which could be before any takeover activity was being taken against the corporation. Although this defense measure is a pre-action defense measure and not a re-action defense measure, we have included it under this part of the chapter because of its financial feature and anti-takeover effect resemblance to the remaining re-active defense measures mentioned here. The main goal of the golden parachute is to make the target less attractive to a takeover by forcing the hostile bidder to pay large amounts from the acquired corporation treasury. Golden parachutes can be as much as tens of millions of dollars once a triggering event, such as a change of control occurs. A golden parachute might not be as an effective defense measure against such tactics as it would be against a change of control event. As of 2015, 70% of fortune 500 companies offered golden parachutes in the event of a change of control to select executive officers (Nelson and Watson 2015).

102.7.7 White Knight and White Squire

Targets that face actual takeover activity by a hostile bidder can recruit a second bidder, a white knight, to acquire the corporation in a friendly deal that will be negotiated with the management instead of being taken over by the hostile bidder. For a white knight to be successful and complete the acquisition, such white knight must outbid the hostile bidder and provide the shareholders a higher value.

102.7.8 Limitations on the Adoption of Anti-takeover Defense Measures

When a corporation faces a takeover threat, the board could adopt anti-takeover defenses if (i) there is an existing threat to corporate policy, and (ii) the defense measure adopted is “reasonable in relation to the threat posed.” When it is clear that a change of control will occur, the sole job of the board is to sell the corporation at the highest price available for shareholders and they are not allowed to take defense actions to stay independent and fend off bidders.

102.8 Deal Protection and Deal Certainty²

Merger agreements include various deal protection to ensuring that the transacting parties remain obligated to consummate the transaction. The key provisions are deal protection devices such as break-up fees, no-shop clauses, force-the-vote provisions, and shareholder voting agreements.

²This section follows Wachtell, Lipton, Rosen & Katz, Takeover Law and Practices, March 2016, <http://www.wlrk.com/files/2016/TakeoverLawandPracticeGuide.pdf>

A break-up fees payable by the target if it terminates the merger agreement to accept a superior proposal. Termination fees of approximately 2–5% of the merger value may deter third parties from acquiring the target that has reached a merger agreement. Break-up fees can be triggered if target's shareholders fail to approve the merger.

A “no-shop” provision in a merger agreement provides that a selling company will not encourage, seek, solicit, provide information to or negotiate with third-party bidders, but the seller is allowed to respond to unsolicited offers by supplying confidential information and to consider and negotiate with respect to certain competing bids. “Go-shop” provisions allow the target company to actively solicit competing offers after the merger agreement signing – usually 30–50 days.

Public company merger agreements generally include provisions requiring the board of directors of the target to recommend that shareholders vote in favor of the merger agreement, except in specified circumstances. Merger agreements often include provisions that permit a party to terminate the agreement to accept a superior proposal, subject to payment of a termination fee and other conditions – commonly known as a “fiduciary out.” A Delaware corporation may submit the merger agreement to shareholders vote even if the board subsequently changes its recommendation.

The “crown-jewel” lock-up is a device in which the target company grants the acquirer an option to purchase a key target asset if the proposed merger does not close. This device may serve to deter competing bidders, since even with a superior bid price, the competing bidders may not get the deal they are seeking (*i.e.*, at best they may get a deal without the crown jewels).

Virtually all domestic public company merger agreements allow the buyer to refuse to close if there has been a “material adverse effect” on or a “material adverse change” in the target company's business.

Traditionally, strategic buyers, with significant balance sheets, were expected to fully commit to the completion of a cash acquisition, whereas financial sponsors are allowed to exit the deal in the event that they were unable to obtain financing.

The reverse termination fee required the buyer to pay a fee in the event the buyer failed to close due to an inability to obtain financing (later expanded to a failure to close for any reason).

The consideration used in a particular transaction depends on the characteristics of the deal and the relative bargaining strength of the parties.

All-cash transactions have the benefit of being of certain, but require cash on hand or ability to borrow, and it has a tax effect on the seller.

All-stock transactions are subject to price risks between signing and closing. Such risk can be hedged by using a price collar.

102.9 The Board's Role in M&A

Corporate governance in the 1980s was dominated by intense merger activity distinguished by the prevalence of leveraged buyouts (LBOs) and hostility. In the early 1990s, substantial merger activity resumed in the second half of the decade,

while LBOs and hostility did not. Internal corporate governance mechanisms appear to have played a larger role in the 1990s (Holmström and Kaplan 2001). Takeovers challenged in courts produced judicial decisions relating to the duties of directors of the board, anti-takeover defenses, and concerns about directors potential conflict of interest. Most takeover cases were adjudicated by the Delaware courts where most of the fortune 500 are incorporated.

Most jurisdiction describe the directors as having two fiduciary duties: (1) The duty of care and (2) The duty of loyalty (Monks and Minow 2011). Duty of care requires a director to exercise due diligence in making decisions by relying on full information. Duty of loyalty requires a director to demonstrate unyielding loyalty to the company's shareholders. Additional and more specific definitions of the board's duties – beyond the legal definitions cited above – were suggested by the business roundtable and the American Law Institute.

The presumed dual fiduciary duties of directors constitute the business judgment rule or standard. The business judgment rule is the standard by which directors are judged when they exercise their fiduciary duties to shareholders during an attempted takeover (relating to pricing and process). The court will not second guess a director's business judgement decision if it can be demonstrated that he/she exercised all possible care and acted with due loyalty (*note that the burden of proof shifted to the director*). *In the M&A context, some special applications of the business judgment rule have developed through litigations challenging directors' conduct [see White & Cooperman].*

102.9.1 Seminal Court Cases on Corporate Governance

In the Trans Union case (1985), the court ruled that directors had not met their duty as fiduciaries by agreeing to sale the company without a sufficient verification process to obtain the best terms. The primary implication of the trans union case was that the decision-making process and not the substance of the decision was of importance, and the court did not rule on the business judgment. Following the trans union decision, the Delaware legislature amended the Delaware general corporation law relating to duties of directors in mergers/acquisition cases, as follows: *1. Once it is recognized that a company is "in play" and it is likely to be sold, directors' obligation is to obtain the best price for shareholders 2. Directors should be fair to all bidders; and 3. Self-interest should not impair directors' decisions* (Weston et al. 2004).

In Unocal V. Mesa petroleum (1985), Unocal anti-takeover defenses included a self-tender offer in which the target made a tender offer for itself in competition with the mesa offer. The Delaware supreme court held that the directors may have acted in their own self-interest in which they favored their own tender instead of objectively searching for the best deal for shareholders. In such instances, the directors are subject to enhanced scrutiny and must demonstrate that (1) based on their business

judgment they had reasonable grounds to believe that there was a danger to the pursuit of a corporate policy that was in the best interest of shareholders and (2) that their defenses were reasonable in relation to the threat.

In the Revlon case (1985), the court held that when it becomes clear that the sale or break up of a company is inevitable, the board has the fiduciary duty to maximize shareholders wealth – by shifting their focus away from defending the company to selling it at the highest price (these duties became known as the Revlon duties). The court established that rather than promote the auction process to maximize shareholders value, Revlon's anti-takeover measures inhibited it.

In the Revlon and Unocal cases, the courts addressed whether under certain circumstances there was a limit to the anti-takeover defenses that a board could undertake to rebuff an unsolicited offer to acquire it. In the *Paramount v. Time* (1989) case, the court stated that Time-Warner was a strategic merger not involving a change in control, therefore, the Revlon duties were not triggered, and the normal business judgment rule standard applied. In the case of *Paramount v. QVC Network* (1993), the supreme court of Delaware held that the directors of Paramount violated their fiduciary duties in not maximizing the selling price of their company. The bidding contest proceeded with Viacom ultimately acquiring Paramount.

Boards must embrace the principles of due diligence, buy versus build analysis, financial analysis, and risk assessment as primary factors in their decision-making and evaluation process for M&A as well as other capital investment proposals. M&A transactions should help drive shareholder value and be aligned with both short-term and long-term strategic objectives and be accretive to the market price of the company's shares as well as the brand, reputation, and consumer perception of its core products and services. Risk needs to be avoided and strategic objectives met.

The board's role in M&As is to oversee the company's management as it negotiates the contours of a particular deal; test and confirm the economic premise of the proposed transaction; confirm the value proposition that the deal offers to the company's shareholders; confirm that management has taken necessary steps to mitigate the risk of the transaction; and confirm that management is planning the post-closing integration adequately. Boards and company executives must address issues of valuation, deal structure tax and securities laws, and often face a buy or sell decision and other structural business decisions and spend about a third of their time with such matters.

The board plays a key role in overseeing the M&A deal and make sure that valuations are assessed properly, that due diligence is complete and that the post-merger integration is successful. The engaged board will develop the company's overall strategic direction and might determine that growth should be driven through acquisition. Successful mergers and acquisitions transaction must reflect the economic needs of both buyer and seller and must convey real and durable value to the shareholders of both companies. Achieving it involves a review and analysis of financial statements, a genuine understanding of how the proposed transaction meets the economic objectives of each party, and a recognition of the tax, accounting, and legal implications of the deal.

102.10 The Legal and Regulatory Framework of M&As

The US has a dual legal system of state and federal governments. Merges are governed by corporation laws of the states in which the companies are incorporated, but the federal government regulates transactions involving securities, antitrust policies, and business dealings in several regulated industries.

The US federal securities laws include the Exchange Act of 1933, the Securities Exchange Act of 1934, and the regulations under the Securities Exchange Commission (“SEC”). Tender offers are subject to the Williams Act of the Securities Exchange Act. In US mergers involving securities, the issuer must disclose important financial information through the registration of securities with the SEC. Each of the 50 states regulates securities transactions pursuant to Blue Sky Laws and almost every state requires that securities sold in the state be registered.

Antitrust issues are administered by the Federal Trade Commission (“FTC”) and the Department of Justice (“DOJ”) and, to a lesser extent, by states. The US antitrust law prohibits mergers and acquisitions that could reduce competition or create a monopoly. The Hart-Scott-Rodino Act (“HSR”) requires pre-mergers and acquisitions notification to the FTC and the DOJ by merging companies to enable the government to analyze the effects of proposed transactions on competition before the acquisitions are approved and consummated. The Committee on Foreign Investment in the United States (“CFIUS”) reviews transactions that could result in foreign control of a US business to determine the effect of such transactions on the national security of the US.

The US antitrust laws were first legislated in 1890 with the passage of the Sherman Act and then in 1914, the enactment of the Clayton Act and various refinements through amendment over time (Abbott 2005). The Hart-Scott-Rodino Antitrust Improvements Act (“HSR” or “HSR Act”) of 1976 requires companies to file pre-merger notifications with the Federal Trade Commission and/or the Antitrust Division of the Department of Justice. After filing the HSR form, the parties cannot close the acquisition for a 30-day waiting period. The government (or another plaintiff) may challenge a merger before it is consummated and seek an injunction blocking the merger, or it may institute litigation based upon alleged violations of the Federal antitrust laws. State attorney generals may also bring actions under the federal antitrust laws.

The Antitrust Division of the DOJ and the FTC have jointly issued Horizontal Merger Guidelines (“Guidelines”) (U.S. Department of Justice and the Federal Trade Commission 2010) outline the principal analytical techniques, practices, and the enforcement policy of the Department of Justice and the Federal Trade Commission with respect to mergers and acquisitions involving actual or potential competitors under the federal antitrust laws.

The Guidelines’ first step in the merger analysis is to identify the relevant product and geographic markets and assess whether the merger would significantly increase concentration in any of those relevant markets. Market concentration is calculated according to the Herfindahl-Hirschman Index (“HHI”) by summing the sum of

squares of the individual firms' market shares. The Agencies consider whether the prospect of entry into the relevant market through merger or acquisition could alleviate adverse competitive effects by expanding output and keep low prices to benefit customers. A merger is not likely to enhance market power if entry into the market could not raise price or otherwise reduce competition compared to the level that would prevail in the absence of the merger. The Agencies credit efficiencies that are likely to be accomplished with the proposed merger. A merger is not likely to enhance market power if imminent failure of one of the merging firms would cause it to exit the relevant market.

Various other federal agencies, including the Federal Communications Commission ("FCC") and the Federal Reserve Board ("FRB") apply additional regulatory requirements relating to mergers in media and communications, banking, utilities, insurance, and airlines. The Sarbanes-Oxley Act that was enacted into law in 2002 and mandated several reforms to enhance corporate responsibility, enhance financial disclosures, and combat corporate and accounting fraud. It also created the Public Company Accounting Oversight Board ("PCAOB") to oversee the activities of the auditing profession. The Dodd-Frank Wall Street Reform and Consumer Protection Act was adopted in 2010.

102.10.1 State Anti-takeover Laws

Delaware General Corporation Law ("DGCL") prohibits an acquirer of 15% or more of a company's outstanding stock from engaging for a 3-year period following the acquisition, in any business combination with the company. Over a third of the states authorize defensive action by a target's board to defend against a hostile bid, including adopting a shareholders' rights plan (a poison pill) without shareholder approval.

102.10.2 Tender Offer

The Securities Exchange Act requires disclosure of important information by anyone seeking to acquire more than 5% of a company's securities by direct purchase or tender offer within 10 days of the acquisition. Within 10 business days of commencement of a tender offer, the target must reply whether to accept or reject the offer, or express no opinion, or explaining that it cannot take a position at that time. If the acquirer completes the tender offer and obtains 90% of the target common shares (in some states, this percentage is as low as 85%), the acquirer can squeeze out the minority shareholders through a short-form merger, without the approval of any other shareholder of the target company, and acquire all remaining target common shares.

102.11 Cross-Border Mergers and Acquisitions

Cross-border M&As have become very popular and in many instances have emerged as a two-way street despite their risk and complexities. In essence, domestic and cross-border transactions are quite similar in terms of the process and analytical requirements. Multinational companies (“MNCs”) increasingly utilize cross-border mergers and acquisitions to avail themselves of significant opportunities to grow and enhance corporate competitiveness, diversify geographically, support their customers abroad, and gain access to natural resources. The European Union and the US were the largest acquirer and target countries accounting in 2019 for 72% and 85%.

The past three decades have witnessed a dramatic expansion in cross-border acquisitions, with the volume expanding from 23% of total merger volume in 1998 to 33% in 2015 (Erel et al. 2012). As the world’s economy becomes increasingly integrated, cross-border mergers are likely to become more important. In recent years, there has been a rapid growth of cross-border M&As flows to emerging countries, including China, India, and Russia, that now account for approximately one-third of overall activities (Bertrand and Betschinger 2011). Cross-border take-overs have become increasingly important, and the outlook is for continuous growth in the future (Humphery-Jenner et al. 2012; Morgan 2017).

The motivation and process of cross-border M&As are in the main like those of domestic M&A but face different legal regimes and economic circumstances (Rossi and Volpin 2002). The theories of cross-border M&As state that (Coeurdacier et al. 2009) gains arise from increased economies of scale or scope. Multinational capital budgeting (Eiteman et al. 2016) for investment in foreign countries applies the same theoretical framework as domestic capital budgeting with very few differences. In international investment, the issue is how to adjust for the various risks, either via the discount rate or the cash flows, but not both at the same time. Although adjusting the discount rate might be easier, adjustment of the cash flow is probably more appropriate.

Mergers and acquisitions are complex transactions with many potential problems and a high failure rate and poor performance due to poor management during the merger process. A typical M&A process commonly follows the following steps (Downey and Technical Information Service 2008):

- Strategic planning.
- Identify and evaluate of potential targets.
- Initial contact.
- Valuation of the target company.
- Due diligence.
- Deal execution includes the negotiation of the deal, and
- Integration – after closing is complete, the acquiring company must start the process of integrating the acquired company into their business.

A KPMG survey (KPMG 1999) found that only 17% of deals added value to the combined company, 30% produced no discernible difference, and 53% destroyed

value. Bruner reviewed the evidence from some 115 M&A studies from 1971 to 2001 (Bruner 2002) and observed that the conventional view that failure is the average outcome of all M&A is false. A company is *more likely* to fail in its M&A under the following circumstances:

- *It enters a fundamentally unprofitable industry.*
- *It lacks the necessary industry know how.*
- *The expected economic benefits (synergy) of the deal are improbable or not incremental to the deal.*
- *It lacks a competition advantage in the business.*
- *It is not very creative in deal structuring, and*
- *Poor post-merger integration.*

To value foreign companies for acquisition, we could apply the same methodologies that are used in valuation of domestic firms, but several international complexities need to be recognized that might affect the outcome (Koller et al. 2010), that include international taxation, forecasting cash flows in foreign and domestic currency, estimating the cost of capital in foreign currency, and incorporating foreign-currency risk in valuations.

A conference on valuation in emerging markets (Bruner et al. 2002) that included some 30 countries concluded that, first, there is currently no clear single “best practice” for the valuation of assets and securities in emerging markets; second, emerging markets differ from developed markets in areas such as accounting transparency, liquidity, corruption, volatility, governance, taxes, and transaction costs – that are likely to affect firm valuation.

Emerging market risks can be incorporated through DCF scenarios by developing alternative scenarios for future cash flows and discounting rates and then weighting the values by the scenario probabilities. The cost of equity for emerging markets is estimated by utilizing the Capital Assets Pricing Model (“CAPM”) and a global risk-free rate, market risk premium, and beta. The cost of debt is reflected by the local yield on corporate bonds to which we add a country risk premium. The Weighted Average Cost of Capital (“WACC”) is then derived for the subject company based on the relative shares of equity and debt. Since companies in emerging markets are often more volatile than in developed markets, we recommend assessing the DCF valuation results with a country risk premium and a multiples.

102.12 Valuation for Mergers and Acquisitions

The three major valuation approaches that are used in mergers and acquisitions (“M&As”) include the income approach, the market approach, and the asset approach, with the first two being the primary valuation methodologies. The main features of the valuation approaches (Arzac 2008; Koller et al. 2010; Damodaran 2006, 2012; Rosenbaum and Pearl 2013), shown in Fig. 4, are as follows:

Fig. 4 Valuation methodologies for M&A. DCF = Discount cash flow, WACC = Weighted average cost of capital, NPV = Net present value, APV = Adjusted present value, FTE = Flow to equity. (Source: Harvey Poniachek)

1. The income approach could be applied in three different versions, depending on the nature of the cash flows, the capital structure of the firm or entity, and the discount rate. The approach derives the enterprise value (“EV”) of a target company based on the present value of the free cash flows that the company expects to generate in the future. The discount rate could be the Weighted Average Cost of Capital (“WACC”) or the cost of debt. The income approach requires a good measure of judgment due to the inherently uncertain business forecasts surrounding merger synergies (Brotherson et al. 2014).
2. The market approach assesses the enterprise value or equity based on comparable companies or comparable M&A transactions, by utilizing various multiples, such as the ratio of the price per share to earnings per share (“P/E”), or the ratio of the enterprise value to earnings before interest and tax (“EV/EBIT”), and several other multiples.
3. The net asset approach defines the value of common equity of a target company at book value as the difference between assets and liabilities, or by adjusting the assets and liabilities to market value and deriving their difference.

102.12.1 The Income Approach

The income valuation approach applies the Fair Market Value (“FMV”) or the investment value standard (King 2008; Fishman et al. 2007), and premises that the target company or entity is a going concern. The valuation determines the target’s worth, but the price paid for it would ultimately be negotiated between the buyer and

Fig. 5 The effect of synergy on the bidding price. (Source: Harvey Ponichchek). Notes: The target's market price per share is \$20, but different prospective acquirers can afford paying much higher prices for the target – depending on what they expect to do with the target following the acquisition. For instance, one prospective acquirer could obtain significant synergies via reduction of cost, expanding of sales and earnings, R&D, and international expansion into new markets. However, not every prospective buyer might have the same opportunities. Therefore, different prospective acquirers are likely to bid for the target at different prices

seller that would consist of the stand-alone value of the target company plus a fraction of the expected synergies. Because different prospective parties expect different synergies from M&As, their offer prices could vary considerably. See Fig. 5 on the effect of synergy and other influences on the bidding price per share.

The income approach applies the discount cash flow (“DCF”) methodology based on solid corporate finance theories (Berk and DeMarzo 2014; Ross et al. 2019) and could be applied to three different circumstances, as follows:

- First, the net present value (“NPV”) methodology, which is often referred to as the WACC methodology, discounts the unlevered free cash flows to the firm (“FCFF”) for the first 5 years and the terminal value to infinity. The terminal value is derived either through a formulary approach based on the last year's FCF, the growth rate to perpetuity and the WACC, or through a multiple of EBIT or EBITDA. The sum of the discounted free cash flow of the forecast period plus the present value of the terminal value determines the enterprise value – from which debt is deducted to derive the equity value. Data used in valuation is often measured with error, therefore, it is appropriate to use several valuation scenarios to estimate the target's value. We note that because the WACC was derived by

using the after-tax interest rate, this approach incorporates the tax benefit of debt implicitly through the cost of capital.

- Second, we could value an unlevered target company's free cash flows to the firm by discounting it at the unlevered cost of capital, and then add the present value of the interest tax shields attributed to debt discounted at the cost of debt, as well as other financial side effects, such as subsidies. This approach is called the adjusted present value ("APV") method.
- Third, the DCF method is based on free cash flows to equity ("FTE") discounted at the cost of equity for an unlevered entity or the cost of equity for a levered company.

Usually three valuation scenarios are derived, including high or optimistic, average, and low or pessimistic, and probabilities are assigned to each to obtain a probability weighted average scenario. The reasonableness of the valuations could be further examined through sensitivity analysis, including an application of a Monte Carlo simulation technique. Control and liquidity discounts and premiums could be applied as necessary (Pratt 2001).

102.12.1.1 Free Cash Flows

The free cash flows from assets equals to earnings before interest and taxes ("EBIT") plus depreciation, which is a noncash expense, minus taxes, minus capital expenditures ("CAPEX"), and minus changes in net working capital ("NWC"). Stated algebraically, FCF is defined as follows:

$FCF = EBIT + \text{Depreciation} - \text{Taxes} - \text{CAPEX} - \text{NWC}$, or alternatively stated as

$$FCF = EBIT (1 - t) + \text{Depreciation} - \text{CAPEX} - \Delta \text{NWC}$$

The definitions of the variables are as follows:

FCF = Free cash flows

EBIT = Earnings before interest and taxes

t is the marginal tax rate

$EBIT (1 - t)$ is EBIT after taxes

CAPEX = Capital expenditure, which equals $\text{Net Fixed Assets}_2 - (\text{Net Fixed Assets}_1 - \text{Depreciation})$

ΔNWC = Change in net working capital, which equals $\text{NWC}_2 - \text{NWC}_1$, and NWC equals $\text{Current Assets (CA)} - \text{Current Liabilities (CL)}$

The net working capital includes cash, receivables, inventory, and payables required for the operation of the business.

102.12.1.2 Terminal Value

A terminal value ("TV") reflects the value of all cash flows from the end of the projected period to perpetuity, and it constitutes a significant component of the

company's enterprise value, and often accounting for as much as 70% of the enterprise value. The terminal value could be estimated in two ways:

- First, through a formulary approach based on the last forecasted FCF, the growth rate, and the discount rate, as follows:

$$TV = FCF (1 + g) \div (WACC - g),$$

where

FCF (1 + g) = The expected growth of free cash flow for the year after the last year of the forecasted period, which is commonly year 6 and onward

WACC = The weighted average cost of capital

g = The expected constant annual growth rate of FCF (1 + g) in perpetuity

- Alternatively, the terminal value could be derived as a multiple of EBIT or EBITDA, where the multiple is derived from comparable companies or comparable M&A transactions. The differences between the two estimates of the TV could be attributed to differences in the discount rate, or growth rate or the expected risk.

102.12.1.3 The Discount Rate

The discount rate should reflect the risk associated with the free cash flows. Based on the capital structure of the company being valued, we derive a weighted average cost of capital or WACC, which serves as the discount rate for the free cash flows of the target company.

The formula for WACC is as follows:

$$WACC = (Wd) Rd(1 - t) + (We) Re,$$

where the variables are specified below:

Wd = The % share of debt in the capital structure, or $D/(D + E)$.

We = The % share of equity in the capital structure, or $E/(D + E)$.

D = Interest bearing debt.

E = Equity, or the market capitalization of the firm, which equals price per share x the number of outstanding shares.

Rd = Pretax cost of debt is the yield to maturity on corporate bonds with the same credit rating and maturity of the subject company or the cost of loans of the subject company.

T = Marginal tax rate.

Re is the cost of equity capital that can be obtained from the Capital Asset Pricing Model or CAPM, as follows:

$$R_e = R_f + \beta (R_m - R_f),$$

where

R_e = Cost of equity or the expected rate of return on the company's equity.

R_f = Risk-free rate of return on government securities over a time horizon consistent with the investment horizon. There are various risk-free rates that could be used, but the practice is to use Treasury Bills for up to 1-year maturity, Treasury Notes for up to 10-year maturity and Treasury Bonds for 30-year maturity.

β = The beta is a measure of the company's stock systematic risk or market risk or non-diversifiable risk, which reflects the company's volatility compared to the overall market index.

$(R_m - R_f)$ = Risk adjusted rate of return on the market index or the market risk premium, or equity risk premium. $(R_m - R_f)$ is usually estimated as the difference between the returns on the broad common stocks market index, such as the S&P500, and medium or long-term government bonds, depending on the horizon of the valuation. The market-risk premium ranges between 4.5% and 5.5% (Goetzmann and Ibbotson 2006; Fernandez et al. 2016).

R_m = Return on the market index, usually represented by the rate of return on the S&P 500 index.

The cost of equity is an estimate of an investor's required rate of return on an investment that could be estimated based on the CAPM; however, application of the CAPM to divisions, business segments, or private companies is hampered by lack of beta information. In such instances, we could derive the betas by using comparable companies through a process of unlevering and relevering, or by applying the Dividend Growth Model ("DGM") as an alternative to CAPM.

102.12.2 The Adjusted Present Value ("APV")

The adjusted present value ("APV") is designed to value operations or assets-in-place (Luehrman 1997; Ross et al. 2019), and values the business in a two-step approach by first valuing the operation, and then value the financial side effects and add both values together to constitute the value of the enterprise.

Specifically, we can value an unlevered target company's free cash flows by discounting it at the unlevered cost of capital, and then estimate and add the present value of the interest tax shields attributed to debt discounted at the cost of debt, as well as other financial side effects, such as subsidies. Because interest payments are tax deductible expenses, debt financing creates an interest tax shield for the firm, that is included explicitly or implicitly in the valuation of the firm.

In applying the APV, we first derive the pro forma income statement and balance sheet for 5 years by utilizing the percent of sales approach. Second, we derive the expected growth rate to perpetuity and the discount rate and derive the terminal

value. The free cash and the terminal value are present valued at the cost of equity for an unlevered company and form the value of the operating business.

In the second step of the APV, we value the financial side effects, which could include the debt shielding tax effect of interest, subsidies, cost of financial distress, hedges, and cost of issuing new securities. For instance, the financial side effects of interest tax shields equal $D \cdot r \cdot t$, where D is the interest-bearing debt, r is the cost of debt, and its terminal value is derived through the formulary approach similarly as was used in the WACC model. The present value of the tax shielding effect for 5 years and to perpetuity provides the value of the financial side effects.

The enterprise value of the firm is the sum of the value of operation plus the value of the financial side effects, that is, $APV = NPV + NPVF$, where NPV is the value of the unlevered firm and $NPVF$ is the present value of the financial side effects that are derived as follows:

- Determine the entity's value without leverage V_u , by discounting its free cash flows at the unlevered cost of capital, R_u , and with a constant debt/equity ratio, R_u is estimated by the following equation: $R_{wacc, u} = E/(D + E) R_e + (D/E) R_d$.
- Determine the present value of the interest tax shield in the following manner: Given the expected debt, D_t at time t , the interest tax shield at $t + 1$ is $D_t \cdot R_t \cdot t$.
- Add the unlevered value, V_u , to the present value of the interest tax shield to determine the value of the entity or company with leverage, V_L .

102.12.2.1 Flow to Equity ("FTE")

Determine the free cash flow to equity ("FCFE") through the following equation:

$$FCFE = FCF - (1 - t) * (\text{Interest Payments}) + \text{Net Borrowing}.$$

(FCFE) = Payment of dividends + repurchase of common equity, after taxes, debt repayments, new debt and preferred stock issues, and all reinvestment requirements.

$$FCFE = (\text{Net Income} + \text{Depreciation} - \Delta \text{Net Working Capital}) - \text{Gross Capital Expenditures} \\ + (\text{New Preferred Equity Issues} - \text{Preferred Dividends} + \text{New Debt Issues} - \text{Principal Repayments})$$

- Determine the equity cost of capital, R_e .
- Compute the contribution to equity value, E , by discounting the free cash flow to equity using the equity cost of capital.
- Discount the cash flow from the firm to the shareholders of the levered firm at the cost of levered equity capital, R_s , by the following three steps approach: (1) Calculate the levered cash flows, LCFs, (2) Calculate R_s .
- Value the levered cash flow at R_s .

The Market Approach

The market approach determines the value of a company or entity by comparing it to comparable companies or comparable transactions. The method is based on the derivation of various multiples, with the most common multiples are as follows:

- The P/E ratio of the price per share to earnings per share.
- The EV/EBIT ratio of the enterprise value to operating income.
- The EV/EBITDA ratio of the enterprise value to gross operating profit + depreciation and amortization.
- EV/FCF the ratio of the enterprise value to operating free cash flow, and
- EV/Sales the ratio of the enterprise value to company sales.

The financial multiples are selected from a sample of comparable companies or comparable M&A transactions and applied to the target company to estimate its range of values. Ideal comparables, also referred to as guideline companies, are in the same industry as the subject company being valued, and same markets, products, growth, profitability, and business risk. The market approach provides a popular valuation methodology, but the reliability of the outcome depends on the goodness of the comparables.

If comparable companies or guideline companies are used, a decision needs to be made whether to use Market Value of Invested Capital (MVIC) or Market Value of Equity (MVE). MVIC is defined as the entire invested capital value of the firm, including equity investment and debt investment.

There are a variety of sources for comparable or guideline companies, including the SEC 10-K filings on the SEC website or through EDGAR; S&P Compustat and S&P Capital IQ, which are searchable database of US and foreign public companies. Comparable transactions, or comparable deals, are commonly used alongside comparable companies. The difference between comparable companies and comparable transaction multiples is that the latter will reflect a “control premium,” typically 30–50%, that is not present the comparable companies. The “control premium” depends on the uniqueness of the assets and to what extent there are close substitutes for the technology, expertise, or capability in question, the distribution of financial resources between the bidder and target, or the possibility that the ex-ante target price was unduly inflated by market rumors. Since publicly traded stocks are minority shares, if a controlling interest is being valued using publicly listed companies – a control premium should be considered.

In the application of the market approach, several adjustments of the ratios might be necessary to reflect differences in the comparables, degree of marketability, and/or liquidity.

- Timing differences between market transactions and the valuation date.
- Strategic or investment value issues.
- Size, depth of management, diversification of markets, products and services, and relative growth and risk.

102.12.3 Asset-Based Valuation

The asset-based approach to valuation is based on the financial accounting concept that the owners' equity is determined by subtracting the book value of a company's liabilities from the book value of its assets (NACVA 2019). Under the generally accepted accounting principles ("GAAP"), most assets on the balance sheet are recorded at historical cost, whereas most long-term liabilities are recorded at the present value, and there is no recognition of intangible assets. Because of the accounting approach, the "book value" of the owners' equity will normally be underestimated. However, the book value could be adjusted to fair market value, by deriving the fair market value of each asset and liability on the balance sheet of the subject company or entity, and then subtract the total adjusted liabilities from the total adjusted assets to derive the adjusted book value. This approach increases the valuation cost and complexity, but it still ignores intangible assets if they are not listed on the balance sheet. This method does not address the operating earnings of the business, and it would not be inappropriate to value a company or entity with intangible assets.

Under GAAP, held-to-maturity securities may not be reflected at fair value and may need to be adjusted. The first-in first-out ("FIFO") method of inventory usually provides the best indicator of fair value for inventory. The value of plant, property, and equipment is typically not at fair value and will need an appraisal if the amounts are significant. If the amount is not significant, an adjusted depreciation using reasonable useful lives and a non-accelerated depreciation method may result in an acceptable estimate of fair value. Other assets may also need a separate appraisal, depending on their nature. Liabilities are usually at fair value. But loans from related parties may need to be adjusted to reflect their fair value using market interest rates.

102.12.3.1 Liquidating Value

Another asset valuation methodology is the liquidating value for firms in financial distress or firms whose operating prospects are very cloudy. This method is not appropriate for a going concern but may be appropriate if there is doubt whether the company would remain in business.

Accounting for Mergers and Acquisitions

All business combinations need to be accounted for as acquisitions in accordance with the 2009 Financial Accounting Standards Board ("FASB") Accounting Standard Codification ("ASC") 805, Business Combinations are addressed by ASC 820, Fair Value Measurements and Disclosure (Flood 2017). Prior to June 2001, business combinations in the USA were accounted for by using either the purchase method or the pooling of interests' method (Morse, Hemming LLP 2014). On June 30, 2001, the FASB released Statement of Financial Accounting Standards ("SFAS") No. 141, Business Combinations, requiring that all business combinations be accounted for by the purchase method. On December 7, 2007, the FASB issued SFAS 141R, which applies to all transactions in which an acquirer obtains control of

one or more businesses. SFAS 141R is the outcome of cooperation between the FASB and the International Accounting Standard Board (“IASB”), thus contributing to convergence between the USA and international accounting standards (Stevens et al. 2008).

ASC 805 requires to perform a valuation process and a purchase price allocation (“PPA”) to the fair value of all assets acquired, liabilities assumed, and contingent liabilities. The three valuation approaches are the income approach, the market approach, and the cost approach. If the fair value of net assets acquired is less than the total consideration paid for the acquired entity, the difference is recorded as goodwill.

Goodwill impairment is addressed by FASB ASC 350. Goodwill is impaired when its *implied* fair value is less than its carrying amount.

102.13 Post-merger Integration

Post-merger integration is critical for M&A success or failure whereby the acquirer needs to integrate people, process, technology, and information (Hofmeyer 2019). The PMI process requires good communication and efficient governance and management practices, significant experience and attention to cultural profiles and individuals’ behavior (Reimann 2006). Management teams that run the merged process often fail behind in meeting deadlines, performance targets, and in evaluating the new people (Ashkenas and Francis 2000). Too many mergers fail due to ineffective PMI processes. To avoid such blunders, it is critical to select integration managers who can appreciate the cultural issues involved, handle them personally, and help others deal with them constructively. Guiding the post-merger integration process takes a special leader who can handle complex circumstances rapidly and successfully.

Three main post-merger integration models include preservation, absorption, and symbiosis (Haspeslagh and Jemison 1991). Preservation selects the best practice of both companies. This approach has limited integration needs, but it may be insufficient for such activities as changing financial reporting requirements for the parent company and policies. In the absorption approach, the acquirer incorporates, or absorbs, the acquired company into their business by utilizing transitioning people, process, technology, and data, and benefiting from economies of scale and cost cutting. Symbiosis selects the best practices of both the target and acquired companies. Although this approach has the greatest potential to achieve synergies over time, it requires significant change of management and increase the level of risk. This type of integration process can take up to a year or longer to complete and has significant effect on day-to-day operation of the business.

102.14 M&A Risk and Success

Companies often fail to achieve the financial objectives and operational synergies that were projected at the time of deal consummation (Crowe Horwath 2013). Failure occurred when acquirers were overoptimistic in their assumptions; acquirers

overestimated expected synergies; acquirers overbid in the heat of the bidding process; and poor post-acquisition integration. Merger performance could be addressed from different perspectives, including:

- Macro benefits of mergers – for the entire economy/sectors, improved efficiency, and operational performance.
- Micro effects are companies / sectors engaged in mergers benefit from enhanced efficiency or redistribution effect.
- Shareholders' value effect following a deal and over time.

The evidence on M&A performance is mixed, as cited below:

- Success and failure of M&As was defined in terms of *the economic profit model* whether $(\% \text{ econ profit} / \text{invested capital in the acquisition}) > \text{WACC}$; where $\text{econ profit} = \text{noplat} - \text{invested capital} \times \text{WACC}$, or $\text{econ profit} = \text{EBIT} (1 - t) - \text{invested capital} \times \text{WACC}$ (Copeland 2000).
- McKinsey & Company's study of 116 mergers between 1972 and 1982 shows that 61% were failure, 23% were successful, and 16% were not accounted for; a more recent survey by McKinsey of 160 acquisitions in 1995–1996 shows that only 12% of the acquirers managed to accelerate their growth over the next 3 years, and 42% lost ground (McKinsey Quarterly 2001).
- Bain's worldwide research project of more than 1,600 publicly traded companies and more than 18,000 deals from 2000 through 2010 shows that M&A was an essential part of successful strategies for profitable growth. During this period, total shareholders return (TSR) average 4.5% per year, compared with 3.3% for companies that were inactive in M&A.
- Prof Bruner states that some 60–70% of all M&A transactions compensate their investors for their opportunity cost (Bruner 2004).
- A research study of mergers by 276 Fortune 500 companies over a 15-year period shows that more than two-thirds resulted in increased efficiency (measured by cost-per-unit of revenue) and huge savings without significantly reducing employment (Trimbath 2002).

A Deloitte survey of 1000 US executives in late 2016 provides insights into factors contributing to success and impediments to successful mergers, as shown in Table 8.

102.15 Closing Comments

Merger waves were observed since the late nineteenth century that were affected by economic and financial conditions, technology, infrastructure, and regulations. M&As cover a wide spectrum of transaction types that are complex and quite risky, and require the services of various professionals, of which the bulk are

Table 8 Impediments to achieving successful M&As

	% of respondents
Insufficient due diligence process	88
Improper target identification	83
Not valuing the target accurately	81
Changing regulatory and legislative environment	81
Failure to effectively integrate	78

procured from outside the corporations. Post-merger integration is vital, and its efficient application could assure successful deals.

M&As are significant corporate investment and restructuring activities that are valued in the context of the DCF and market multiples. When the choice is organic investment versus external investment through mergers and acquisitions, the decision is usually in favor mergers.

M&As are subject to intensive regulations related to securities issuing, antitrust, and corporate governance that are applied worldwide. Funding of mergers are through cash, stocks, and a combination of both, with implications on risk sharing between the acquirers and targets.

The Covid-19 crisis might have prompted the evolution of alternative transactions that could reduce risk and required investments.

Accrual Accounting and Risk: Abnormal Sales Growth, Accruals Quality, and Returns

103

Liu Min Shirley

Abstract

This study proposes a new business risk proxy, unexpected sales growth (AG), which is measured as the difference between a firm's sales growth rate in year t and its benchmark, the weighted average of sales growth rate over the past 3 years. I find that the AG is statistically, economically, significantly associated with other risk measures of risk (e.g., beta, volatility of cash flows, operating cycle, and negative earnings occurrences). I find that the more the sales growth of a firm in the current year deviates from its benchmark – the higher business risk the firm – the lower the accrual quality, and the higher future abnormal returns the firm, which support Penman's (2016) theoretical conclusion that accrual accounting is for risk.

103.1 Introduction

This study is motivated by the expected important relationship between accruals quality and uncertainty embedded in the sales growth, a type of business risk, and the lack of empirical evidence on this association. Previous studies test and find that the volatility of sales inversely influences the accruals quality. However, if one could perfectly predict the sales growth, one could perfectly estimate the changes in the

accounts related to the sales. In other words, the estimable sale volatility would not increase the estimation errors in the accruals for the accounts related to sales given other conditions fixed, consequently, would not deteriorate the accruals quality. Therefore, I argue that the unexpected (hereafter abnormal) sale growth, which may cause the estimation errors in the accruals of the accounts related to sales, thereby, lowering accruals quality. Since the abnormal sales growth could cause the uncertainty in future earnings (or cash flows) which could infer the firm's value, even when the firm's profit margin is fixed, a risk that needs to be compensated if it can't be diversified away, therefore, I would expect that the more deteriorated sales growth is associated with a higher rate of returns.

Abnormal sales growth (hereafter AG) is measured as the difference between a firm's sales growth rate in year t and its weighted average sales growth rate over the preceding 3 years, which serves as a benchmark or expected value for sales growth in the current year. Accounting textbooks explain that changes in a firm's total accruals are associated with changes in sales relevant accounts such as accounts payable and accounts receivable. If sales grow at a constant rate over time, the sales relevant accounts are also stable. If there are unexpected changes in the sales growth rate, the amount of accruals in sales relevant accounts would fluctuate and be difficult to predict, thereby, resulting in unexpected accruals. Dechow and Dichev (2002) and McNichols (2002) measure the accruals quality as the standard deviation of residuals obtained from regressing working capital accruals on cash from operations in the current period, prior period, and future period (while controlling for change in revenues and plant, property, and equipment). Therefore, I hypothesize that the residuals from the accruals regression should be related to AG based on the relationship between unexpected sales growth rate and unexpected accruals.

The abnormal sales growth rate proposed in this study conceptually differs from the volatility of sales in Francis et al.'s (2005) modified Jones (1991) model. The volatility of sales in their paper reflects fluctuation in the level of sales. AG reflects fluctuation in changes in sales growth rate. Francis et al. (2005) find that the total accruals quality of a firm depends more on a firm's business risk than on managerial discretion. I conjecture that AG captures an additional dimension of business risk that goes beyond just changes in sales. The empirical results are consistent with this expectation. Adding AG as an explanatory variable to the Francis et al. (2005) regression of total accruals quality on economic fundamental variables (size, volatility of cash flows, volatility of sales, operating cycle, and occurrence of negative earnings over past 10 years) increases the R-square of the model by nearly ten percentage points.

This paper also investigates whether the impact of AG on total accruals quality depends on the sign of abnormal sales growth. I hypothesize that for firms recently experiencing negative AG, an increase in AG would increase total accruals quality. This effect manifests because these firms' economic fundamentals are approaching a steady state (less uncertainty of future earnings) and tend to perform better. On the other hand, for firms recently experiencing positive AG, their accruals quality should decrease with further increases in AG because changes in economic fundamentals may cause more volatility in the firms' business operations – higher level uncertainty

for future earnings. The empirical results presented later in this chapter are consistent with these expectations.

Penman (2010, page 670) and Ohlson (2014) reason that growth risk is one of fundamental risks that is inherent in the business of the firm. Sales can drive the growth in net operating assets, which influences residual earnings, the driver of value of the firm. Moreover, the “growth risk is driven by the risk of sales not growing as expected.” Therefore, I expect that abnormal sales growth shall influence the value of the firm. Although this theory is very convincing, there is a lack of empirical evidence on the relationship between unexpected sales growth rate and valuation. To examine the relationship between abnormal sales growth rate and abnormal returns, using monthly return data, I form ten portfolios sorted on AG ranks in the preceding year and test the significance of the Jensen’s-alpha for each portfolio using the Fama and French four-factor model. Results of the four-factor model show that portfolios in the two-lowest and two-highest tiles of decile sorted by AG ranks have higher abnormal returns and larger beta (i.e., higher systematic risk). The portfolio with the lowest AG rank in the preceding year has a, on average, 18.48% abnormal returns in the current year, suggesting that the returns are compensated to riskier assets. By investigating the relationship between AG and future abnormal returns, this study adds empirical evidence to Penman’s valuation theory about the uncertainty ingrained in the abnormal sales growth and firm values.

Desai et al. (2004) suggest trading strategies, which combine the level of total accruals and sales growth. This study is different from Desai et al. (2004) in a few ways. First, this study uses the changes in sales growth rate as opposed to the nominal level of sales growth. Additionally, this study incorporates the measure of accruals quality suggested by Francis et al. (2005) and not the total accruals level. Second, I estimate abnormal returns measured as Jensen’s-alpha, the intercept of the Fama-French four factor regression model using the monthly return series. Desai et al. (2004) use size-adjusted returns as the abnormal return variable.

To examine whether and how the firms’ characteristics change with the changes in AG of the firms, I form ten portfolios, which are sorted basing upon AG ranks. For portfolios where AG is greater than zero, the firms’ profitability, sales, and assets nearly monotonically decrease with an increase in AG. Firms with slightly positive AG have a large size, moderate profitability (i.e., return on equity and return on assets) and market to book ratio (PB), and slightly slower sales growth rate (8.59%) compared with that of a full sample (13.84%). On the other hand, for portfolios where AG is less than or equal to zero, I find that firms’ profitability, sales, and assets nearly monotonically increase with an increase in AG.¹ These results suggest that when a firm approaches its steady state, it has a smaller magnitude of sales growth rate, large assets, large sales, large net income, a negative external financing ratio, (which could be indicated by the reduced the firm’s common equity), the highest total accruals quality, (which is measured as in Francis et al. 2005), and lower market

¹A firm with slightly negative (or close to zero) AG has relatively stable sales growth, almost no fluctuation in sales growth.

risk (proxied by beta). These findings are consistent with Ohlson's (2008) analysis of accruals and growth and offer a possible explanatory factor to the accrual anomaly suggested by Ohlson and Bilinski (2015).

The empirical evidence collectively suggests that the measure of abnormal sales growth rate proposed by this study can be a proxy for uncertainty ingrained in sales growth, a type of operating risk, driving the accruals quality and the abnormal returns, which compensate investors for bearing higher risk (i.e., operating /growth risk and accruals quality/information risk). This study extends the current literature by providing first-hand empirical evidence on the effects of abnormal sales growth on accruals quality and future returns and on how the characteristics of firms change with the change in abnormal sales growth rate. The results in this chapter are robust to sensitivity tests such as alternative measures of abnormal returns and various econometrics methods.

This chapter proceeds as follows. Section 103.2 reviews relevant literature and develops hypotheses. Section 103.3 outlines the methods used to test the hypotheses. Section 103.4 describes the samples and presents descriptive statistics for the variables used in my analyses. Section 103.5 reports the empirical results. Section 103.6 presents the results of robust tests and additional analyses. Section 103.7 concludes.

103.2 Background and Hypotheses Development

103.2.1 Abnormal Sales Growth and Accruals Quality

The Generally Accepted Accounting Principles (GAAPs) require that firms prepare their financial statements basing upon the accruals accounting system because, in a short interval of time, the accrual accounting reflects a firm's real business operating and the true value of the firm compared with the cash-based accounting system. A cash-based accounting system recognizes revenues when the firm receives cash, and records expenses when cash is paid out. Accruals accounting requires firms to book revenues when a transaction finishes and the amount of the cash related to the transaction and the time of receiving cash can be reasonably estimated.

On one hand, the accrual accounting system is more appropriate than the cash-based accounting system. It is quite common that a vendor may not be able to receive the cash immediately after shipping the goods to its customers. If this scenario happens to the firm at its fiscal year end, shall this firm record the revenues for the goods shipped to its customers even if it has not received the cash yet? The cash-based accounting system does not recognize the revenues until the firm receives the cash from its customers. But the accruals accounting system recognizes the revenues if the amount of cash and the time of receiving cash related to these transactions can be reasonably estimated. Therefore, accruals accounting reflects the actual time when transactions really happen. Thus, accruals accounting is more accurate in terms of reflecting a firm's real business operating compared to cash-based

accounting. Dechow (1994) discusses the circumstances, under which accruals are a better measurement of a firm's performance than cash.

On the other hand, human judgment is involved in the process of estimating the amount of receivables and timing of receiving cash – estimation of accruals. The managers of firms may manage earnings by manipulating accruals such as booking revenues when it should not book and write off a large amount of bad debt when it is inappropriate to do so. Therefore, the good and bad sides of accruals accounting could play a role in the financial reports. Thus, it is important to know whether a firm's financial reports have a high or low accruals quality.

DeAngelo (1986) uses total accruals from a prior period ($t-k$) as a measure of the “normal” total accruals. Then, DeAngelo (1986) defines the “abnormal” total accruals (ΔTA_t) as the difference between current total accruals and normal total accruals, which can be separated into discretionary and nondiscretionary accrual components.

$$\Delta TA_t = (TA_t - TA_{t-k}) = (DA_t - DA_{t-k}) - (NA_t - NA_{t-k}) \quad (1)$$

DeAngelo assumed that the average change in nondiscretionary accruals ($NA_t - NA_{t-k}$) is approximately zero, then a change in total accruals ($TA_t - TA_{t-k}$) primarily reflects a change in discretionary accruals ($DA_t - DA_{t-k}$). This assumption is too restricting. Jones (1991) relaxes this assumption.

To estimate the expected total accruals, Jones (1991) suggests a regression model that total accruals is a function of a change in revenues and gross property, plant, and equipment in year t for firm j . The unexplained residuals (ϵ) from the following model, Eq. (2), are the proxies for the level of discretionary component of accruals. Total accruals include changes in working capital accounts (i.e., accounts receivable, inventory, and accounts payable) that depend to some extent on changes in revenues. Therefore, Jones (1991) controls for change in revenues to reflect the economic environment of the firm. Gross property, plant, and equipment are also included to control for the portion of total accruals related to the nondiscretionary depreciation expenses.

$$TCA_{j,t} = \beta_{0,j} + \beta_{1,j}Rev_{j,t} + \beta_{2,j}PPE_{j,t} + \epsilon_{j,t} \quad (2)$$

Jones (1991) does not consider one role of accruals that is to shift or adjust the recognition of cash flows over time so that the adjusted earnings better measure firm performance (Dechow and Dichev 2002) (hereafter DD). DD propose the following firm-level time-series regression model, Eq. (3), mapping the working capital accruals in the current period to cash flows in the prior, current, and future periods. The residuals ($\epsilon_{j,t}$) of Eq. (3) are the portion of total working capital accruals unrelated to realized cash flows. The standard deviation of these residuals is a firm-level measure of accruals quality.

$$\Delta WC_{j,t} = \beta_{0,j} + \beta_{1,j}CFO_{j,t-1} + \beta_{2,j}CFO_{j,t} + \beta_{3,j}CFO_{j,t+1} + \epsilon_{j,t} \quad (3)$$

McNichols (2002) combines the DD model and the Jones (1991) model and suggests that the total working capital accruals are the function of cash flows in

prior, current, and future periods, and changes in revenues and in gross property, plant, and equipment in year t for firm j . The new combined model increases the adjusted R-square of the DD regression model, which indicates an improvement in the prediction of total accruals.

Francis et al. (2005) further refine the combined model suggested by McNichols (2002). Francis et al. (2005) use the industry level estimated total accruals as the benchmark of total accruals for a firm j at year t . The standard deviation of the residuals of the regression, Eq. (4), of total accruals on the cash flows in prior, current, and future periods, and changes in revenues and in gross property, plant, and equipment in year t for firm j over years $t-4$ through t is the proxy for the total accruals quality (hereafter AQ) for the firm j at year t . The larger the AQ is, the lower the accruals quality is.

$$TCA_{j,t} = \phi_{0,j} + \phi_{1,j}CFO_{j,t-1} + \phi_{2,j}CFO_{j,t} + \phi_{3,j}CFO_{j,t+1} + \phi_{4,j}\Delta Rev_{j,t} + \phi_{5,j}PPE_{j,t} + v_{j,t} \quad (4)$$

DD identified five innate factors affecting accruals quality: firm size (Size), standard deviation of cash flows from operations (STDCFO), standard deviation of sales revenues (STDSale), length of operating cycle (OperCycle), and incidence of negative earnings realizations (NegEarn). Extending DD, Francis et al. (2005) argue that total accruals quality (AQ) can be broken down to innate accruals quality reflecting a firm's business environment and discretionary accrual quality affected by the management. The fitted value from the annual regression of Eq. (5) is the innate accruals quality and residuals of the Eq. (5) are discretionary accruals that could be a proxy for earnings management.

$$AQ_{j,t} = \lambda_0 + \lambda_1 Size_{j,t} + \lambda_2 STDCFO_{j,t} + \lambda_3 STDSales_{j,t} + \lambda_4 OperCycle_{j,t} + \lambda_5 NegEarn_{j,t} + \mu_{j,t} \quad (5)$$

Following Francis et al.'s (2005) argument that the innate factors of accruals quality reflect a firm's business environment, I argue that a change in sales growth rate should affect the firm's accruals quality because the sales growth rate can reflect the level of operating risk, a type of business risk, of the firm (Ohlson 2014; Penman 2010). The change in sales growth rate can represent the change in a firm's level of operating (business) risk, thereby, reflecting the change in the business environment of the firm.² Thus, a change in sales growth rate in period t should be associated with the accruals quality currently or subsequently.

² Accounting textbooks show that the amount of accruals is associated with the amount of sales. The more sales a firm has in a given year t , the larger amount of receivable and payable associated with the sales the firm has. One would expect that the fluctuation in sales would cause fluctuation in accruals amount, therefore, impact on accruals quality as well. Not all firms with a change in sales growth have comparable accounting system that can capture changes in accruals related to change in sales growth immediately. Then, these firms may have unexplained accruals called discretionary accruals (Jones 1991), or accruals quality (Francis et al. 2005).

Furthermore, theoretically, for the firms with steady growth rate ($AG=0$), the accrual quality decreases with either an increase or a decrease in the growth rate because any deviation from the steady state may create unexpected accruals associated with abnormal change in the growth rate, which lower the firms' accrual quality given that I define the lower accruals quality as the larger amount unexplainable accruals. Using abnormal sales growth rate as the proxy for the change in sales growth rate and for the change in the level of operating risk, I expect that the unexpected sales growth rate (AG) is related to accruals quality (AQ). My first hypothesis is stated in alternative form below.

H1: The further the sales growth rate of a firm deviates from its expected value, the lower the accruals quality of the firm.

A change in sales growth can be upward ($AG>0$) or downward ($AG<0$). For the purpose of my analyses, I refer to firms with positive AG as high growth firms, firms with negative AG as low growth firms, and firms with a zero AG as steady growth firms. My analyses focus on the high and low growth firms because there is no firm with a zero AG . For the high growth firms ($AG>0$), if sales growth increases, the larger the value of the abnormal sales growth, the more volatile the business operation of the firm is, thereby, the firm is more likely to have more volatile accruals and lower accruals quality (i.e., larger value of the standard deviation of the residuals of the regression Eq. (5) above). Therefore, I expect that, for firms with positive unexpected sales growth, the accrual quality decreases with the increase in the sales growth rate. Thus, for the high growth ($AG>0$) firms, H1 can be stated in the alternative form as following:

H1A: Accruals quality of high growth firms is negatively associated with abnormal sales growth rate.

For the low growth firms ($AG < 0$), if sales growth rate increases, the larger the value of the abnormal sales growth, the less volatile the business operating of the firm is, thereby, the firm is more likely to have less volatile accruals and higher accruals quality. Therefore, I expect that, for firms with negative abnormal sales growth, the accrual quality increases with the increase in the sales growth rate. Thus, for the low growth firms, H1 can be stated in the alternative form below:

H1B: Accruals quality of low growth firms is positively associated with abnormal sales growth rate.

103.2.2 Abnormal Sales Growth and Abnormal Returns

The previous literature suggested the market overprices the high growth firms (e.g., Graham and Dodd 1934; Lakonishok et al. 1994; Doukas et al. 2002; Desai et al. 2004) and investors can long low growth firms (value firms with low M/B, P/E, P/C ratios) and short high growth firms (glamour firms with high M/B, P/E, P/C ratios) to generate hedge profits. Desai et al. (2004) suggested a trading strategy combining the level of total accruals and sales growth rate.

Penman (2010, page 670) says that growth risk is priced by capital market and "... growth risk is driven by the risk of sales not growing as expected." However, there is a lack of empirical research on the relationship between abnormal sales

growth and valuation. Basing on the above discussion that a change in sales growth rate ($AG \neq 0$) represents the change in the firm's operating risk, I expect that abnormal sales growth rate (AG) is associated with a firm's future stock performance. Therefore, my second hypothesis is stated in the alternative form as following.

H2: The further the sales growth rate of a firm deviates from its expected value, the higher future returns of the firm will have.

The analyses on the relationship between abnormal sales growth rate (AG) and future returns for the high and low growth firms are similar to those for the relationship between AG and AQ. Therefore, H2 can be restated below in alternative forms separately for high and low growth firms.

H2A: The future returns of high growth firms positively associated with abnormal sales growth rate.

H2B: The future returns of low growth firms negatively associated with abnormal sales growth rate.

The next section discusses the empirical method used to test the above hypotheses.

103.3 Methods Used to Test Hypotheses

103.3.1 Model Used to Test H1

To capture the effect of unexpected change in sales growth on the accruals quality in the current period, I add abnormal sales growth rate (proxied for the change in business risk or environment) to the regression Eq. (4).

$$AQ_{j,t} = \lambda_0 + \lambda_1 AG_{j,t} + \lambda_2 AGLag1_{j,t} + \lambda_3 Assets_{j,t} + \lambda_4 STDCFO_{j,t} + \lambda_5 STDSales_{j,t} + \lambda_6 OperCycle_{j,t} + \lambda_7 NegEarn_{j,t} + \mu_{j,t} \quad (6)$$

where, $AQ_{j,t}$ is accruals quality. Following Francis et al. (2005), I estimate the regression Eq. (4) cross-sectionally by industry-year. I group firms into the 48 Fama and French (1997) industries. The $AQ_{j,t}$ is estimated as the standard deviation of the residuals of regression Eq. (4) over years t-4 through t for firm j at year t. The larger (smaller) value of AQ is the poorer (better) of the accruals quality. Please refer to the detailed calculation of AQ in the appendix.

$AG_{j,t}$ is the variable of abnormal sales growth for firm j in year t, measured as the difference between sales growth rate for firm j in year t and the benchmark of firm j's sales growth rate, which is measured as the weighted average of sales growth from years t-3 to t-1. $SaleGrowth_{j,t}$ is computed as $\left(\frac{Sales_{j,t}}{Sales_{j,t-1}} - 1 \right)$.

$$AG_{j,t} = SaleGrowth_{j,t} - SalesGBechmark_{j,t}$$

$$SalesGBechmark_t = 0.3 \times SalesG_{t-3} + 0.3 \times SalesG_{t-2} + 0.4 \times SalesG_{t-1}$$

In Sect. 103.2, the H1A predicts that, for high growth firms ($AG > 0$), the firms' abnormal sales growth rate is negatively associated with the firm's accruals quality. Therefore, I expect, for the high growth firms ($AG > 0$) in year t , the coefficient on the variable AG in the regression Eq. (6) to be positive ($\lambda_1 > 0$). The H1B predicts that, for the low growth firms ($AG < 0$), firms' abnormal sales growth rate is positively associated with the firm's accruals quality. Thus, I expect, for the low growth firms ($AG < 0$), the coefficient on the variable AG in the regression Eq. (6) to be negative ($\lambda_1 < 0$).

$AGLag1_{j,t}$ is one period of lag value of abnormal sales growth for a firm j in year t . A change in sales growth in the prior year may have an impact on accruals quality in the current year. The time series impact of AG on accruals quality is unclear and has not been documented in previous literature either. I do not predict the sign of λ_2 .

$Assets_{j,t}$ captures the size effect, measured as the log value of total assets. $STDCFO_{j,t}$ is cash flow variability, measured by the standard deviation of firm j 's rolling 10-year cash flows from operation, scaled by total assets. $STDSale_{j,t}$ is sales variability, measured as the standard deviation of the firm j 's rolling 10-year sales revenues, scaled by total assets. $OperCycle_{j,t}$ is operating cycle, measured by log of the sum of the firm j 's days account receivable and days inventory. $NegEarn_{j,t}$ is the occurrence of negative earnings realization, measured by the firm j 's proportion of losses over the prior 10 years. Following DD and Francis et al. (2005), one may expect that firms with smaller size, larger cash flow volatility, longer operating cycles, and a higher incidence of losses, to have poorer accruals quality. This indicates that $AQ_{j,t}$ is negatively associated with $Assets$ and positively associated with $STDCFO_{j,t}$, $STDSale_{j,t}$, $OperCycle_{j,t}$, and $NegEarn_{j,t}$ in Eq. (6).

103.3.2 Model Used to Test H2

To test my second hypothesis that a firm's abnormal sales growth in current period (t) is associated with its stock performance in future period ($t+1$), the Jensen-alpha approach (or the calendar-time portfolio approach)³ is used to assess the risk-adjusted abnormal returns of portfolios based on the decile of ranked abnormal sales growth in the preceding year.

The four factor model (Fama and French 1993; Carhart 1997) is adopted to compute the abnormal returns of each of the ten portfolios using monthly return data series.

³The Jensen-alpha approach is an alternative to the buy-and-hold abnormal returns calculating the calendar-time portfolio returns for firms in each decile of abnormal sales growth in preceding year, and calibrating whether portfolio returns are abnormal in a multifactor regression (Kothari and Warner 2007, 24-27). I use four-factor model in this study.

$$R_{p,t} - R_{f,t} = \alpha_{p,t} + \beta_{p,t} (R_{m,t} - R_{f,t}) + s_{p,t} SMB_t + h_{p,t} HML_t + u_{p,t} UMD_t + \varepsilon_{p,t} \quad (7)$$

Where,

$(R_{p,t} - R_{f,t})$ = the portfolio risk-adjusted return in month t ;

$(R_{m,t} - R_{f,t})$ = the risk-adjusted market return at time t ;

SMB_t = the size factor at time t , calculated as the difference between the returns on a portfolio of small stocks and a portfolio of big stocks;

HML_t = the book-to-market factor, calculated as the difference between the returns on a portfolio of high book-to-market equity (BE/ME) stocks and a portfolio of low BE/ME stocks.

UMD_t = the stock momentum at time t , representing the difference between two high prior return portfolios and two low prior return portfolios.⁴

In the returns test, the estimated intercept coefficient, $\alpha_{p,t}$, from regression Eq. (7) for each value-weighted portfolio is interpreted as the abnormal returns in excess of what could have been earned by passive investment in these four factors. Each portfolio is rebalanced every fiscal year during the sample period (January 1974 through December 2011) basing on the ranks of AG of sample firms in the preceding year.⁵

Basing on the construct of AG, the proxy for risk, I would expect that the Jensen-alpha is greater than zero ($\alpha_{p,t} > 0$) for the portfolios with the lowest and the largest rank of AG in the preceding year.

103.4 Sample and Descriptive Statistics

103.4.1 Sample Selection and Data

Table 1 describes the sample selection procedure. I begin from all firms with available annual financial data in Compustat to compute the abnormal sales growth and total accruals for the period of years from 1964 through 2011. Following Francis et al. (2005), the calculation of a firm- and year-specific accruals quality (AQ) needs the previous 9 years of data ($t-1, \dots, t-9$), and the AQ is based on five annual residuals. The sample also excludes firms in financial industry because firms in financial industry have different financial structures from other industry's firms and are under different regulations. Then, the accruals sample is restricted to firms with at least 7 year data and with 178,008 firm-year observations for 15,736 distinct firms. Because the sample selection procedure requires firms with at least 7 year financial data in Compustat and

⁴Thanks to Ken French for providing these factors on his website: <http://mba.tuck.dartmouth.edu/pages/faculty/ken.french>.

⁵In year t , a firm enters into a portfolio based on decile of ranked AG in the next month after its financial reports for prior year released if it had an AG falling into the range of that given decile of ranked AG at the end of year $t-1$, and leaves the portfolio 12 months after entering into it if its AG rank changes in the next year.

Fig. 1 Illustration of hypotheses

at least 12 month stock returns data in CRSP, it may bias my sample to surviving firms, which tend to be larger and more successful than the population. However, I expect that this restriction would decrease the variation in AQ, making it more difficult to detect the effect of environmental factors on AQ, which makes, if there is the sample selection bias, my results should be more reliable. The accruals quality results are available for a 38-year period beginning from year 1973 ending at year 2010.⁶

Because testing my H2 needs monthly return data from CRSP, to keep sample firms containing annual data sample and monthly return data series, I restrict my final sample of annual data to firms with available monthly return data and necessary annual financial data. These procedures lead to the final annual data sample with 103,965 firm-year observations and 10,480 distinct firms.

Because the relationship between AG and AQ are opposite for a firm with a positive change in sales growth and a firm with a negative change in sales growth, I further divide my sample into two subsamples. If a firm has a positive (negative or no) change in sales growth in year t , then, the firm belongs to the high (low) growth subsample. There are 43,683 (60,282) firm-year observations with 8,752 (10,038)

⁶The based year in my sample is year 1964; therefore, the 1st year to have a firm-year observation of AQ is 1973. Because the AQ calculation needs 1-year lead cash flows data, the AQ in year 2010 needs cash flows data from year 2011.

Table 1 Sample selection

Descriptions	Firm-year observations	Distinct firms
Firm-years in Compustat fundamental annual database from 1964 to 2012 (including all observations with available data to compute total accruals and abnormal growth)	341,143	31,695
Less firm-years with		
Missing Compustat data to compute accruals quality	178,008	15,736
And excluding financial institutions		
<u>Accruals Sample</u>	<u>163,135</u>	<u>15,959</u>
Less firm-year without return data in CRSP	59,170	5,479
<u>Final Sample</u>	<u>103,965</u>	<u>10,480</u>

distinct firms in the high (low) growth subsample over the 38-year period (1973–2010).

The next step is to obtain monthly return series from CRSP. For the final annual sample, there are 1,160,905 firm-year-month observations of available monthly returns beginning in January 1974 ending in December 2011. Each value-weighted (equal-weighted) portfolio basing on the ranks of abnormal sales growth in preceding year has 465 time series observations.

To avoid the effects of outliers, I winsorize the data at two tails (1% and 99% of the variable distribution).

103.4.2 Sample Summary Statistics

Table 2 reports the summary statistics for the pooled final sample. The number of firms each year ranges from about 1,700 to 3,800 firms per year,⁷ which is close to Francis et al. (2005) sample firm year distribution.⁸ Mean and median values of AQ are 0.0447 and 0.0323, respectively; 80% of the values are in the range of 0.0044–0.0985. These results are close to those in Francis et al. (2005) (having mean and median values of AQ 0.0442 and 0.0313, respectively, and 80% of the values in the range of 0.0107–0.0943). The slight difference in AQ statistics between my sample and theirs may be caused by the over-time variation in AQ (Francis et al. 2005, 306).

The mean and median values of abnormal sales growth (AG) are -0.1032 and -0.0336 , respectively; 80% of the values are in the range of -0.4746 – 0.2725 .

⁷The earliest year available in my sample is 1973 with 275 firms. However, it is not representative in my sample. Since 1973, there are about 1,700–3,800 firms per year. The sample reaches its largest number of distinct firms per year in 2002 (3,862), then declines over year toward the end of the sample period (2,621 distinct firms in year 2010).

⁸The number of firms each year in Francis et al. (2005) sample ranges from about 1,500 per year in the early 1970s to about 3,500 firms per year toward year 2001.

Table 2 Sample descriptive statistics ^a

Variable	Mean	Median	Std Dev	25%	75%	10%	90%
SALE	1590.66	211.03	4297.84	51.21	928.81	15.63	3565.41

OperCycle	3.8544	3.9922	0.8067	3.6336	4.2889	2.9456	4.5933
NegEarn	0.2314	0.1000	0.2874	0.0000	0.4000	0.0000	0.7000
Leverage	0.2736	0.2319	0.3187	0.0684	0.3890	0.0000	0.5528

^aThe donation of each variable for year t is suppressed in this table.

The sample contains 103,965 firm-year observations for 10,480 distinct firms over the 38-year period (1973–2010).

The summary statistics for AG indicate that the sample firms' sales growth has declined on average over the sample period (1973–2010), but firms in 75th (90th) percentile have their sales growth increased, on average, by 8.86% (27.25%) over the sample period. Untabulated summary statistics show that there is a large variation in AG overtime. The year 2002 (and 2009) has the lowest (next to lowest) sales growth, $AG = -0.30825(-0.276)$ for year 2002 (2009) among the sample period, indicating that the sales growth for all firms declined, on average, by 30.8% (27.6%) in year 2002 (2009). The summary statistics on abnormal sales growth is consistent with the macroeconomic condition over years in the USA. The year 2002 is the year after internet bubble and the economy was slow in that year; the year 2009 is the year post financial crisis of year 2008 (and late 2007). The mean value of AG for year 2010 is 0.018266, indicating that the sales growth of the sample firms in the year 2010 increased by 1.8266% on average, consistent with the economy recovery reported in the press.

Moreover, Table 2 shows the summary information on selected financial variables. The sample firms are large (median market value of equity is about 157.53 million dollars and median assets are about 194.06 million dollars), profitable (median income before extraordinary items are about 5.42 million dollars, median return on equity is 9.49%), and growing (median sales growth is 8.77%).

Furthermore, Table 2 also reports the summary statistics for the innate factors, affecting accruals quality, identified in Dechow and Dichev (2002). The mean and median values of log value of the total assets (Size) are 5.4316 and 5.2682, respectively. The mean and median values of cash flow variability over past

10 years (STDCFO) are 0.1383 and 0.0808, respectively. The mean and median values of sales variability over the past 10 years (STDSale) are 0.4091 and 0.2809, respectively. The values of mean and median of the log value of operating cycle (OperCycle) are 3.8544 and 3.9922, correspondingly. The mean and median values of incidence of negative earnings (NegEarn) over the past 10 years are 0.2314 and 0.1, respectively. The mean and median values of incidence of negative earnings (NegEarn) over the past 10 years are 0.2314 and 0.1, respectively. The mean and median values of ratio of total interest-bearing debt to total assets (Leverage) are 0.2736 and 0.2319, respectively. Overall, compared with Francis et al.'s (2005) sample, the sample firms in this study are more volatile in cash flows and sales over the past 10 years and have more frequent occurrence of negative earnings. These results may be due to inclusion of the 2007/2008 financial crisis period in this sample.

103.5 Empirical Results

103.5.1 Results of Testing H1

103.5.1.1 Correlation Results

High-Growth Subsample

Panel A of Table 3 reports the Pearson (above the diagonal) and Spearman (below the diagonal) correlations for the variables used in a high growth subsample (firms with a positive change in sales growth) analyses.

The Pearson correlation between AG and its one period lag is -0.1092 , statistically significant at less than 0.0001 level, indicating a firm with a positive change in sales growth may have a negative change in sales growth in the prior year. However, the Spearman correlation between AG and its one period lag is 0.0036 but not statistically significant. The Pearson (Spearman) correlation between AG and AQ is 0.2750 (0.2239) and statistically significant at less than 0.0001. Recall the larger AQ, the poorer accruals quality. This result indicates that the accruals quality of a firm with a positive change in sales growth ($AG > 0$) decreases with the increase of abnormal sales growth (AG), consistent with my H1a in Sect. 103.2..

Panel A of Table 3 also reports that the Pearson (Spearman) correlation between the abnormal sales growth (AG) and the log value of the total assets (Size) is -0.16 (-0.1749) and statistically significant at less than 0.0001, indicating that a firm with a large amount of sales growth tends to be smaller in size, which is consistent with conventional information that small firms are usually high growth firms. The Pearson (Spearman) correlation between abnormal sales growth (AG) and volatile of cash flows (STDCFO) and volatile of sales (STDSale) are 0.2745 and 0.1741 (0.2926 and 0.2076), respectively, both of which are statistically significant at less than 0.0001, indicating that the volatile of cash flows and of sales increases with the increased change in sales growth for a firm with a positive change in sales growth in year t . The Pearson (Spearman) correlation between abnormal sales growth

(AG) and external financing (XFIN) is 0.2858 (0.2005), statistically significant at less than 0.0001, indicating that the likelihood of external financing increases with the increased change in sales growth for a firm with a positive change in sales growth in year t . This result is consistent with rational expectation that a firm more likely needs external financing when it experiences high sales growth.

Low-Growth Subsample

Panel B of Table 3 reports the Pearson (above the diagonal) and Spearman (below the diagonal) correlations for the variables used in low growth subsample (firms with a negative change in sales growth) analyses.

The Pearson (Spearman) correlation between AG and its one period lag is 0.4245 (0.2106), statistically significant at less than 0.0001 level, indicating a firm with a negative change in sales growth may have a negative change in sales growth in prior year. The Pearson (Spearman) correlation between AG and AQ is -0.1617 (-0.1848) and statistically significant at less than 0.0001, indicating that the accruals quality for low growth firms, where AG is less or equal to zero ($AG \leq 0$), increases with the increase of abnormal sales growth (AG), consistent with my H1b in Sect. 103.2.

Results in panel B of Table 3 also show that the Pearson (Spearman) correlation between abnormal sales growth (AG) and log value of the total assets (Size) is 0.1714 (0.2085) and statistically significant at less than 0.0001, indicating that a large firm's sales growth tends to approach its steady stage, which is consistent with conventional information that large firms usually are mature firms and have stable sales growth. The Pearson (Spearman) correlation between abnormal sales growth (AG) and volatile of cash flows (STDCFO) and of sales (STDSale) are -0.3384 and -0.2021 (-0.3750 and -0.2562), respectively, both of which are statistically significant at less than 0.0001, indicating that the volatile of cash flows and of sales decreases with the increasing sales growth for a firm with a negative change in sales growth in year t . The Pearson (Spearman) correlation between abnormal sales growth (AG) and external financing (XFIN) is -0.2048 (-0.1193), statistically significant at less than 0.0001, indicating that the likelihood of external financing decreases with increasing sales growth for a firm with negative change in sales growth in year t . This result is still consistent with rational expectation that a firm less likely needs more external financing when its sales growth approaches a steady state.

These results for the low growth subsample are generally opposite to those for the high growth subsample. While supporting my H1 that the AG is associated with the accruals quality and firm's business risk or the business environment volatile, those results are consistent with my H1A that a firm's business risk (or the business environment volatile) increases with the increasing sales growth for the firm with a positive change in sales growth (more volatile sales growth), and with my H1B that a firm's business risk (or the business environment volatile) decreases with the increasing sales growth for the firm with a negative change in sales growth (lower volatile sales growth).

Table 3 Pearson (above the diagonal) and Spearman (below the diagonal) correlations for variables in analyses. (I suppress the subscripts j, t of each variable in the table.)

^aResults in panel A of Table 3 are based on a high-growth subsample of 43,683 firm-year observations and 8,752 distinct firms over the 38-year period (1973–2010).

^bResults in panel B of Table 3 are based on a low-growth subsample of 60,282 firm-year observations and 10,038 distinct firms over the 38-year period (1973–2010).

^cThe bolded correlation coefficients are statistically significant at less than 5% level.

103.5.1.2 Regression Results

This subsection reports two types of regression results of testing H1A and H1B. I first use the F test in the ordinary least square (OLS) regressions to validate the model, Eq. (6), examining whether AG is a good explanatory variable for AQ. Then, I use the Fama and MacBeth (1973) annual regression method to further test H1.

Ordinary Least Square Regressions

Panels A and B of Table 4 shows F tests for the validation of seven regression models with AG as an independent variable, using high growth and low growth subsample, respectively. Each model adds one more independent variable (I.V.) to the prior regression model. The F test statistics for the associated change in R-squares, when an I.V. is added to the previous model, indicates whether the newly added I.V. is a suitable explanatory variable for the dependent variable. A significant increase in the R-squares associated with newly added I.V. can be interpreted as that the newly added I.V. is a good explanatory variable for the dependent variable.⁹ Therefore, whether increment in R-square associated with the newly added AG, the I.V., is statistically significant (shown by F test statistics) can infer whether abnormal sales growth (AG) is a good explanatory variable to total accruals quality (AQ).

The model 1 in Panel A of Table 4 shows that 9.74% of the variation of accruals quality (AQ) can be explained by only one independent variable AG, and the F statistics for this model is 3572.92, indicating that the model 1 is statistically valid. The estimated coefficients of AG are range from 0.0160 (in the model 7) to 0.0372 (in the model 1) and are all statistically significant at 0.01 levels, consistent with my H1A that the accrual quality decreases with an increase in the sale growth rate.

The next to the last column in Panel A of Table 4 shows that, in model 3, the variable Size contributes most to the change in R-square (11.01% increment to model 2). The variable of one period lag of AG also can explain a portion of variation in AG, but the sign of the coefficient of one period lag of AG flipped from negative (−0.0019) to positive (0.0017), when adding more control variables identified by Dechow and Dichev (2002). The results in Table 4 suggest that the negative sign of the coefficient of AGLag1 is likely due to the omitted correlated independent variables (e.g., Size, STDCFO). The sign of the coefficient of AGLag1 was corrected once including the omitted independent variables.

Using the low-growth subsample, the analyses for the results in Panel B of Table 4 are similar to those, using high-growth subsample, reported in Panel A of Table 4. The estimated coefficients of AG range from −0.0076 (in the model 7) to −0.0241 (in the model 1), indicating that accrual quality increases with an increase in sales growth rate. The result supports my H1B.

⁹Here, the current model is the full model, while the prior model without the newly added independent variable is the nested model. When an independent variable is added to the nested model, the R-square changes. If the R-square of the current model is significant, shown by F-test statistics, larger than that of the prior model, I can infer the newly added independent variable is a good explanatory variable for the dependent variable (Greene 2008, 81–92).

^a. Results in panel A of table 3 are based on a high-growth subsample having 43,683 firm-year observations and 8,752 distinct firms over a 38-year period (1973-2010).

^b. Results in panel B of table 3 are based on a low-growth subsample having 60,282 firm-year observations and 10,038 distinct firms over a 38-year period (1973-2010).

The bolded coefficients are statistically significant at less than 5% level. Please refer variable definitions to Table 106.2.

The goal of using the F test in the OLS regression in this subsection is to validate whether AG is a good explanatory variable for AQ. Therefore, I omit the details of other regression analyses here. Next subsection reports the Fama and MacBeth (1973) method regression results and details the implication of regression results of examining the relationships between abnormal sales growth (AG) and accruals quality (AQ).

Fama-MacBeth (1973) Regressions

High-Growth Subsample Panel A of Table 5 reports the results of estimating Eq. (6) for the high-growth subsample ($AG > 0$). The based model is the model 1 as Francis et al. (2005). Coefficients of all independent variables in the based model have the same signs as those reported in Francis et al. (2005). The based model has an adjusted R-square of 0.307, slightly lower than Francis et al.'s (2005), which may be due to different sample periods in two studies.¹⁰

The model 2 in Panel A of Table 5 adds the variable of abnormal sales growth (AG) to the based model (Dechow and Dichev 2002; Francis et al. 2005). The coefficient on AG is 0.011, statistically significant at less than 0.01 level with a 9.25 of the Fama-Macbeth t-statistics, and 20.37 (9.87) of Z_1 (Z_2) test statistics (Fama and MacBeth 1973),¹¹ indicating that the AQ increases by 0.011 unit with one-unit increase in the AG for a high-growth firm in year t holding other factors constant. The result that the variable AG is still statistically significant at less than 0.01 level and have a relatively large magnitude (0.011) in the regression with the presence of standard deviation of sales suggests that the variable AG captures an aspect of innate (fundamental) determinants of AQ, which is different from the volatile of sales (STDSale). The untabulated results of testing multicollinearity show that there is no multicollinearity issue in this regression model.¹² The adjusted R-square of the model 2 increased to 0.319 from 0.307 of the based model, indicating that the variable AG still can explain a good amount of variation in AQ after controlling for traditional innate accruals factors (i.e., size, volatiles of

¹⁰This study uses firms in Compustat in later years than Francis et al. (2005). The average accounting quality of Compustat sample firms in recent years are generally lower than that of sample firms in earlier years because Compustat has expanded its database and included more small firms, which usually have a lower accounting quality than large firms.

¹¹Here, FM.T-stat is the Fama Macbeth t-statistics computed as $FM.T - stat = \frac{\bar{t}\sqrt{N-1}}{stdev(t)}$. Z_1 and Z_2 statistics test whether the time-series mean t-statistics from yearly regressions is statistically different from zero, computed as $Z_1 = \frac{1}{\sqrt{N}} \sum_{i=1}^N \frac{t_i}{\sqrt{k_i(k_i-2)}}$, $Z_2 = \frac{\bar{t}}{stdev(t)\sqrt{N-1}}$, where t is t-statistic and k is the degrees of freedom for year i , and N is the number of years.

¹²All VIFs are less than 10.

cash flows and sales, operating cycle, and occurrence of negative income).¹³ The untabulated results also show that the root of the mean of squared error (MSE) of the model 2 is less than that of the based model. Since the model with the minimum MSE is a better choice than other models, results of the model 2 suggest that the AG is one of the omitted variables in accruals quality regression models.

The model 3 in Panel A of Table 5 examines the effect of one period lag value of AG on the accruals quality controlling for the traditional accruals innate factors and AG. The coefficient on the one period lag of AG is 0.001 and not statistically significant at 5% levels in the FM t-test and Z_2 test statistics of time series t-stat. The adjusted R-square of the model 3 increased to 0.355 from that of the model 2 (0.319). The VIF and Tolerance tests show there is no multicollinearity issue in the model 3. However, the untabulated OLS regression results basing on robust t-statistics show that the coefficient of one period lag of AG is statistically significant at 0.000 level. The prior period change in sales growth may affect the next period total accruals (such as account receivables and account payables, and even the cash flows). Therefore, I decide to leave the AGLag1 in the model 3.

Coefficients on all traditional innate factors of accruals quality in all of three regression models have the signs same as predicted and documented in previous studies (e.g., DD; Francis et al. 2004 and Francis et al. 2005): size (Size) is negatively related to AQ; volatile of cash flows and sales in past 10 years, operating cycle, and occurrence of negative earnings (i.e., STDCFO, STDSale, OperCycle, and NegEarn, respectively) are positively associated with AQ.

Notes for panels A and B:

- (1) Z_1 and Z_2 statistics test whether the time-series mean t-statistics from yearly regressions is statistically different from zero.

$$FM.T - stat = \frac{\bar{t}\sqrt{N-1}}{stdev(t)}, \quad Z_1 = \frac{1}{\sqrt{N}} \sum_{i=1}^N \frac{t_i}{\sqrt{k_i(k_i-2)}}, \quad Z_2 = \frac{\bar{t}}{stdev(t)\sqrt{N-1}}, \quad \text{where } t \text{ is}$$

t-statistic and k is the degree of freedom for year i, and N is the number of years (N=38 in this table).

- (2) The bolded coefficients are statistically significant at less than 5% level.

Low-Growth Subsample Panel B of Table 5 reports the results of estimating Eq. (6) for the low-growth subsample ($AG < 0$). Similar to the previous analyses for the high-growth subsample, I still focus on the analyses on the effect of AG on AQ. The model 2 in Panel B of Table 5 adds the variable of abnormal sales growth (AG) to the based model. The coefficient on AG is -0.003 , statistically significant at 0.05 level with a -2.35 of Fama and Macbeth t-statistics, and $-6.56(-2.05)$ of Z_1

¹³ The magnitude of incremental R-square by adding an independent variable is related to the order of adding that independent variable. And also the regression method used in this subsection is annual regression different from OLS regression used in previous analyses.

^aResults in panel A of Table 3 are based on a high-growth subsample of 43,683 firm-year observations and of 8,752 distinct firms over the 38-year period (1973–2010).

^bResults in panel B of Table 3 are based on a low-growth subsample of 60,282 firm-year observations and of 10,038 distinct firms over the 38-year period (1973–2010).

(Z_2) test statistics (Fama and MacBeth 1973),¹⁴ indicating that the AQ decreases 0.003 units with one-unit increase in the AG for a low-growth firm in year t , holding other factors constant. The results indicate that, for low-growth firms, the variable AG captures a dimension of innate determinants of AQ, which is different from volatile of sales (STDSale). The untabulated results of testing multicollinearity show that there is no multicollinearity issue in this regression model and model 3. The adjusted R-square of model 2 increased to 0.294 from 0.288 of the based model, indicating that the variable AG still can explain some variation in AQ after controlling for traditional innate accruals factors.

Results of the model 3 in Panel B of Table 5 suggest that the variable of one period lag of AG is a good explanatory variable for AQ. The coefficient on $AGLag1$ is 0.002, statistically significant at 0.01 level with a 2.75 of Fama and Macbeth t -statistics, and 5.91 (2.81) of Z_1 (Z_2) test statistics (Fama and MacBeth 1973). The adjusted R-square of the regression model 3 increased to 0.353 from 0.294, that of model 2.

Similar to the results in Panel A of Table 5, the coefficients of all traditional innate factors of accruals quality in all of three models have the same signs as those documented in previous literature.

103.5.2 Results on Ranked AG Portfolio Returns (H2)

Panel A of Table 6 reports results of regression Eq. (7), four-factor model (Fama and French 1993; Carhart 1997), where the dependent variable, $(R_{p,t} - R_{f,t})$, is the monthly-return difference between value-weighted portfolio returns and risk-free rate in that month. Each portfolio is constructed based on the rank of AG in the preceding year and rebalanced annually. T-test statistics are reported below the corresponding estimated coefficients for a 456-month time series regression of each portfolio. Therefore, the intercept estimate coefficient, α , is interpreted as the abnormal returns in excess of what could have been earned by the passive investment in these four factors.

The largest monthly abnormal returns are 0.0154 (0.0082) for the lowest (highest) sales growth decile sample firms, statistically significant at 0.01 level. These results are not surprising because the glamour and value stock phenomenon have been well documented in finance and accounting literature. However, the interesting questions are why investing these lowest sales growth firms gains the highest excess returns, and whether the excess returns were earned because of underpricing the low-growth firms or compensating for bearing the higher risk of these low-growth firms.

¹⁴ Here, FM.T-stat is the Fama Macbeth t -statistics computed as $FM.T - stat = \frac{\bar{t}\sqrt{N-1}}{stdev(\bar{t})}$. Z_1 and Z_2 statistics test whether the time-series mean t -statistics from yearly regressions is statistically different from zero, computed as $Z_1 = \frac{1}{\sqrt{N}} \sum_{i=1}^N \frac{t_i}{\sqrt{k_i(k_i-2)}}$, $Z_2 = \frac{\bar{t}}{stdev(\bar{t})\sqrt{N-1}}$ where, t is t -statistic and k is the degrees of freedom for year i , and N is the number of years.

Recall H1 predicts that a large change in sales growth rate is associated with higher information risk (proxied by AQ) no matter which direction the change is. And the results analyzed in Sect. 103.5.1 support H1 (H1A and H1B). Therefore, the excess returns for lower/higher sales growth portfolios may be related to firms' business risk and information risk that can't be diversified away. Then, beta, the proxy for systematic risk, may help us to disentangle the low/high sales growth excess return puzzle.

The results of estimating beta in column (2) in Table 6 show that the bottom decile of the AG ranked portfolios has the largest beta (1.1631) compared with other deciles of AG ranked portfolios, and statistically significant at 0.001 level, and the 2nd lowest sales growth portfolio has the 2nd largest beta (1.1096) statistically significant at 0.001 level. The 3rd (4th) largest estimated beta, 0.9964 (0.987) is from the highest (2nd highest) sales growth portfolio. The monthly excess returns for the highest (2nd highest) sales growth portfolio is 0.0082 (0.0081). The smallest (second smallest) beta is 0.9019 (0.9280) for the smallest (second smallest) change in sales growth portfolio with the AG rank of 6 (5). The results on portfolio excess returns and beta, at least partially, support the argument that the higher excess return earned by the portfolios with the largest change in (upward or downward) sales growth is required by investors for bearing higher risk. These results are consistent with H2A and H2B that AG is related to the future returns in the predicted directions, and further support that the new risk proxy suggested by this study, AG, is associated with excess returns and the systematic risk beta.

Size effect on excess returns has been well documented. Results in this study support the size effect on excess returns too. However, only portfolios with a big swing in sales growth rate can harvest abnormal returns by investing small firms. The coefficients on SMB for the lowest, second lowest sales growth portfolios in the four-factor regressions are 0.5113 and 0.3118, statistically significant at 0.01 levels. Similarly, the coefficient on SMB for the highest sales growth portfolio is 0.1884, statistically significant at 0.01 level.

The coefficients on HML (book-to-market factor) are generally negative, which may be due to portfolios constructed by the ranks of changes in sales growth that capture the growth factor as well. The coefficients on momentum factor (UMD) do not have a special pattern as those of beta coefficients.

The panel B of Table 6 reports results of abnormal returns for equal-weighted portfolios, which are qualitatively similar to those of value-weighted portfolios. However, the excess return pattern in equal-weighted portfolios is weaker than that in value-weighted portfolios. The pattern for the systematic beta is the same as that in the value-weighted portfolio. The size effect on the equal-weighted portfolios is more pronounced than that on the value-weighted portfolios. This result is not surprising because I do not control for the market capital of sample firms in the equal-weighted portfolios. Results reported in Panel B of Table 6 are consistent with my H2.

In the above portfolio tests, after controlling for growth factor (HML) in the four-factor regressions, the statistically significant Jensen-alpha further suggests that abnormal sales growth captures the different dimension of business risk from traditional growth proxies. And this result is also economically meaningful that

one can earn 18.48% abnormal annual returns by holding firms with the lowest AG rank in the preceding year.¹⁵

In a sum, one can see that correlation and regression results support H1 and H2: the larger change in sales growth rate (either upward $AG > 0$, or downward $AG < 0$) is associated with higher business risk, poorer accruals quality, and larger future returns. This result partially overlaps with but is different from the findings in Liu (2021), which documents that abnormal sales growth rate is negatively associated with the 1-year-ahead size-decile adjusted return but positively associated with unexpected current-period earnings. The results of Liu (2021) and this study indicate that the capital market is rational in terms of not being over optimistic about the sales growth by counting the growth glamor effect in the estimated value of the firm, therefore, requiring higher return to compensate the risk embedded in the sales growth rate in both downward and upward direction.

103.6 Additional Tests

103.6.1 Robust Tests

103.6.1.1 Firm-Specific, Industry, and Year Effects

To address the firm-specific effect, I also run the AQ regressions on AG using the fixed effect (by firms) model (i.e., Eq. (8) below).

$$AQ_{j,t} = \lambda_0 + \lambda_1 AG_{j,t} + \lambda_2 AGLag^1_{j,t} + \lambda_3 Assets_{j,t} + \lambda_4 STDCFO_{j,t} + \lambda_5 STDSales_{j,t} + \lambda_6 OperCycle_{j,t} + \lambda_7 NegEarn_{j,t} + \sum_{t=1973}^{2010} b_{t-1973} Y_t + \sum_{i=2}^{48} i_{i-1} Ind_{j,t} + \mu_{j,t} \quad (8)$$

where $\sum_{t=1973}^{2010} b_{t-1973} Y_t$ are the year dummy variables for years 1973–2010; and $\sum_{i=2}^{48} i_{i-1} Ind_{j,t}$ are the industry dummy variables, where industries are classified as in Fama and French (1997).

The results of the regression Eq. (8) using firm fixed effect are qualitatively same as those reported in Tables 4 and 5, with larger R-squares. That might be due to that adding year and industry dummy variables could explain more variations in AQ.¹⁶

¹⁵Results of the value-weighted portfolio tests show that Jensen-alpha is 1.54% per month, then, will be 18.48% (1.54% x 12) annually.

¹⁶Results of regression Eq. (8) using firm-fixed effect regression method are not tabulated here, and available upon request.

103.6.1.2 Unexpected Sales Growth (AG) and Volatility of Sales.

To investigate the extent to which the abnormal sales growth (AG) contributes to the accruals quality model (i.e., Eq. (8)) compared to volatility of sales documented in Francis et al. (2005), I compute the standardized coefficients on the abnormal sales growth (AG) and volatility of sales (*STDSales*) in the regression Eq. (8). The untabulated results show that the coefficients on AG and *STDSales* are quantitatively same as those reported in terms of magnitude of absolute values of coefficients and statistical significance levels.¹⁷

103.6.1.3 Alternative Econometric Methods

To ensure that the reported results are robust to different econometric estimate methods, I repeat the analysis for Tables 5, clustering the standard errors by the firm to account for possible correlation of regression residuals (Petersen 2009). The estimated coefficients are qualitatively same, with corresponding t-statistics larger than those obtained by Fama and MacBeth (1973) regression procedure.

103.6.1.4 Firm-Level Abnormal Return

I also rerun the regression Eq. (7) at the firm level by the ranks of AG in the preceding year. The results of firm-level regressions are qualitatively similar to those of value-weighted and equal-weighted portfolio-level regressions, but with smaller adjusted R-squares.

103.6.2 Additional Tests

Section 103.5 analyzes the relationship between unexpected sales growth (AG) and accruals quality (AQ) and future returns. Results in Table 6 provide some explanation for the abnormal returns of the lowest and highest sales growth portfolios, so to speak, AG represents the change in operating risk, and therefore, it is associated with AQ, abnormal returns, and beta.

This subsection further disentangles the relationships between certain firms' characteristics and AG. Table 7 reports mean value of each variable of each portfolio, which is sorted based on the decile ranks of AG in the current year.

Table 7 shows that mean values of sales, total assets, market capital, income before extraordinary items increase in the increasing in the AG ranks when moving from the rank 1 to the rank 6, then decrease with the increasing in the ranks of AG, when moving from the rank 6 to the rank 10. The mean values of sales growth increase monotonically along with the increase in AG ranks. The portfolios with the AG rank of 5, 6, and 7 have firms with almost no change in sales growth, suggesting that these firms are about in the steady stage in terms of sales growth.

¹⁷The standardized coefficients on the AG and *STDSales* are 0.135 and 0.148, respectively, and statistically significant at 0.001 levels for the high-growth firms (AG > 0). Results are available upon request.

^aThe donation of each variable for year t is suppressed in this table.
The statistics reported in this table are obtained from a sample that contains 103,965 firm-year observations for 10,480 distinct firms for the 38-year period (1973–2010).

The interesting variable is AQ, mean values of which decreases monotonically with the increase in AG ranks from AG rank of 1 to that of 6, then, increases monotonically with the increase in the AG ranks from AG ranks of 6 to that of 10. These results further support my H1A and H1B, the larger change (either upward with $AG > 0$ or downward with $AG < 0$) in sales growth rate is related to the poorer accruals quality (larger amount of AQ).¹⁸

The annual buy-and-hold return (Ret_f) for the year t monotonically increases with the increase in AG ranks, from annual returns of 0.0248 to of 0.4730 for portfolios with the AG ranks of 2-10. These results are consistent with the convention that the capital market rewards the high growth firms in the current year without controlling other factors. The mean value of annual returns for the portfolio with the lowest rank of AG is 0.0844, higher than that for portfolios with the AG ranks of 2-4, which may be due to the compensation of holding riskier assets.

The mean values of PB ratio (i.e., ratio of closing price to the book value of per share at the end of year) of two tails of AG ranks are larger ones, indicating the market prices firms with the more volatile in growth higher than firms with small change in sales growth (i.e., AG rank of 5). This may be because investors require more returns for holding riskier assets, partially supporting that AG is a risk proxy. The other side of the coin of compensating risk is that the market may overprice the lowest sales growth firms (the PB ratios for portfolios with AG ranks of 1 and 2 are 3.9789 and 8.7072, respectively). But these two portfolios have the highest portfolio abnormal returns in next year reported in Table 6. Therefore, the higher PB ratio in year t may not be due to the market mispricing. This result could be a puzzle for fundamental accounting researchers. Future research can investigate the low sales growth anomaly.

The business environment measures, operating cycle (OperCycle), and occurrence of negative earnings (NegEarn) are larger for the two tails of the AG ranks again. The longer the operating cycle and more frequent incidence of negative earnings are riskier of the firm. These results further suggest that AG is a risk proxy representing the change in the level of business risk of a firm.

The firms with the largest value of AG rank have the largest mean values of Leverage (0.3932), XFIN (0.0824), and Ddebt (0.0315), indicating that these firms are most active in external financing, and raise capital by borrowing. These results are consistent with convention that a firm in a high-growth state is more likely to expand its business by borrowing or issuing new/seasonal equity, which is inferred in Table 7.

The puzzle to us is that portfolio with the lowest AG rank, the slowest sales-growth-firm group, has the second highest external financing activity, and is the most likely to raise capital by issuing new/seasonal equity.

¹⁸Record, the larger (smaller) amount of AQ is the poorer (better) accruals quality.

103.6.3 Discussion

The abnormal sales growth (AG), the new risk proxy, proposed by this study represents a change in the level of operating risk, is associated with accruals quality and future returns. The results in this study have to be interpreted with caution because the sample firms used in this study tend to be large and profitable, compared to the Compustat population. The currently available accrual quality measures all suffer the possible measurement errors (Leone et al. 2006). I am aware that I may miss some explanatory variables of accruals quality as well. Further, some puzzles identified in this study could be future research.

103.7 Summary and Conclusion

I explore the possible relationship between the unexpected sales growth and accruals quality and future returns, inspired by Ohlson (2008) that analytically demonstrates a broader growth/risk equivalence concept and Penman (2010) that explains the uncertainty embedded in the sales growth in an accountant view. I argue that abnormal sales growth (AG) captures the uncertainty embedded in the sale growth, a type of operating (i.e., business) risk. AG is measured as the difference between sales growth rate in the current year and its benchmark, a weighted-average of sales growth rate over the past 3 years. The measure of AG suggests that a change in both directions of upward ($AG > 0$) and downward ($AG < 0$) reflects a change in business risk. This middle point, where AG is zero, is critical because it represents a firm's steady state of sales growth.

According to the value of AG, I divide my sample into a high- ($AG > 0$) and low-growth subsample ($AG < 0$). For the high-growth subsample ($AG > 0$), the larger the value of AG, the greater the uncertainty of sales growth (i.e., operating risk). For the low growth subsample ($AG < 0$), a larger value of AG indicates a lower operating risk because of less volatility in sales growth. The results for the high-growth subsample show that AG is positively correlated with the systematic risk (Beta) and the business risk proxies documented in Francis et al. (2005) (e.g., volatile of cash flows from operations, operating cycle, incidence of negative earnings over past 10 years). The converse is true for the low-growth subsample. Further, the results of the regressions of accruals quality (AQ) on AG show that the AG and AQ are positively (negatively) significantly associated, using the high-(low-) growth subsample. These results indicate that the accruals quality improves when the two tails of AG approach to zero. In other words, the accruals quality is the best when the firm is in the steady state.

Moreover, Francis et al. (2005) suggest that the accruals quality (AQ) includes two components: innate and discretionary components. The innate factors of accruals quality reflect the business environment of a firm. The results of this study extend the findings in Francis et al. (2005) by adding another explanatory factor to the accrual quality model. The contribution of the AG variable to estimation of accruals quality is highly significant: AG explains 9.7% (8.7%) of variation in accruals quality for high- (low-) growth subsample firms. The F test shows the

increments in R-squares are statistically significant at the 0.05 conventional levels. The magnitude of impact of AG on AQ is almost the same as that of volatility of sales (*STDSales*) on AQ in the regressions of accruals quality (AQ) on AG, *STDSales*, and other control variables. This indicates that AG captures different dimension of business risk other than volatility of sales and its impact on accruals quality is also economically meaningful compared to fundamental factors identified in the previous literature.

Finally, I examine the relationship between AG and future returns. The abnormal returns of the value-weighted portfolio with the lowest rank of AG in preceding year are the largest (18.48% annual abnormal returns on average). This result may be due to the market compensating stockholders of riskier assets. Exploring all possible detail reasons for this result is beyond the scope of this study, which could be a future research topic.

This study adds new evidence to accounting literature by demonstrating that the abnormal sales growth contains information uncertainty of future profitability estimated by expected future cash flows, which is reflected in the accruals quality, the proxy for information risk as Francis et al. (2005), and is associated with future returns. The empirical findings of this study confirm that accruals accounting is for risk (Penman 2016).

Acknowledgments Min (Shirley) Liu cordially thanks James A. Ohlson, Jeff Madura, Mark Kohlbeck, and workshop participants at Florida Atlantic University for their helpful comments on the early draft of this manuscript. The author also gratefully thanks the organizers of the 2017 Journal of Accounting, Auditing & Finance Conference, Cheng-Few Lee, and the participants of the research session of the 2021 AAA Spark and 2021 AAA Annual Meeting Webinar for their insightful suggestions on this manuscript. All remaining errors are my own.

Appendix

Accruals Quality

The calculation of total accruals quality (*AQ*), innate and discretionary component of accruals quality, follows the empirical procedures in Francis et al. (2004 and 2005), adopting the form that larger value of the *AQ* is a worse accruals quality. The accruals quality is measured on a firm- and year-specific basis, using the accounting data for rolling 10-year windows, $t-9 \dots t$. This procedure requires firms with time-series data. This requirement biases the sample toward surviving firms (larger and more successful firms). However, the advantage of using the firm as its own benchmark over long window outweighs the sample selection bias (Eason et al. 1992).

I measure accrual quality using modified Dechow and Dichev's (2002) model.

$TCA_{j,t} = \phi_0 + \phi_1 \cdot {}_jCFO_{j,t-1} + \phi_2 \cdot {}_jCFO_{j,t} + \phi_3 \cdot {}_jCFO_{j,t+1} + \phi_4 \cdot {}_j\Delta Rev_{j,t} + \phi_5 \cdot {}_jPPE_{j,t} + v_{j,t}$ (4) Where, $TCA_{j,t}$ = firm j's total current accruals in year t, calculated as $TCA_{j,t} = \Delta CA_{j,t} - \Delta CL_{j,t} - \Delta Cash_{j,t} + \Delta STDEBT_{j,t}$; $CFO_{j,t} = NIBE_{j,t} - TA_{j,t}$, firm j's cash flow from operations in year t; $NIBE_{j,t}$ = firm j's net income before extraordinary items

(Data #18) in year t ; $TA_{j,t} = \Delta CA_{j,t} - \Delta CL_{j,t} - \Delta Cash_{j,t} + \Delta STDEBT_{j,t} - DEPN_{j,t}$, firm j 's total accruals in year t ; $\Delta CA_{j,t}$ = firm j 's change in current assets (Data #4) between year $t-1$ and year t ; $\Delta CL_{j,t}$ = firm j 's change in current liabilities (Data #5) between year $t-1$ and year t ; $\Delta Cash_{j,t}$ = firm j 's change in cash (Data #1) between year $t-1$ and year t ; $\Delta STDEBT_{j,t}$ = firm j 's change in debt in current liabilities (Data #34) between year $t-1$ and year t ; $DEPN_{j,t}$ = firm j 's depreciation and amortization expense (Data #14) in year t ; $\Delta Rev_{j,t}$ = firm j 's change in revenues (Data #12) between year $t-1$ and year t ; $PPE_{j,t}$ = firm j 's gross value of PPE (Data #7) in year t . For each firm-year, I estimate equation (4) by industry (classified as Fama and French 1997) and year. These estimations yield firm- and year-specific residuals, $v_{j,t}$, which form the basis for the accrual quality metric, $AQ_{j,t} = \sigma(v_{j,t})$, equal to the standard deviation of firm j 's estimated residuals over year $t-4$ through t . The larger (small) the standard deviation of residuals is the poorer (better) the earnings quality.

Other Variables Used in Analyses

Sales = gross sales, scaled in millions.

AT = total assets, unit is million dollars.

Mcap = market value of the firm in million dollars.

IB = income before extraordinary items.

ROE = return on equity for year t .

SaleGrowth = sales growth in year t , computed as the difference of sales over time $t-1$ and time t , divided by sales in year $t-1$ ($\Delta Sales_{t-1,t} / Sales_{t-1}$).

AG = abnormal sales growth year t , computed as below.

$$AG_t = SaleGrowth_t - SalesGBechmark_t$$

$$SalesGBechmark_t = 0.3 \times SalesG_{t-3} + 0.3 \times SalesG_{t-2} + 0.4 \times SalesG_{t-1}$$

InnateAQ = innate component of accruals quality.

DisAQ = discretionary component of accruals quality.

Size = log value of total assets.

STDCFO = cash flow variability over the past 10 years.

STDSale = sales variability over the past 10 years.

OperCycle = operating cycle.

NegEarn = incidence of negative earnings over the past 10 years.

Leverage = total interest bearing debt to total assets.

PB = ratio of closing stock price per share at the end of fiscal year t to book value per share at the end of year t .

ROA = return on total assets for year t .

XFIN = external financing activities, computed as: $XFIN = DEquity + Ddebt$

DEquity = net cash received from the sale (and/or purchase) of common and preferred stock less cash dividend paid deflated by total assets

Ddebt = net cash received from the issuance (and/or reduction) of debt deflated by total assets [(DATA#111-DATA#114+DATA#301)/DATA#6]

Ret_f = 12-months buy-and-hold returns during the fiscal year $t-1$ to t , computed as:

$$Ret_f_{j,t} = \frac{P_{j,t} - P_{j,t-1}}{P_{j,t-1}} - 1$$

Where $P_{j,t}$ is firm j 's daily closing stock price at the end of fiscal year t , and $P_{j,t-1}$ is firm j 's daily closing stock price at the end of fiscal year $t-1$.

Applications of Book-Tax Difference in Accounting and Finance Research

104

Nan-Ting Kuo and Shang-En Yu

Abstract

The difference between book income and taxable income or book-tax difference has received considerable interests from both the literature and policymakers. In this chapter we discuss the concept of book-tax difference and its empirical measures and we also review the literature exploring the information contained in book-tax differences. Prior studies consistently find that book-tax differences are informative about earnings management and tax avoidance behaviors. In addition, we also discuss the concept of book-tax conformity and its empirical measures, where it is a country-level factor in contrast to book-tax difference that is firm specific. The idea of book-tax conformity is highly related to that of book-tax differences because increasing book-tax conformity is a usually claimed means to curb the growing trend of book-tax differences as well as hinder the behind earnings management or tax avoidance behaviors. Prior literature suggests that increasing book-tax conformity may incur substantial costs in decreasing the informativeness of accounting earnings and it is debated about whether book-tax conformity can deter earnings management, while these question the potential benefits of increasing book-tax conformity.

104.1 Introduction

In the United States, the growing divergence between book and taxable incomes has attracted much attention and analysis (Mills et al. 2002; Desai 2003; Hanlon and Shevlin 2005). This expanding divergence raises concerns about misleading financial or tax reporting because it signals that firms may increasingly overstate book income or understate tax liability. As the review made by Hanlon and Heitzman (2010) points out, the presence of book-tax differences raises considerable interests to the accounting and finance studies and it is linked to many important research areas such as the informational role of taxable income relative to book income or the measurement of corporate tax avoidance.

As the increasing trend of reported book-tax differences has received considerable interests in the literature, the first purpose of our paper is to review the literature regarding book-tax differences and its application in the accounting and finance studies. To this end we will clarify the concept of book-tax differences, elaborate commonly used empirical measures and their potential problems, and provide a literature review for studies exploring the effects of book-tax differences. Our literature review focuses on the information content of book-tax differences as the presence of book-tax differences is an indicator for aggressive accounting or tax reporting practices.

In addition, we will discuss book-tax conformity, where we emphasize that it is a country-level measure in contrast to book-tax difference that is a firm-level measure. Book-tax conformity is closely related to the literature of book-tax differences because the former is a plausible strategy to mitigate the increasing growth trend in firm-level book-tax differences as well as the accompanied concerns about earnings manipulation and tax avoidance. We will discuss common empirical measures of book-tax conformity and review the related literature. Following Hanlon and Heitzman (2010), our literature review focuses on the effects of increasing book-tax conformity on decreasing the informativeness of accounting earnings numbers as this is a major debate regarding whether it deserves to increase the degree of book-tax conformity.

This chapter is organized as follows. In Sect. 104.2 we discuss the concept of book-tax differences and its empirical measures. Section 104.3 reviews the literature exploring the effects of book-tax differences. Section 104.4 introduces the concept and empirical measures of country-level book-tax conformity, which is closely related to the idea of firm-level book-tax differences. Section 104.5 reviews the literature exploring the effects of book-tax conformity. Concluding remarks appear in Sect. 104.6.

104.2 The Concept and Empirical Measures of Book-Tax Differences

Conceptually, book-tax differences arise from the divergences between accounting income (i.e., book income) and taxable income and they are driven by various factors. The fundamental of these differences is that accounting income and taxable

income are measured with two systems with quite different objectives that in turn lead to different rules. The reasons for their differences are discussed as follows, where our discussions are abstracted from Hanlon and Heitzman (2010).

In theory, the measurement of accounting income follows the conceptual framework of financial accounting standards (GAAP), where the main objective is to capture the underlying economics of transactions and provide relevant information for financial reporting users such as equity investors or contracting parties. By contrast, taxable income is measured based on tax rules, while tax rules are enacted for a more political purpose in that they are purported to raise fiscal revenues for governments, direct certain private sector activities such as encouraging firms to engage in R&D and innovation activities, or stimulate the economy through for example cutting personal income taxes to enhance consumption.

Moreover, while the calculation of accounting income is accrual based, the calculation of taxable income is basically a mix of cash basis and accrual basis, which does not allow recognizing estimated expenses before the realization of cash payments or deferring the recognition of unearned revenues. In particular, the location where the earnings made is crucial because it is the jurisdiction of the location that can levy tax on the earnings. By contrast, the location where the earnings are made is irrelevant under financial accounting because financial accounting standards require that all earnings from controlled entities are aggregated into a consolidated financial statement.

Furthermore, managers' aggressive reporting for accounting or tax purposes is also a likely source of the book-tax differences, where it may result from aggressive financial reporting due to upward earnings management or from aggressive tax reporting due to tax avoidance. Specifically, when managers engage in upward earnings management, they will record a book-tax difference in the financial statements if they choose to report unmanaged taxable income. On the other hand, when managers engage in tax avoidance and take actions to lower reported taxable income, they will also record a book-tax difference if they choose to report unmanaged accounting income.

Note that reporting a book-tax difference is a less costly method for either aggressive financial reporting or aggressive tax reporting. For aggressive financial reporting, book-tax differences provide relevant information to market participants about the quality of reported earnings in the sense that recoding book-tax differences hurts investor perceptions about the credibility of reported earnings. To avoid reducing perceived earnings quality, managers can choose to report higher amount of taxable income and paying taxes on the inflated earnings they manipulate, but this leads to higher tax payments, suggesting that recording book-tax differences saves taxes and therefore it is a less costly method.

For aggressive tax reporting, reporting book-tax differences is likely to attract the attentions from the taxing authority and it may be used as an indicator of tax avoidance, which increases the likelihood of detection for the understatement of taxable income by the taxing authority. To avoid detection by the taxing authority, managers can choose to report lower accounting income to conform to the understated taxable income, but this leads to higher reporting costs due to the lower reported earnings so managers may still choose to record book-tax differences.

Accordingly, there exists a trade-off between recoding book-tax differences and paying higher taxes or bearing higher reporting costs when manager attempt to engage in aggressive tax or accounting reporting.

The above discussions suggest that accounting income and taxable income are linked to some extent but in most situations they are not conformed for various transactions, leading to the call for book-tax conformity that we will discuss in subsequent sections. In most cases, all of these factors operate concurrently to determine the level of book-tax differences a firm reports. If book income is calculated with the same rules as taxable income, then book-tax differences will not present. However, because accounting rules divergent from tax rules in that the former focuses on measuring economic performance while the latter focuses on levying taxes, the presence of book-tax differences is quite common. In this regard, it is well recognized in the literature that there are many possible determinants of book-tax differences and prior studies usually intend to develop models or identify settings to study a particular determinant.

To conduct the research, prior studies typically partition the book-tax difference measures based on the underlying causes of the relations explored, but doing so raises an important issue that this stream of literature employs several measures of book-tax differences because it is usually not clear about the reasoning for why a particular book-tax difference measure is used for the research question explored. We clarify this issue with following reviews about the commonly used measures of book-tax differences, where our classifications and explanations closely follow Evers et al. (2016) by condensing their arguments.

Recall that a firm's reported book-tax difference is calculated as the difference between its reported book income and taxable income, where book income is the income from financial statements and taxable income is the income used to determine tax liability. Because data for taxable income is unavailable, it is usually inferred by grossing up current tax expenses with the statutory corporate income tax rate. In this regard, the basic measure of book-tax differences (denoted as total BTD) is as presented in Eq. (1).

$$\text{Total BTD} = \text{Pre-tax book income} - \text{Estimated taxable income} \quad (1)$$

$$\text{Estimated taxable income} = \text{Current tax expenses} / \text{Statutory tax rate} \quad (2)$$

Equation (1) presents the basic definition of book-tax differences as it captures both the temporary and the permanent components of book-tax differences. Equation (2) shows how to estimate taxable income. Since tax return data are usually unavailable, taxable income must be estimated with current tax expenses retrieved from financial statements (Manzon and Plesko 2002).

Although total BTD is intuitively appealing due to its straightforward computation, it is criticized as being subject to serious measurement errors arising from, for instance, different consolidation rules for book and tax purposes, tax credits, foreign operations, or loss firms (Hanlon 2003; Kvaal and Nobes 2012; Evers et al. 2016). Hence, total BTD is rarely used as the main proxy in the research design, and it must

be complemented by other measures of book-tax differences to ensure the robustness of empirical results.

As summarized in Evers et al. (2016), some studies (e.g., Hanlon et al. 2012) separate total BTD into temporary BTD and permanent BTD, which are calculated based on following Eqs. (3) and (4) respectively.

$$\text{Temporary BTD} = \text{Deferred tax expenses} / \text{Statutory tax rate} \quad (3)$$

$$\text{Permanent BTD} = \text{Total BTD} - \text{Temporary BTD} \quad (4)$$

Temporary BTD arises due to the timing difference in the recognition between book income and taxable income with regard to specific revenue or expense items. Temporary BTD can be estimated by grossing up deferred tax expenses with the statutory tax rate (Moore 2012) as the timing difference is reconciled through the recognition of deferred tax expenses. A specific example is that many firms use different depreciation methods to calculate book income and taxable income, where the difference between these two incomes is a timing difference and it is temporary in nature as it will reverse in the future. Accordingly, temporary BTD is regarded as containing information about non-tax accruals such as depreciation (Hanlon and Heitzman 2010).

Permanent BTD arises from the difference between book and taxable income that is not a timing difference and thereby will not reverse in the future, where it is determined with the difference between total BTD and temporary BTD (Wilson 2009; Lisowsky et al. 2013). Permanent BTD is used as an indicator of tax shelters in the literature (Plesko 2004; Frank et al. 2009; Shevlin 2002) because it represents a decrease in taxable income without affecting book income, while this feature suggests that the presence of permanent BTD is indicative of aggressive tax reporting. Consistent with this idea, Wilson (2009) provides empirical evidence that the construction of most tax shelters leads to permanent BTD.

To more precisely capture tax reporting aggressiveness, Frank et al. (2009) develop a model as following Eq. (5) to measure discretionary permanent differences (denoted as *DTAX*), where *DTAX* is measured with the regression residuals. By considering factors reflecting the non-discretionary portion of permanent BTD, the residuals represent the portion of permanent BTD that removes the effects of determinants unrelated to tax aggressiveness so they are supposed to capture intentional tax aggressiveness.

$$\text{PermanentBTD} = \alpha + \beta * \text{Non-discretionary items} + \gamma * \text{Other statutory adjustments} + \varepsilon \quad (5)$$

In Eq. (5), *DTAX* is estimated with the residual term ε . The model of Frank et al. (2009) is based on the idea that the construction of tax shelters often leads to the presence of permanent BTD. Accordingly, the development of their model is intended to exclude the effects of tax planning resulted from temporary differences. In addition, permanent BTD may reflect items not considered as related to aggressive

tax reporting such as changes in the tax cushions, changes in valuation allowance, goodwill and other intangible assets or tax credits. Hence, *DTAX* is estimated by regressing permanent BTD on items known to induce non-discretionary permanent differences and statutory adjustments that are likely unrelated to tax aggressiveness, where the resultant residuals remove the effects of determinants unrelated to tax aggressiveness and thus they are supposed to capture the intentional tax aggressiveness or the discretionary portion of permanent BTD.

Similarly, Desai and Dharmapala (2006) develop a model as Eq. (6) to measure discretionary total BTD, which is intended to capture the portion of total BTD that is most likely to represent tax aggressiveness, where the residual term ε represents discretionary total BTD. Specifically, the first step of their model is to calculate total BTD based on Manzon and Plesko (2002) and the second step is regressing total BTD on total accruals.

$$\text{Total BTD} = \beta * \text{Total accruals} + \text{Firm fixed effects} + \varepsilon \quad (6)$$

The behind logic for Eq. (6) is that total BTD can be attributable to earnings management and tax avoidance. To the extent that total accruals capture the effects of earnings management, the residual from the regression represent the portion of total BTD that cannot be explained by earnings management and thereby it can represent the effects of tax avoidance. Econometrically speaking, because earnings management is reflected on accruals, the control for total accruals removes the effects of earnings management from total BTD, which leads residuals to capture the remaining effects of total BTD. In this regard, discretionary BTD estimated from Eq. (6) represents the part of total BTD that can be attributable to tax avoidance.

The final measure of book-tax differences is developed by Wilson (2009) who estimates BTD by removing the effects of tax sheltering, where the ultimate aim is determining BTD of tax shelter firms and non-shelter ones. Using a sample of firms that were disclosed to engage in tax shelter by the US Treasury or by the Press, his approach first determines the tax savings from the notes of these firms' financial statements and then determines the tax benefits by grossing up the identified tax savings with applicable statutory income tax rate. His measure of book-tax differences is obtained by removing those tax benefits from total BTD.

It is noteworthy that all measures of book-tax differences require the estimate of taxable income as an input so the measurement errors from estimated taxable income are a common concern underlying all measures of book-tax differences. Thus, it deserves further discussions about the problems of estimating taxable income with Eq. (2).

Specifically, using current tax expenses to infer taxable income is a common approach employed by numerous prior studies (e.g., Gleason and Mills 2002; Lev and Nissim 2004). The underlying logic behind this approach is that since current tax expenses contain the taxes levied on the taxable income of current year, an estimate of taxable income can be inferred by dividing current tax expenses by the tax rate. This is particularly the case because although taxable income is unobservable, current tax expenses are usually disclosed in the notes of financial statements.

However, this approach leads to a biased estimate of taxable income for a number of reasons. First, from the perspective of income statement presentation, tax expense and taxable income do not exactly match because tax expense reflects only items regarding profit and loss from continuing operations and it excludes taxes related to other comprehensive income or taxes related to equity and discontinued operations. By contrast, tax return does not present similar partition of these items. Because current tax expense is one of the two components (the other is deferred tax expense) constructing tax expense, the mismatch of presentations between income statement and tax return naturally induces measurement error to estimating taxable income from current tax expenses (Kvaal and Nobes 2012).

Second, this approach holds only with a single tax jurisdiction (Hanlon 2003). For a multinational company that is taxed by different jurisdictions, it is necessary to separately estimate domestic and foreign current tax expenses and grossing up them with domestic and foreign tax rates respectively. However, the information disclosed in financial statements is not always sufficient to enable this approach as the disclosure of foreign tax expenses is usually absent. This is particularly troublesome if a company has operations over several countries so that its foreign tax expenses are an aggregation of multiple tax rates across different jurisdictions. Consequently, for a taxable entity with operations across several jurisdictions, even manually collected data from tax disclosures may not ensure an accurate estimate of taxable income. Relatedly, special tax regimes from such as extractive industries may confound the relation presented in Eq. (2), while this suggests that Eq. (2) only holds when current tax expenses is a function of statutory tax rate.

Third, taxation is asymmetric in that governments only tax profits but do not share losses, while this feature precludes negative taxes. Therefore, for a negative taxable income, current tax expenses should be zero and the relation in Eq. (2) will not hold. As suggested by Atwood et al. (2010), a possible solution to address this issue is to exclude all sample firms with negative pre-tax book income or negative current tax expenses, but this solution unavoidably omits a large proportion of sample and it may thus not only confound the reliability of empirical models but also affects the interpretation of the results. A related issue is that net operating loss carryforwards and carrybacks may lead to negative current tax expenses, while this complicates the application of Eq. (2) because offsetting tax losses to taxable income makes current tax expenses deviate from true taxable income. As suggested by Manzon and Plesko (2002), a possible solution is to subtract the changes in the balances of tax loss carryforwards from Eq. (2). However, a primary limitation of this approach is data availability for loss carryforwards since their disclosures are not always mandatory and even if mandatory (e.g., as required by IFRS or US GAAP), the information disclosed is typically not standardized and this enhances the difficulty in collecting this information.

Fourth, the difference in the consolidation rules between financial and tax reporting may also induce noises to using current tax expenses as a proxy for taxable income. This is exactly the case for the US environment (Manzon and Plesko 2002) and even more so for comparisons across countries due to the substantial differences in consolidation rules across countries.

Finally, adjustments of prior years' taxable income or reverses of tax cushions for contingent tax liabilities make current tax expenses deviate from the function of current year's taxable income, which further complicates the application of Eq. (1).

In summary, although the relation presented in Eq. (1) is straightforward, it is subject to a number of flaws. When applying book-tax differences in the empirical tests, we need to scale them by such as total assets or market value of equity. The estimated book-tax differences may have positive or negative values.

104.3 Review of Literature Related to Book-Tax Differences

Prior literature provides ample evidence supporting that both income tax expenses and reported book-tax differences contain useful information to the market, where such information derives from the idea that taxable income is an alternative performance measure or a benchmark measure relative to financial accounting income. To date, the evidence suggests that book-tax differences contain information relevant to evaluate potential earnings management or tax avoidance behaviors, where book-tax difference measures are specifically designated to investigate aggressiveness in either or both financial and tax reporting. The results of this stream of literature are applicable to both accounting and finance studies as the information role of taxable income is a common topic in both studies, while such information effect is distinguished from the effect of tax avoidance. Because this research requires knowledge in both tax rules and accounting standards, it is often conducted by tax researchers.

Specifically, the focus of prior literature is on the link between book-tax differences and aggressive reporting practices, where higher book-tax differences are not only associated with more earnings management or lower financial reporting quality (e.g., Badertscher et al. 2009; Frank and Rego 2006; Hanlon 2005; Phillips et al. 2003, 2004; Tang and Firth 2011) but also associated with more tax avoidance (e.g., Desai 2003; Frank et al. 2009; Mills 1998; Tang and Firth 2011; Wilson 2009).

The idea that book-tax differences contain the information about earnings quality is well recognized (e.g., Penman 2001). The behind reasoning for this idea is that accounting accruals allow more discretion than do tax rules and thereby temporary book-tax differences are informative about the discretion embedded in non-tax accounting accruals such as bad debt expenses, warranty expenses or deferred revenues. This reasoning is not applicable to permanent book-tax differences because they are not driven by the process in recognizing accounting accruals. It is also suspected that firms reporting book income higher than taxable income are likely to manipulate book income upward, where such suspicion arises from the Enron and WorldCom scandals. However, it is difficult to judge manipulation based on the sign of book-tax differences because while positive book-tax differences signal upward earnings management, negative book-tax differences (i.e., book income is lower than taxable income) could also lead to earnings quality concerns if firms take a "big bath" or use "cookie-jar" reserves, given that related write-offs or expense accruals are often not deductible for tax purposes.

To examine the information contained in book-tax differences for earnings quality, prior studies have adopted various empirical designs and the overall results are quite consistent, where book-tax differences are informative about the quality of financial accounting earnings. For example, Joos et al. (2000) find that firms reporting large book-tax differences (in absolute value) have weaker earnings-return relations. Phillips et al. (2003) find that firm-year observations with a small earnings increase tend to have larger deferred tax expenses, while this suggests that deferred tax expenses (or temporary book-tax differences) contain information about pre-tax earnings management (also refer to Phillips et al. 2004). Hanlon (2005) presents evidence that book-tax differences are informative about the persistence of pre-tax earnings and pre-tax accruals, while the market understands this information implication. Lev and Nissim (2004) document a positive relation between future earnings growth and the ranked ratio of taxable income over book income and this ratio can predict stock returns, suggesting that equity investors may have difficulty in processing the information contained in book-tax differences from a pricing perspective. Based on the perspective of credit ratings agencies, Ayers et al. (2010) find that large changes in book-tax differences seem to be associated with more negative revisions in credit ratings.

Extending this stream of literature, Chi et al. (2014) provide evidence consistent with market mispricing of book-tax differences. Weber (2009) finds that analysts as sophisticated financial statement users do not fully understand the information contained in book-tax differences when making earnings forecasts. Dhaliwal et al. (2017) find a positive association between the variation in estimated taxable income and cost of equity capital. Hanlon et al. (2012) and Kuo and Lee (2016) find that larger book-tax differences are associated with higher audit fees, suggesting that auditors also use the information of book-tax differences to plan their works. By separating total book-tax differences into temporary and permanent portions, Moore and Xu (2018) report that temporary book-tax differences, either levels or variability, are consistently positively associated with costs of private debt, whereas permanent book-tax differences are not.

On the other hand, there is also evidence suggesting that book-tax differences contain information about tax avoidance behaviors. For example, Mills (1998) reports that firms with large book-tax differences are more likely to be audited by the IRS and thereby have larger audit adjustments. Wilson (2009) finds that firms accused of engaging in tax shelter tend to have larger book-tax differences. Further, recent studies provide mixed evidence on the effects of borrowers' book-tax differences on private loan costs. Hasan et al. (2014) find that tax avoidance measured with book-tax differences is positively associated with covenant requirements and interest rate spreads, particularly for firms with higher discretionary accruals. By contrast, Kim et al. (2010) find a negative association between aggressive tax avoidance and private loan costs. Desai (2003) argues that the increasing divergence between book and tax income is evidence of aggressive tax reporting. However, Shevlin (2002) notes that it must be cautious by drawing inferences about the levels or trends of tax avoidance based on book-tax differences.

The above studies suggest that book-tax differences capture at least some element of tax avoidance. Of course, book-tax differences by definition only capture non-conforming tax avoidance, while this limits using them as a measure to compare tax avoidance activities across firms with different levels of importance on financial accounting earnings.

104.4 The Concept and Empirical Measures of Book-Tax Conformity

It has been an ongoing debate in the literature and among policymakers about whether book and tax income measures should conform to one common measure (i.e., increase the degree of book-tax conformity). This debate arises because there is a growing divergence between book and taxable incomes (Mills et al. 2002; Desai 2003; Hanlon and Shevlin 2005), while such divergence raises concerns about misleading financial or aggressive tax reporting because it signals that firms may increasingly overstate book income or understate tax liability, leading to more firm-level reported book-tax differences as elaborated in previous sections.

A potential solution to mitigate these concerns is increasing the conformity between book and taxable incomes because increased book-tax conformity enhances the cost for firms to simultaneously manage taxable income downward and book income upward (Yin 2001; Desai 2005). Accordingly, book-tax conformity has emerged in policy circles as a means of reducing the perceived ability of firms to manage earnings and evade taxes.

Proponents of increased book-tax conformity (e.g., Yin 2001; Desai 2003, 2005; Whitaker 2005; Shaviro 2009) argue that a higher degree of book-tax conformity constrains managers' discretion and incentives to engage in aggressive financial and tax reporting because increased book-tax conformity forces firms to trade off the desire to report high book income numbers to shareholders and the desire to report low income numbers to tax authorities, resulting in improved financial reporting quality and lesser tax avoidance. In addition, increased book-tax conformity also leads to lower compliance costs. For example, Kuo and Lee (2016) find that a higher degree of book-tax conformity is associated with lower fees that firms pay for their auditors.

However, opponents (Hanlon et al. 2005, 2008; Hanlon and Shevlin 2005; McClelland and Mills 2007) question the claimed benefits from such forced trade-off because the implementation of book-tax conformity would not be as simple as the proponents argue and it is also uncertain about the unintended consequences due to behavioral responses on the part of firms. More importantly, increased book-tax conformity incurs a substantial cost – a decrease in the information content contained in accounting earnings numbers – because the objectives of accounting and tax reporting are divergent and enforced conformity will lead accounting earnings numbers to deviate from its objective of providing useful information to guiding investment decisions.

We then review the empirical measures of book-tax conformity. Before proceeding, we first clarify that book-tax conformity pertains to the extent to which book and taxable incomes are conformed so it represents a country-level measure, which is in contrast to firm-level book-tax difference that represents a gap between a firm's accounting income and taxable income that are reported on financial statements and tax returns respectively. Prior studies exploring the effects of book-tax conformity mostly use a cross-country sample because this research design can exploit the variations of book-tax conformity across countries. This is a natural design since book-tax conformity is a country-level concept with the levels varying across jurisdictions (Atwood et al. 2012).

When measuring book-tax conformity, early studies (Ali and Hwang 2000; Guenther and Young 2000; Hung 2001; Burgstahler et al. 2006) rely on a dummy variable that simply categorizes the contemplated countries into high and low conformity. This binary categorization is derived based on the similarity between tax laws and accounting standards in measuring income, which represents the perceived extent that accounting provisions of the tax law conform to financial accounting standards (Watrin et al. 2014). Hence, this binary measure is rather subjective (Tang 2015) and it also raises a serious econometric issue from correlated omitted country-level institutional factors.

In contrast to this subjective binary measure, Atwood et al. (2010) develop a model to estimate the level of required book-tax conformity across country-year, which measures "the flexibility that a firm has to report taxable income that is different from pre-tax book income." Their model is presented as following Eq. (7).

$$CTE = \alpha + \beta_1 * PTBI + \beta_2 * ForPTBI + \beta_3 * DIV + \varepsilon \quad (7)$$

where *CTE* is current tax expense, including both domestic and foreign current tax expenses; *PTBI* is pre-tax book income; *ForPTBI* is the estimated foreign pre-tax book income (foreign tax expense/total tax expense $\times$ *PTBI*); *DIV* is dividends; *CTE*, *PTBI*, *ForPTBI*, and *DIV* are scaled by total assets.

The book-tax conformity measure is calculated as the scaled ranking of the root mean squared errors (RMSEs) obtained from country-year estimates of Eq. (7). Because RMSE in Eq. (7) represents the standard error of *CTE* for a given level of *PTBI* not explained by the model, it provides an indication of the overall amount of discretion that managers have to report different book income and taxable income. Consequently, a higher RMSE corresponds to lower book-tax conformity.

Atwood et al.'s (2010) measure is widely used in the literature. However, a potential concern for their measure is that its estimate is based on the information retrieved from consolidated financial statements and this may confound the validity of using current tax expenses to represent taxable income.

To address the issues due to consolidated financial statements, Watrin et al. (2014) develop a book-tax conformity measure based on the relation between single financial statements and tax accounts, where they justify this approach by claiming that the determination of taxable income is according to single financial statements in European countries featured with high book-tax conformity. Watrin et al. derive their

measure by first calculating permanent BTD at the single entity level and then assigning a rank to each country-year based on the country-year mean of the absolute values of permanent BTD, such that countries with higher rankings have lower aggregated BTDs and thereby have higher book-tax conformity. .

Based on similar approach as Atwood et al. (2010), Tang (2015) develops another measure by defining required book-tax conformity as the variation in total BTD “that cannot be explained by opportunistic book and tax reporting for firms in a given country and year.” Specifically, Tang’s measure is targeted at disentangling total BTD into the portion arising from the innate differences between accounting and tax rules and the portion arising from opportunistic book and tax reporting. To this end, she first regresses total BTD on the proxies for earnings management and tax avoidance and their interaction term, where earnings management is proxied by discretionary accruals and tax avoidance is proxied by the difference between the statutory tax rate and the effective tax rate. She then uses the RMSEs from the regression to measure the extent to which book and taxable incomes diverge due to the innate differences between accounting and tax rules, thereby reflecting the degree of required book-tax conformity.

The measures developed by Atwood et al. (2010), Watrin et al. (2014), and Tang (2015) are similar in that all of them use pre-tax book income and taxable income to gauge the degree of book-tax conformity. However, this raises a concern that while a higher required book-tax conformity leads firms to report lesser book-tax differences, the opposite is not necessarily true and we cannot conclude that there is a complete book-tax conformity just because we observe that pre-tax income equals taxable income. Even in an environment where accounting and tax rules are quite divergent and the degree of book-tax conformity is low, the different components of income may offset each other so that pre-tax income coincidentally equals to taxable income as if these two incomes were conformed. Nevertheless, despite their imperfection these measures are still important to the literature as they provide a numerical measure that facilitates subsequent studies to investigate the effects of book-tax conformity.

Indeed, although there are many divergences between accounting and tax rules in measuring income, these two systems are aligned at some level. While these two income amounts often diverge to a large extent in a dual reporting system, there is still basic alignment in the fundamental accounts of such as sales or cost of goods sold. Consistent with this notion, there is a stream of literature exploring whether tax cuts drive earnings management for the purpose of saving taxes, where firms shift income from high- to low-taxed years and the evidence supports significant shifting in financial accounting earnings (Scholes et al. 1992; Guenther 1994; Maydew 1997).

104.5 Review of Literature Related to Book-Tax Conformity

As argued by Hanlon and Heitzman (2010), it is difficult to examine what would happen if book-tax conformity were adopted because an idea research design requires a switch from a book-tax conformity system to a non-conformed system

(or vice versa). Absent such as natural experiment, most of the research has primarily focused on a testable item: whether increased book-tax conformity decreases the information content of accounting earnings numbers. Despite the weakness of research designs, most prior studies document a substantial loss of information in accounting earnings.

Specifically, while accounting standards allow managerial discretion that could decrease the informativeness of earnings due to managers' opportunistic reporting incentives, it is possible that managers use the discretion to convey private information to the market rather than use it to mislead investors (e.g., Dechow 1994; Subramanyam 1996; Beaver and Engel 1996). That is, managers use at least some of their discretion on the recognition of accounting numbers to signal value relevant information to market participants. Consequently, if managers were required to report earnings based on tax rules as in an environment with high book-tax conformity, they would lose at least some of their ability to signal value relevant information through reporting accounting numbers. Furthermore, increased book-tax conformity would increase firms' incentives to report lower accounting earnings numbers to avoid taxes (e.g., the use of LIFO for inventory accounting even though it lowers reported book income), where this adds bias to the earnings numbers as a measure of economic income.

Consistent with this line of reasoning, Hanlon et al. (2005) provide evidence that taxable income estimated based on accounting rules in the U.S. is about 50% less informative to equity investors than book income, while this suggests that the loss of information to investors is likely significant if book income were recognized on the basis of tax rules. Using a more powerful research design, Hanlon et al. (2008) explores a sample of US firms required to convert from cash-basis tax accounting to accrual-basis tax accounting with no change in their financial reporting methods, where these firms used accrual basis accounting before and after the tax law change for book purposes. They find that relative to control firms that always used the accrual basis for tax accounting, converting firms have less informative earnings after conversion, while this finding suggests that requiring firms to pay taxes on book income leads to information loss on earnings. They further argue that "noise in earnings could increase with conformity because of managers' inability (due to the tax cost of doing so) to convey private information useful to external stakeholders through earnings. If managers are constrained in relaying this private information via earnings, noise in earnings will increase, reducing the ERC (earnings response coefficient). Conversely, if book-tax conformity causes firms to report more accurately, as its proponents suggest, then noise will decrease and the ERC will increase. Our empirical results are consistent with increased book-tax conformity increasing the amount of noise in earnings, reducing its informativeness."

In addition to explore US firms, another stream of literature uses an international setting to explore the effects of book-tax conformity on earnings informativeness. By comparing the effects of country-specific factors on earnings informativeness, Ali and Hwang (2000) find that earnings are less informative in countries with higher book-tax conformity. Guenther and Young (2000) find that earnings are more closely linked to economic activity in countries such as the USA or the UK because in these

countries accounting standards are more independent from the tax standards, allowing managers more discretion to convey private information and thereby leading earnings to better reflect economic performance. Atwood et al. (2010) explore whether increased book-tax conformity affects the persistence of earnings and the ability of earnings to predict future cash flows. They find that both earnings persistence and the ability of earnings to predict future cash flows are low when book-tax conformity is high, where their findings suggest that increased book-tax conformity likely reduces earnings quality.

Building on the insight that book-tax conformity induces information loss of earnings, Blaylock et al. (2017) argue that such information loss is more for equity investors than for debt investors and they further document that increased book-tax conformity leads firms to rely more on debt capitals, suggesting that book-tax conformity is also a finance topic as it affects capital structure. Atwood et al. (2012) report that increased book-tax conformity reduces the incentives for firms to engage in tax avoidance.

Some studies explore how book-tax conformity affects earnings management. Using an international setting, Leuz et al. (2003) employ a dummy variable indicating whether a country has high or low book-tax conformity and find an insignificant association between book-tax conformity and earnings management. Burgstahler et al. (2006) use a similar setting and they also find no significant association between book-tax conformity and earnings management for public firms, while this association is positive for private firms. Using the book-tax conformity measure of Atwood et al. (2010) and similar earnings management measures as Leuz et al. (2003), Burgstahler et al. (2006), and Blaylock et al. (2015) document a robust positive association between book-tax conformity and earnings management in an international setting. However, Tang (2015) uses her book-tax conformity measure and finds that a higher level of book-tax conformity is associated with lower earnings management. The results of these studies suggest that there is still no consensus about whether increased book-tax conformity can deter earnings management.

Overall, prior evidence suggests that increasing book-tax conformity decreases earnings informativeness because it reduces the ability of managers to use their discretion to signal value relevant information given that tax incentives confound managers' intent to recognize income in a timely manner and induce them to report a book income number targeted at tax planning rather than measuring economic performance. However, as Hanlon and Heitzman (2010) point out, we know very little about how book-tax conformity affects other corporate decisions.

104.6 Conclusion

Our entry discusses the concept and empirical measures of book-tax differences. Although there are a variety of book-tax difference measures, all of them are based on a key element: estimated taxable income. Because tax return data are usually unavailable, taxable income must be estimated and this raises concerns about the measurement errors as well as the validity of the resultant book-tax

difference measures. We also review the literature exploring the effects of book-tax differences and the literature reviewed consistently suggests that book-tax differences contain useful information to market participants, where this information derives from the idea that taxable income is an alternative performance measure relative to book income. In this regard, prior studies suggest that book-tax differences contain information relevant to evaluate potential earnings management or tax avoidance behaviors. In addition, we also discuss the concept and empirical measures of book-tax conformity, given that increasing the degree of book income aligning to taxable income is a usually claimed means to curb the growing trend of book-tax differences reported by firms as well as the behind aggressive financial or tax reporting practices. The literature we reviewed about book-tax conformity suggests that increasing book-tax conformity will decrease the informativeness of accounting earnings numbers. Given that there is still debated about whether increasing book-tax conformity can deter earnings management as its proponents claimed, the information loss induced by book-tax conformity might incur substantial costs that more than offset the benefits of conformity from such as reducing compliance costs. Overall, as Hanlon and Heitzman (2010) suggest, we need more evidence to better understand the influences of increasing book-tax conformity on corporate decisions.

Evaluating Portfolio Risk Management: A New Evidence from DCC Models and Wavelet Approach

105

Rabeh Khalfaoui, Aviral Kumar Tiwari, and Xuan Vinh VO

Abstract

We analyzed the volatility dynamics of three developed markets (the UK, USA, and Japan), during the period 2003–2011, by comparing the performance of several multivariate volatility models, namely, Constant Conditional Correlation (CCC), Dynamic Conditional Correlation (DCC), and consistent DCC (cDCC) models. To evaluate the performance of models, we used four statistical loss functions on the daily Value-at-Risk (VaR) estimates of a diversified portfolio in three stock indices: FTSE 100, S&P 500, and Nikkei 225. We based on one-day ahead conditional variance forecasts. To assess the performance of the abovementioned models and to measure risks over different timescales, we proposed a wavelet-based approach, which decomposes a given time series on different time horizons. Wavelet multiresolution analysis and multivariate conditional volatility models are combined for volatility forecasting to measure the co-movement between stock market returns and to estimate daily VaR in the time-frequency space. Empirical results show that the asymmetric cDCC model of (Aielli, G. P. Consistent estimation of large scale dynamic conditional correlations, working paper n.47, University of Messina, Department of Economics,

Statistics, Mathematics and Sociology, 2008) is the most preferable according to statistical loss functions under raw data. The results also suggest that wavelet-based models increase predictive performance of financial forecasting in low scales according to number of violations and failure probabilities for VaR models.

105.1 Introduction

Financial managers and traders are mostly interested in measuring market risk. The most widely used measure of risk management is the Value-at-Risk (VaR), which was introduced by Jorion (1994). Forecasting VaR is based on the volatility models. The well-known volatility model is the generalized autoregressive conditional heteroskedasticity (GARCH) model of Engle (1982) and Bollerslev (1986). The success of this model has subsequently led to a family of univariate and multivariate GARCH models, which can capture the different behavior in financial returns. The development of this family of models has led to the development of conditional VaR forecasts.

The literature on multivariate GARCH models is large and expanding. Engle and Kroner (1995) defined a general class of multivariate GARCH (MGARCH) models. The popular ones are diagonal VEC model of Bollerslev et al. (1988), the BEKK model of Engle and Kroner (1995). While popular, these models have limitations. See Bauwens et al. (2006) for more details. In particular, diagonal VEC lacks correlation between the variance terms, BEKK can have poorly behaved likelihood function (making estimation difficult, especially for models with more than two variables). VEC has a large number of free parameters (which make it impractical for models with more than two variables). To deal with the curse of the dimensionality, Engle (2002) proposed the dynamic conditional correlations (DCC) model, which generalizes the specification of Bollerslev (1990) by assuming a time variation of correlation matrix. Tse and Tsui (2002) defined a multivariate GARCH model, which includes time-varying correlations and yet satisfies the positive-definite condition. Ling and McAleer (2003), McAleer et al. (2009), and Caporin and McAleer (2009, 2010) proposed another family of multivariate GARCH models, which assume constant conditional correlations, and do not suffer from the problem of dimensionality, by comparison with the VEC and BEKK models. The utility of these models is that modeling conditional variances allow large shocks to one variable to affect the variances of the other variables. However, accurate prediction of the stock market volatility is still a great challenge and this phenomenon has received further attention by scholars, for instance, some recent studies such as those

of Tang et al. (2021), Akkoc and Cevcir (2019), Allard et al. (2020), Hou et al. (2019), Khalfaoui et al. (2019), and Ashfaq et al. (2020), among others. The abovementioned scholars have been employed in their research studies different volatility models, including VAR-DCC-GARCH, DCC-GARCH, DCC-MIDAS, HAR, SVAR-DCC-GARCH. Based on the HAR framework, Tang et al. (2021) conclude that oil future intraday information supports to increase the forecasting performance of the US stock market volatility. Akkoc and Cevcir (2019), highlighted a time-varying co-movement and volatility spillovers from oil and gold markets to Turkish stock market.

Another important topic in the financial econometrics is the asymmetric behavior of conditional variances. The basic idea is that negative shocks have a different impact on the conditional variance evolution than do positive ones of similar magnitude. Cappiello et al. (2006), Aielli (2008), and Palandri (2009) extended the DCC model of Engle (2002) to an asymmetric DCC model, which is a generalization of the DCC model (authors develop a model capable of allowing for conditional asymmetries not only in volatilities but also in correlations). Authors used several asymmetric versions of the DCC model. In our entry, we based on a version that allows asymmetry in conditional variance. This phenomenon was raised by Nelson (1991) in introducing the Exponential GARCH (EGARCH) model, and was also considered by Glosten et al. (1993) (GJR-GARCH models), Rabemananjara and Zakoian (1993), and Zakoian (1994) (Threshold GARCH models) for the univariate case. More recently, several empirical studies based on symmetric and asymmetric multivariate GARCH models have been employed in the area of finance. For instance, Cappiello et al. (2006) used the asymmetric generalized-DCC (AG-DCC) specification to investigate asymmetries in conditional variances and correlation dynamics of three groups of continents (Europe, Australia, and North America). They provide evidence that equity returns show strong evidence of asymmetries in conditional volatility, while little is found for bond returns. Chiang et al. (2007) applied a DCC model to nine Asian stocks and confirm a contagion effect during the Asian crisis. Ho et al. (2009) applied various multivariate GARCH models to investigate the evidence of asymmetry and time-varying conditional correlations between five sectors of Industrial Production of the USA. They provide also, strong evidence of asymmetric conditional volatility in all sectors and some support of time-varying correlations in various sectoral pairs. Buttner and Hayo (2011) used a bivariate DCC model to extract dynamic conditional correlations between European stock markets. Chang et al. (2011) employed several multivariate GARCH models (CCC, DCC, VARMA-GARCH and VARMA-AGARCH) to model conditional volatility in the returns of rubber spot and futures in major rubber futures and rubber spot Asian markets, in order to investigate volatility transmissions across these markets. Their results provide the presence of volatility spillovers and asymmetric effects of positive and negative return shocks on conditional volatility. Kenourgios et al. (2011) applied the AG-DCC model and a multivariate regime-switching Gaussian copula model to capture nonlinear correlation dynamics in four emerging equity markets (Brazil, Russia, India, and China) and two developed markets (the USA and UK). Arouri et al. (2011)) employed a VAR-GARCH

approach to investigate the return linkage and volatility transmission between oil and stock markets in Gulf Cooperation Council countries. Lahrech and Sylwester (2011) used DCC multivariate GARCH models to examine the dynamic linkage between the USA and Latin American stock markets. Their results show an increase in the degree of co-movement between Latin American equity markets and US equity ones.

In this study, we employ three multivariate GARCH models, such as the CCC model of Bollerslev (1990), the DCC model of Engle (2002), and the cDCC model of Aielli (2008). These models impose a useful structure on the many possible model parameters. However, parameters of the model can easily be estimated and the model can be evaluated and used in a straightforward way. Our empirical methodology follows a two-step approach. The first step applies these dynamic conditional correlation models to model conditional volatility in the returns of three developed stock markets (the UK, USA, and Japan stock markets), in order to examine the evidence of time-varying conditional variances and correlations between stock markets. Moreover, in order to show the asymmetric effects of positive and negative return shocks on conditional volatility the EGARCH and GJR-GARCH models of Nelson (1991) and Glosten et al. (1993), respectively, were employed for modeling univariate conditional volatility. In the second step, we reexamine the dynamic conditional correlation analysis among the three major developed stock markets through a novel approach, wavelet analysis. This technique is a very promising tool as it is possible to capture the time and frequency varying features of co-movement within a unified framework, which represents a refinement to previous approaches. This wavelet-based analysis takes into account the distinction between the short- and long-term investor. From a portfolio diversification view, there exist a kind of investors who are more interested in the co-movement of stock returns at higher frequencies (lower scales), that is, short-term fluctuations, and also, there exist a kind of investors whose focus is on the relationship at lower frequencies (higher scales), that is, long-term fluctuations. The study of the co-movement of stock market returns, i.e., dynamics of variances and correlations, across scales is crucial for risk assessment of a portfolio. In terms of risk management, a higher co-movement (higher covariances) among the assets of a given portfolio implies lower gains. According to investors or traders, evaluating the co-movement of assets is a great importance to best assess the risk of a portfolio. Several applications of wavelet studying the co-movement of stock indices have been applied, including Khalfaoui et al. (2015), Ko and Lee (2015), Sharkasi et al. (2005), Rua and Nunes (2009), Rua (2010), and Masih et al. (2010). In a more recent study, Tiwari et al. (2013, 2016), Mensi et al. (2016), Albulescu et al. (2017), Das et al. (2018), Nasreen et al. (2020), Sharif et al. (2020), Huang and Huang (2020), Choi (2020), Das and Kumar (2018), Zhang et al. (2017), Uddin et al. (2019), and Zaremba et al. (2019) have used wavelet tools to analyze the dependence between several stock markets. Sharif et al. (2020) had examined the time-varying dependence structure between oil price volatility shocks, stock market price, the novel Covid-19 pandemic, the geopolitical risk, and the economic policy uncertainty in the USA using the wavelet coherence analysis and the wavelet-based Granger causality tests. Their results uncover that the effect of the Covid-19 crisis on the geopolitical risk is

significantly higher than on the economic policy uncertainty. Further, the results document that the US stock markets initially reacted to oil price shock rather than Covid-19 events occurring from Wuhan and other regions. Huang and Huang (2020) studied the dynamics of the co-movement between China's crude oil futures and international crude oil futures (WTI and Brent) at several timescales. The authors had employed the wavelet coherence and phase relation techniques to discuss the intensity of the co-movement and the direction of the co-movement between markets as well as the lead-lag relationship of future oil prices changes. According to their methods, they found heterogeneous co-movement between China's crude oil future markets and international crude oil future markets over wavelet scales. Furthermore, the authors documented that the strength of the co-movement between future markets is weak and the direction of the co-movement is unstable across time and frequency. Choi (2020) applied the continuous wavelet analysis to revisit the impact of the economic uncertainty due to Covid-19 pandemic on the volatility of S&P 500 index. The results show that the S&P 500 volatility index was influenced by the economic policy uncertainty in terms of Covid-19 crisis.

In the same vein, Das and Kumar (2018) have extended the research of Ko and Lee (2015) by employing the multiple and partial wavelet coherence techniques to investigate the nexus between international economic policy uncertainty and the stock market prices in 11 developed economies and 6 emerging economies. Their major results revealed that the stock markets in the emerging countries were more sensitive to domestic economic policy uncertainty. In the forecasting perspective, Zhang et al. (2017) and Uddin et al. (2019) have analyzed the predictability of different time series using wavelet approaches. Overall, the results of the abovementioned scholars were crucial and shed new light upon the forecastability performance.

In this chapter, we also investigate the selection of the multivariate GARCH models used in the two approaches (with and without wavelet analysis) to identify which model has the best out-of-sample forecasting performance. The assessment of the forecast performance of these models is based on out-of-sample one-day ahead conditional matrix forecasts. However, to measure model performance we used four statistical loss functions. Hansen et al. (2003), Hansen and Lunde (2005), Becker and Clements (2008), and others, showed that evaluation of univariate volatility forecast is well understood, while for an applied point of view there are no clear guidelines available on model evaluation and selection in multivariate setting (see Laurent et al. 2011).

The empirical evidence showed that the conditional variances and correlations of the UK, USA, and Japan stock market returns were dynamic and the three markets were highly correlated. We also showed that the cDCC model of Aielli (2008) is better than the CCC and DCC models based on one-day ahead out-of-sample forecasts. With regard to wavelet-based multivariate conditional volatility approach, our findings suggested a multi-scale behavior of the three markets under study, which decompose the total spillover into three sub-spillovers and decomposes the market risk measured by VaR into wavelet VaR (WVaR) estimates. In addition, this new approach helps traders and investors to reduce risk management on their investing time horizons.

The purpose of the chapter is four-fold. First, we estimated multivariate conditional volatility for stock market returns using several recent models of multivariate conditional volatility. Second, we investigated the importance of volatility spillovers on the conditional variance across the three developed markets. Third, we focused on the forecasting performance of the multivariate conditional volatility models under study for the last 250 days of the data set. Forecast comparison is based on four different loss functions including the mean squared error, the mean absolute error, the mean absolute percentage error, and the logarithm loss error. Fourth, we proposed a wavelet-based multi-resolution analysis in order to combine between traditional multivariate conditional volatility models and wavelet decomposition. The combination of wavelet decomposition and dynamic conditional correlation models were introduced to analyze the co-movements and volatility spillovers between three developed markets on multi-scale framework, based on behavior of investors. Finally, we compared the performance of wavelet-based multivariate conditional volatility model against the traditional one for one-day ahead forecast.

The structure of the chapter is organized as follows: Sect. 105.2 presents the data used for the empirical analysis and the multivariate conditional volatility methodology. Section 105.3 reports the empirical results under raw data. Wavelet analysis is discussed in Sect. 105.4. Finally, concluding remarks are stated in Sect. 105.5.

105.2 Methodology and Empirical Specifications

105.2.1 Data

Our data on stock market prices consist of the S&P 500, FTSE 100, and NIKKEI 225 composite indices for the USA, UK, and Japan. We employed daily data over the period from 01 January 2003 to 04 February 2011. Indices are obtained from DataStream. We use daily data in order to retain a high number of observations to adequately capture the rapidity and intensity of the dynamic interactions between markets.

Returns of market i (index i) at time t are computed as $r_{i,t} = \log(P_{i,t}/P_{i,t-1}) \times 100$, where $P_{i,t}$ and $P_{i,t-1}$ are the closing prices for day t and $t-1$, respectively. The times series plots are displayed in Fig. 1.

105.2.2 Descriptive Statistics

The summary statistics of the data are given in Table 1. In panel A (Table 1), for each return series, the mean value is close to zero. For each return series the standard deviation is larger than the mean value. Each return series displays a small amount of skewness and large amount of kurtosis and the returns are not normally distributed.

Fig. 1 Time series plots of FTSE 100, S&P 500, and NIKKEI 225 stock market indices. We plot daily level of the stock market indices (left panel) and corresponding returns (right panel) in the period covering 01 January 2003 to 04 February 2011

In panel B (Table 1), unconditional correlation coefficients in stock market index returns indicate strong pairwise correlations. The correlation between S&P 500 and FTSE 100 is positive and larger than the correlation between NIKKEI 225 and FTSE 100. This could be due to the high trade share between the two markets.

The results of the unit root tests for all sample of level prices (in logs) and returns in each market are summarized in Table 2. The Augmented Dickey-Fuller (ADF) and Phillips-Perron (PP) tests are used to explore the existence of unit roots in individual series. The results show that all returns are stationary.

Table 1 Descriptive statistics

Panel A: Summary statistics							
	Mean	Max	Min	Std. Dev.	Skewness	Kurtosis	Jarque-Bera
FTSE 100	0.0199	9.384	−9.265	1.252	−0.0914	9.019	7180.19*
S&P 500	0.0187	10.957	−9.469	1.314	−0.256	11.410	11,508.39*
NIKKEI 225	0.0097	13.234	−12.111	1.544	−0.466	8.889	7048.35*

Notes: Entries in bold indicate that the null hypothesis is rejected at 1% significance level

105.2.3 Model Specifications

The econometric specification used in our study has two components. To model the stock market return we used a vector autoregression (VAR). To model the conditional variance, we used a multivariate GARCH model.

A VAR of order p , where the order p represents the number of lags that includes N variables can be written as the following form:

$$Y_t = \Phi_0 + \sum_{i=1}^p \Phi_i Y_{t-i} + \varepsilon_t, \quad t = 1, \dots, T \tag{1}$$

where $Y_t = (Y_{1t}, \dots, Y_{Nt})'$ is a column of observations on current values of all variables in the model, Φ_i is $N \times N$ matrix of unknown coefficients, Φ_0 is a column

vector of deterministic constant terms, $\varepsilon_t = (\varepsilon_{it}, \dots, \varepsilon_{Nt})'$ is a column vector of errors. Following Brooks (2002), the main advantage of the VAR is that there is no need to specify which variables are the endogenous variables and which are the explanatory variables because in the VAR, all selected variables are treated as endogenous variables. That is, each variable depends on the lagged values of all selected variables and helps in capturing the complex dynamic properties of the data. Note that selection of appropriate lag length is crucial. If the chosen lag length is too large relative to the sample size, the degrees of freedom will be reduced and the standard errors of estimated coefficients will be large. If the chosen lag length is too small, then the selected lags in the VAR analysis may not be able to capture the dynamic properties of the data. The chosen lag length should be free of the problem of serial correlation in the residuals. Our basic VAR will have the three stationary variables, first log differences of FTSE 100, S&P 500, and NIKKEI 225 stock market prices (will be defined in empirical section).

We focused on the modeling of multivariate time-varying volatilities. The most widely used model is DCC one of Engle (2002) which captures the dynamic of time-varying conditional correlations, contrary to the benchmark CCC model (Bollerslev 1990) which retains the conditional correlation constant. The CCC specification can be presented as:

$H_t = D_t R D_t$, where, $D_t = \text{diag} \sqrt{h_{i,t}}$ is a diagonal matrix with square root of the estimated univariate GARCH variances on the diagonal. R is the time-invariant symmetric matrix of the correlation returns with $\rho_{ii} = 1$.

In CCC model, the conditional correlation coefficients are constant, but conditional variances are allowed to vary in time.

The specification of the DCC model is as follows:

$$r_t = \mu + \sum_{s=1}^p \Phi_s Y_{t-s} + \varepsilon_t, \quad t = 1, \dots, T, \quad \varepsilon_t | \Omega_{t-1} \sim N(0, H_t) \quad (2)$$

$$\varepsilon_t = (\varepsilon_{UK,t}, \varepsilon_{US,t}, \varepsilon_{JP,t})' = H_t^{1/2} z_t, \quad z_t \sim N(0, I_3) \quad (3)$$

$$H_t = E(\varepsilon_t \varepsilon_t' | \Omega_{t-1}) \quad (4)$$

where, r_t is a 3×1 vector of the stock market index return, ε_t is the error term from the mean equations of stock market indices (Eq. 1), z_t is a 3×1 vector of *i.i.d* errors, and H_t is the conditional covariance matrix. Equation 1 can be rewritten as follows:

$$\begin{bmatrix} r_{UK,t} \\ r_{US,t} \\ r_{JP,t} \end{bmatrix} = \begin{bmatrix} \mu_{UK} \\ \mu_{US} \\ \mu_{JP} \end{bmatrix} + \begin{bmatrix} \phi_{11}^s & \phi_{12}^s & \phi_{13}^s \\ \phi_{21}^s & \phi_{22}^s & \phi_{23}^s \\ \phi_{31}^s & \phi_{32}^s & \phi_{33}^s \end{bmatrix} \begin{bmatrix} r_{UK,t-s} \\ r_{US,t-s} \\ r_{JP,t-s} \end{bmatrix} + \begin{bmatrix} \varepsilon_{UK,t} \\ \varepsilon_{US,t} \\ \varepsilon_{JP,t} \end{bmatrix}$$

To represent the Engle's (2002) DCC-GARCH model for the purpose of this study, let $r_t = (r_{UK,t}, r_{US,t}, r_{JP,t})'$ be a 3×1 vector of stock market returns, such that, r_{UK} , r_{US} , and r_{JP} are the returns of FTSE 100, S&P 500, and NIKKEI 225 indices, respectively: $r_t | \Omega_{t-1} \sim N(0, H_t)$.

The DCC-GARCH specification of the covariance matrix, H_t , can be written as:

$$H_t = D_t R_t D_t \quad (5)$$

where $D_t = \text{diag}(\sqrt{h_{UK,t}}, \sqrt{h_{US,t}}, \sqrt{h_{JP,t}})$ is 3×3 diagonal matrix of time-varying standard deviation from univariate GARCH models; i.e., $h_{i,t} = \omega_i + \alpha_i \varepsilon_{i,t-1}^2 + \beta_i h_{i,t-1}$, $i = UK, US, JP$, and $R_t = \{\rho_{ij}\}$ is the time-varying conditional correlation matrix.

The estimation procedure of DCC-GARCH model is based on two stages. In the first stage, a univariate GARCH model is estimated. In the second step, the vector of standardized residuals $\eta_{i,t} = r_{i,t} / \sqrt{h_{i,t}}$ is employed to develop the DCC correlation specification as follows:

$$R_t = \text{diag}(q_{11,t}^{-1/2}, \dots, q_{33,t}^{-1/2}) Q_t \text{diag}(q_{11,t}^{-1/2}, \dots, q_{33,t}^{-1/2}) \quad (6)$$

where $Q_t = (q_{ij,t})$ is a symmetric positive definite matrix. Q_t is assumed to vary according to a GARCH-type process:

$$Q_t = (1 - \theta_1 - \theta_2) \bar{Q} + \theta_1 \eta_{t-1} \eta'_{t-1} + \theta_2 Q_{t-1} \quad (7)$$

The parameters θ_1 and θ_2 are scalar parameters to capture the effects of previous shocks and previous dynamic conditional correlation on current dynamic conditional correlation. The parameters θ_1 and θ_2 are positive and $\theta_1 + \theta_2 < 1$. $\bar{Q}$ is 3×3 unconditional variance matrix of standardized residuals $\eta_{i,t}$. The correlation estimators of Eq. 7 are of the form:

$$\rho_{ij,t} = \frac{q_{ij,t}}{\sqrt{q_{ii,t} q_{jj,t}}}$$

In the DCC model the choice of $\bar{Q}$ is not obvious as Q_t is neither a conditional variance nor correlation. Although $E(\eta_{t-1} \eta'_{t-1})$ is inconsistent for the target, the recursion in Q_t does not have a martingale representation. See Aielli (2008) for further details. Aielli (2008) proposed the corrected Dynamic Conditional Correlation (cDCC) to evaluate the impact of both the lack of consistency and the existence of bias in the estimated parameters of the DCC model of Engle (2002). He showed that the bias depends on the persistence of the DCC dynamic parameters. Aielli (2008) showed that the lack of consistency of the three-step DCC estimator depends strictly on the persistence of the parameters driving the correlation dynamics and on the relevance of the innovations. The bias is an increasing function of both θ_1 and $\theta_1 + \theta_2$. The parameter estimates obtained from fitting DCC models are small, and close to zero for θ_1 and close to unit for $\theta_1 + \theta_2$. In order to resolve this issue, Aielli (2008) introduces the cDCC model, which has the same specification as the DCC model of Engle (2002), except for the correlation process Q_t is reformulated as follows:

$$Q_t = (1 - \theta_1 - \theta_2) \bar{Q} + \theta_1 \eta_{t-1}^* \eta'^*_{t-1} + \theta_2 Q_{t-1} \quad (8)$$

where $\eta_t^* = \text{diag}\{Q_t\}^{1/2}\eta_t$.

To investigate the asymmetric properties of stock market returns we introduce the conditional asymmetries in variance. Cappiello et al. (2006) estimate several asymmetric versions of the dynamic conditional correlation models. The version that we use is based on the following specification:

$$r_t = \mu + \sum_{s=1}^p \Phi^s r_{t-s} + \varepsilon_t, \quad t = 1, \dots, T, \quad \varepsilon_t \mid \Omega_{t-1} \sim N(0, H_t)$$

$$H_t = D_t R_t D_t, \quad \text{where } D_t = \text{diag}\left(\sqrt{h_{11,t}}, \sqrt{h_{22,t}}, \sqrt{h_{33,t}}\right)$$

$$h_{it} = \omega_i + \alpha_i \varepsilon_{i,t-1}^2 + \gamma_i \mathcal{I}_{\{\varepsilon_{i,t} < 0\}} \varepsilon_{i,t-1}^2 + \beta_i h_{i,t-1} \quad \text{for } i = UK, US, JP$$

$$R_t = Q_t^{*-1} Q_t Q_t^{*-1}, \quad \text{where } Q_t^* = \text{diag}\{\sqrt{q_{11,t}}, \sqrt{q_{22,t}}, \sqrt{q_{33,t}}\}$$

$$Q_t = (1 - \theta_1 - \theta_2)\overline{Q} + \theta_1 \eta_{t-1} \eta'_{t-1} + \theta_2 Q_{t-1}$$

105.3 Empirical Results

In this section we initially employed a vector autoregressive (VAR) model to examine the relationship among stock market returns of the three developed countries. Our model is estimated on a set of stationary variables. These variables are returns in stock market prices for the UK, USA, and Japan. Table 3 reports the findings of the VAR(8) model (lags is selected using AIC criterion).

Table 3 VAR diagnostic test

	FTSE 100 [p-value]	S&P 500 [p-value]	NIKKEI 225 [p-value]

Notes: VAR model was estimated using eight lags (the lag was selected using AIC criterion). P-values show statistical significance of the results

105.3.1 Conditional Variance and Volatility Analysis

This subsection presents the empirical results from symmetric and asymmetric multivariate models. In the first step the univariate GARCH(1,1) model for each stock market is fitted. We model the conditional variance as a GARCH(1,1), EGARCH(1,1), and TGARCH(1,1). In the second step the symmetric multivariate GARCH(1,1) models, such as Constant Conditional Correlation (CCC), the Dynamic Conditional Correlation (DCC), the corrected Dynamic Conditional Correlation (cDCC), and the asymmetric multivariate GARCH(1,1) models, such as; aCCC, aDCC, and a-cDCC are fitted.

105.3.1.1 Symmetric and Asymmetric Univariate GARCH Analysis

Table 4 reports the model estimates (panel A) and related diagnostic tests (panel B) for the three models and for the three stock markets. Firstly, panel A of Table 4 shows that the parameters in the conditional variance equations are all statistically significant, except for the α 's in the EGARCH model for the three markets. The estimated value of β (GARCH effect) is close to unity (in all models the estimated values are greater than 0.90) and is significant at the 1% level for each model. This indicates a high degree of volatility persistence in the UK, USA, and Japan stock market returns. Secondly, results given by the GARCH(1,1) model assume that positive and negative shocks will have the same influence in conditional volatilities forecasts. In order to identify the asymmetry in conditional volatilities, we fitted the univariate EGARCH(1,1) and TGARCH(1,1) models. This asymmetry is generally referred to as a “leverage” and a “Threshold” effects. The EGARCH(1,1) model captures this “leverage” asymmetry and the TGARCH(1,1) captures this “threshold” asymmetry. The EGARCH (Exponential GARCH) model of Nelson (1991) is formulated in terms of the logarithm of the conditional variance, as in the EGARCH(1,1) model,

$$\log(h_t) = \omega + \alpha \frac{|\varepsilon_{t-1}|}{\sqrt{h_{t-1}}} + \gamma \frac{\varepsilon_{t-1}}{\sqrt{h_{t-1}}} + \beta \log(h_{t-1})$$

The parametrization in terms of logarithms has the obvious advantage of avoiding nonnegativity constraints on the parameters. The TGARCH (Threshold) GARCH model or GJR-GARCH model defined by Glosten et al. (1993) and Zakoian (1994) augments the GARCH model by including an additional ARCH term conditional on the sign of the past innovation,

$$h_t = \omega + \alpha \varepsilon_{t-1}^2 + \delta \mathcal{I}_{\{\varepsilon_{t-1} < 0\}} \varepsilon_{t-1}^2 + \beta h_{t-1}$$

The results showed that the asymmetric parameter γ or δ is positive and significantly different from zero at the 5% level in the EGARCH(1,1) model, indicating that UK, USA, and Japan stock markets exhibit a leverage effect with positive shocks (good news) and significantly different from zero at 1% level in the

TGARCH(1,1) model, identifying that the UK, USA, and Japan stock markets exhibit a threshold effect with positive effect. To select the adequate model for our data, we compare the three models using three criteria; such as the Log-likelihood, Akaike Information Criterion (AIC), and Schwarz Information Criterion (SIC). We showed that the asymmetric GARCH model; TGARCH(1,1) has a superior goodness of fit for the data employed. For instance, AIC in the TGARCH(1,1) is lower than in GARCH(1,1) and EGARCH(1,1) models.

Panel B of Table 4 depicts the Ljung-Box statistics computed on the standardized residuals and squared standardized residuals. We showed that all the $Q(24)$ and $Q_s(24)$ values do not reject the null hypothesis of no serial correlation in the standardized residuals and squared standardized residuals at 1% level.

105.3.1.2 Symmetric and Asymmetric Dynamic Conditional Correlation Analysis

In the second step, the symmetric and asymmetric multivariate GARCH(1,1) models were estimated in order to investigate the constant and time-varying conditional correlation in the stock markets under study. To fit these models, the standardized residuals of the univariate GARCH(1,1) models specification (discussed in the first step of our study) was employed for the estimation of the symmetric models: CCC, DCC, cDCC and asymmetric models: aCCC, aDCC, a-cDCC. The DCC and cDCC estimates of the conditional correlations between the volatilities of the FTSE 100, S&P 500, and NIKKEI 225 returns are given in Tables 7 and 8. Results showed that all coefficients are statistically significant at 1% and 5% levels.

For the CCC model (Tables 5 and 6), the correlation between FTSE 100 and S&P 500, FTSE 100 and NIKKEI 225 and S&P 500 and NIKKEI 225 are each positive and statistically significant at 1% level, and the highest correlation is between FTSE 100 and S&P 500 followed by the correlation between FTSE 100 and NIKKEI 225. This indicates the positive co-movement between the three markets. For instance, we found that the co-movements between the UK and USA are higher than the co-movements between USA and Japan. However, we remarked that estimated constant conditional correlation coefficients of the sample stock markets do not seem to be informative on dynamic linkages and co-movements between the abovementioned markets. To evaluate the dynamic (pairwise) correlation structure of the UK, USA, and Japan stock markets, we employed the DCC and cDCC models in trivariate framework.

For the DCC and cDCC models (Tables 7 and 8), the estimated parameters θ_1 and θ_2 capture the effect of lagged standardized shocks; $\eta_{t-1}\eta'_{t-1}$, and $\eta^*_{t-1}\eta^{*'}_{t-1}$ and lagged dynamic conditional correlations; Q_{t-1} , on current dynamic conditional correlations, respectively. We remarked that these parameters are significant, and this statistical significance in each market indicates the presence of time-varying stock market correlations. Following the dynamic conditional variance, the three markets under study produce similar behavior and the estimated conditional variance shows a sharp spike in the period between 2007 and 2008 (The maximum value of estimated conditional variance is in 21 October 2008 for FTSE 100 returns, in 16 October 2008

Notes: The estimates are produced by the univariate GARCH(1,1), EGARCH(1,1), and TGARCH(1,1) models. The univariate variance estimates are introduced as inputs in the estimation of CCC, DCC, and cDCC models. The estimated coefficient ω denotes the constant of the variance equation, α represents the ARCH term, and β is the GARCH coefficient. γ and δ are the asymmetric effects. *, **, and *** indicate significance at 10%, 5%, and 1%, respectively. Q(24) and Q_s(24), respectively, represent the Ljung-Box Q statistics of order 24 computed on the standardized residuals and squared standardized residuals. Value of the estimated coefficient is multiplied by 10⁴ for the EGARCH model. Values in bold indicate the selected model

Table 5 CCC diagnostic test for standardized residuals

	Log-likelihood: -7233.3	AIC: 6.8872 SIC: 6.9194

Q _s (12) [p-value]	26.1324 [0.0102]	17.1204 [0.1451]	13.3307 [0.3454]

Notes: The CCC model of Bollerslev (1990) assumes that the conditional variance for each return, h_{it} , $i = \text{UK, US, JP}$, follows a univariate GARCH process. The specification is as:

$$r_t = \Phi_0 + \sum_{s=1}^p \Phi_s r_{t-s} + \varepsilon_t, \quad \varepsilon_t \mid \Omega_{t-1} \sim N(0, H_t)$$
$$\varepsilon_t = H_t^{1/2} z_t, \quad z_t \sim N(0, \mathcal{I}_3)$$
$$H_t = E(\varepsilon_t \varepsilon_t' \mid \Omega_{t-1})$$

where $r_t = (r_{UK,t}, r_{US,t}, r_{JP,t})'$ is the vector of stock market index returns, $\varepsilon_t = (\varepsilon_{UK,t}, \varepsilon_{US,t}, \varepsilon_{JP,t})'$ is the error term from the mean equation of stock market indices (Eq. 2), z_t is 3×1 vector of i.i.d errors, and H_t is the conditional covariance matrix, which satisfies the following equation: $H_t = D_t R D_t$, where $D_t = \text{diag}(h_{UK,t}^{1/2}, h_{US,t}^{1/2}, h_{JP,t}^{1/2})$, and $R = \{\rho_{ij}\}$, for $i, j = \text{UK, US, JP}$, is the unconditional (time-invariant) correlation matrix. The off-diagonal elements of the conditional covariance matrix are given by: $H_{ij} = h_{it}^{1/2} h_{jt}^{1/2} \rho_{ij}$, $i \neq j$. ***, ** and * indicate significance at 10%, 5%, and 1%, respectively. Q(24) and Q_s(24), respectively, represent the Ljung-Box Q statistics of order 24 computed on the standardized residuals and squared standardized residuals.

Table 6 CCC estimates

	FTSE 100	S&P 500	NIKKEI 225
FTSE 100	1	0.5692* (0.0149)	0.2583* (0.0212)
S&P 500		1	0.1751* (0.022)
NIKKEI 225			1

Notes: The table summarizes the estimated invariant correlations between the UK, USA, and Japan stock markets, as they are produced by CCC model. Values in parentheses are standard errors. ***, **, and * indicate significance at 10%, 5%, and 1%, respectively

for the S&P 500 returns, and in 03 November 2008 for NIKKEI 225 returns). This period is related to the US subprime financial crisis. This financial crisis led the UK, USA, and Japan capital markets to abrupt downturns, dramatically increasing systematic volatility.

We conclude that the estimates of the conditional variances based on DCC and cDCC models suggest the presence of volatility spillovers in the UK, USA, and Japan stock market returns. As shown in Fig. 2, we remarked also that the dynamic conditional correlations of the three markets under study show considerable variation, and can vary from the constant conditional correlations (ρ_{UK-US} , ρ_{UK-JP} and ρ_{US-JP}) indicating that the assumption of constant conditional correlation for all shocks to returns is not supported empirically. We stated that during the period 2003–2006, correlations between the UK and USA decreased (58% to 38%), as indicated in Fig. 2. Whereas, after 2006 we remarked a substantial increase of correlations between the UK and USA, which might be due to the Afghanistan, Iraq, and Libyan wars and the American subprime financial crisis.

Table 7 DCC estimates

	θ_1	θ_2	Log-likelihood	AIC
Panel A: Model estimates				
Coefficient	0.005218*	0.992655*	−7211.0	6.8679
Std.error	0.001416	0.002210		
t-stat (p-value)	3.685 (0.000)	449.10 (0.000)		
Panel B: Diagnostic test for standardized residuals				
	FTSE 100	S&P 500	NIKKEI	
Q(12) (p-value)	21.6339 (0.041)	16.2283 (0.181)	13.9273 (0.305)	
Qs(12 (p-value))	25.7240 (0.011)	18.5131 (0.100)	13.3440 (0.344)	

Notes: The estimates of a symmetric version of Engle (2002) DCC model are computed. The specification is as follows:

$$r_t = \Phi_0 + \sum_{s=1}^p \Phi_s r_{t-s} + \varepsilon_t, \quad \varepsilon_t \mid \Omega_{t-1} \sim N(0, H_t)$$
$$\varepsilon_t = H_t^{1/2} z_t, \quad z_t \sim N(0, \mathcal{I}_3)$$
$$H_t = D_t R_t D_t$$
$$D_t = \text{diag} \left(h_{UK,t}^{1/2}, h_{US,t}^{1/2}, h_{JP,t}^{1/2} \right)$$
$$h_{it} = \omega_i + \alpha_i \varepsilon_{i,t-1}^2 + \beta_i h_{i,t-1}, \quad i = UK, \quad US, \quad JP.$$

The dynamic conditional correlation R_t is a time-varying matrix defined as: $R_t = Q_t^{*-1} Q_t Q_t^{*-1}$ where $Q_t^{*-1} = \text{diag} \left(\sqrt{q_{11,t}}, \sqrt{q_{22,t}}, \sqrt{q_{33,t}} \right) \cdot Q_t = (1 - \theta_1 - \theta_2) \bar{Q} + \theta_1 \eta_{t-1} \eta_{t-1}' + \theta_2 Q_{t-1}$ where $\eta_t = D_t^{-1} \varepsilon_t \cdot \bar{Q}$ is the unconditional covariance matrix of η . The elements of H_t are $H_{ij} = h_{it}^{1/2} h_{jt}^{1/2} \rho_{ij}$ where $\rho_{ij} = 1$. ***, **, and * indicate significance at 10%, 5%, and 1%, respectively. Q (24) and Qs(24), respectively, represent the Ljung-Box Q statistics of order 24 computed on the standardized residuals and squared standardized residuals

Table 8 cDCC estimates

	θ_1	θ_2	Log-likelihood	AIC
Panel A: Model estimates				
Coefficient	0.005282*	0.992716*	−7210.5	6.8674
Std.error	0.001430	0.002047		
t-stat (p-value)	3.692 (0.000)	448.80 (0.000)		
Panel B: Diagnostic test for standardized residuals				
	FTSE 100	S&P 500	NIKKEI	
Q(12) (p-value)	21.6228 (0.041)	16.3030 (0.177)	13.9019 (0.307)	
Qs(12 (p-value))	25.6085 (0.012)	18.5792 (0.099)	13.357 (0.343)	

Notes: Aielli (2008) proposed a consistent DCC model. He suggested that the DCC correlation Q_t should take a slightly different from than given in DCC model. The specification is similar to that in DCC, except for Q_t which becomes: $Q_t = (1 - \theta_1 - \theta_2) \bar{Q} + \theta_1 \eta_{t-1}^* \eta_{t-1}^{*'} + \theta_2 Q_{t-1}$, $\eta_t^* = \text{diag}(Q_t)^{1/2} \eta_t$. ***, **, and * indicate significance at 10%, 5%, and 1%, respectively. Q(24) and Qs(24), respectively, represent the Ljung-Box Q statistics of order 24 computed on the standardized residuals and squared standardized residuals

Fig. 2 Time-varying conditional variances (left column) and conditional correlations (right column) from DCC model. The pictures on the left column: (a), (c), and (e) refer to conditional variances of the UK, USA, and Japan stock market indices and those on the right column: (b), (d) and (f) report conditional correlations among the same group of stock market indices. The blue line (horizontal) is the constant conditional correlation estimate

The diagnostic tests for standardized residuals of CCC model are shown in Table 5 and those of DCC and cDCC models are shown in panel B of Tables 7 and 8. Ljung-Box $Q(12)$ and $Q_s(12)$ statistics for the residuals models indicate no serial correlation in either the standardized residuals $Q(12)$ or the squared standardized residuals $Q_s(12)$, inferring that the fitted models are appropriate for the data employed.

To investigate the asymmetry in the conditional volatility we fitted the aCCC, aDCC, and a-cDCC models. The results are reported in Table 9. In the asymmetric

Table 9 Asymmetric DCC estimates

	θ_1	θ_2	Log-likelihood	AIC	BIC
aCCC			−7169.5	6.8293	6.8696
aDCC	0.0055 (0.00162)*	0.9913 (0.00295)*	−7148.3	6.8111	6.8565
a-cDCC	0.0056 (0.00162)*	0.9913 (0.00273)*	− 7148.0	6.8108	6.8565

Notes: This table presents estimates coefficients for the asymmetric CCC [aCCC], the asymmetric DCC [aDCC] model, and the asymmetric cDCC [a-cDCC] model. The specification is similar to those in DCC and cDCC models (given in Tables 7 and 8), except of the conditional variances which follow the asymmetric TGARCH model of Glosten et al. (1993)

case, we focused on the TGARCH(1,1)-based model to model the asymmetric behavior in the conditional volatilities. The results from Table 4 indicate that TGARCH(1,1) model compared to GARCH(1,1) and EGARCH(1,1), achieves a significant improvement in the log-likelihood function, AIC and SIC. As shown in Table 4 the TGARCH(1,1) model has the lowest AIC and SIC, and maximize the log-likelihood value. For instance, the AIC values are −6.5556, −6.4577, and −6.1792 for the FTSE 100, S&P 500, and NIKKEI 225 returns, respectively. The log-likelihood values are 6900.5, 6797.5, and 6504.5 for the FTSE 100, S&P 500, and NIKKEI 225 returns, respectively. The apparent superiority of the TGARCH specification compared with EGARCH models is that the former is more robust to large shocks. This intuition is supported by Nelson and Foster (1994). The authors showed that the TGARCH model is the consistent estimator of the conditional variance of near diffusion processes. The asymmetric dynamic conditional correlation estimates are all significant at 1% level (as shown in Table 9). Based on the log-likelihood values and AIC criterion reported in the last two columns of Table 9, the asymmetric cDCC (a-cDCC) is superior to the aCCC and aDCC. Moreover, as it can be seen, the log-likelihood values and AIC criteria of aDCC and a-cDCC are nearly equivalent; hence the choice of model needs to be made on other grounds (see the following subsection).

The values in parentheses are standard errors. * indicate significance at 1% level. Log-likelihood is the log-likelihood value. AIC is the Akaike information criterion. Values in bold indicate the selected model.

105.3.2 Forecast Performance Evaluation

To evaluate the volatility forecasting performance of different multivariate GARCH models and to compare between them, further loss functions can be used. The popular statistical loss functions employed to assess the accuracy of competing models in the forecasting of volatilities over daily trading horizon are Mean squared Error (MSE), Mean Absolute Error (MAE), Mean Absolute Percentage Error (MAPE), and Logarithm Loss Error (LLE). These loss metrics are expressed as follows:

$$\text{MSE}_k = \frac{1}{M} \sum_{m=1}^M (\zeta_{m,k} - \hat{\sigma}_m^2)^2 \quad (9)$$

$$\text{MAE}_k = \frac{1}{M} \sum_{m=1}^M |\zeta_{m,k} - \hat{\sigma}_m^2| \quad (10)$$

$$\text{MAPE}_k = \frac{1}{M} \sum_{m=1}^M \left| \frac{\zeta_{m,k} - \hat{\sigma}_m^2}{\hat{\sigma}_m^2} \right| \quad (11)$$

$$\text{LLE}_k = \frac{1}{M} \sum_{m=1}^M [\log(\zeta_{m,k}) - \log(\hat{\sigma}_m^2)]^2 \quad (12)$$

where M is the number of forecast data points; $\zeta_{m,k} = \kappa' H_m \kappa$ denotes the portfolio volatility forecast generated by model k for day m ; $\hat{\sigma}_m^2$ is the actual volatility on day m .

The assessment of the forecast performance of the various volatility models described in Sect. 105.2.3 is based on out-of-sample one-day ahead prediction conditional variances and correlations. This forecasting study is done by first removing the last 250 observations from our sample starts from 02 January 2003 and ends 04 February 2011. A forecast of volatilities and correlations are generated for the period $n + 1$, where n is the size of the first sample to be estimated starts 02 January 2003 and ends 19 February 2010 (the estimation is based on three models: CCC, DCC, and cDCC). The second sample, starting 03 January 2003 and ending on $n + 1$, is used to forecast the volatility and correlation of $n + 2$ based on the estimated models (CCC, DCC, and cDCC) for the second sample. The procedure of estimation and forecasting steps is repeated 250 times for the available sample from 02 January 2003 to 04 February 2011. For instance, forecasting the DCC model is as follows: the initial sample consists of the first 1862 daily observations, i.e., 02 January 2003 to 19 February 2010. The last 250 trading days constitute the sample for which we compute one-day ahead forecasts. We re-estimated the DCC model basing on the initial sample every day using a recursive method (all estimations and forecasts are computed with OxMetrics 6). After that, we computed the conditional variance and conditional correlation forecast values. These forecast values are used to compute the loss functions of the weighted portfolio defined before. More specifically, we produce the 250 one-day ahead forecasts ζ_m , where $\zeta_m, m = n + 1, \dots, n + 250$ is the forecast of the conditional variance.

The actual volatility $\hat{\sigma}_m^2$ is unobservable. The use of squared returns as a proxy for actual volatility is used in the literature (see Kang et al. 2009; Sadorsky (2006); Wei et al. 2010). In our empirical study, the proxies of actual volatilities are as follows: for forecasts based on the unfiltered return series (original stock market return series), we proxied the actual volatility by the squared returns, r_m^2 .

Table 10 Volatility forecast performance

	Symmetric models			Asymmetric models		
	CCC	DCC	cDCC	aCCC	aDCC	a-cDCC
MSE	0.16923	0.15971	0.15986	0.09237	0.08652	0.08639
MAE	0.40981	0.39822	0.39844	0.30178	0.29195	0.29170
MAPE	313.908	304.884	304.990	221.732	214.423	214.199
LLE	111.794	111.208	111.220	105.430	104.763	104.744

Notes: The table reports the loss functions over the 250 forecasting observations for the symmetric and asymmetric dynamic conditional correlation models. The MSE, MAE, MAPE, and LLE of the weighted portfolio are computed as follows: $MSE_k = M^{-1} \sum_{m=1}^M (\varsigma_{m,k} - \hat{\sigma}_m^2)^2$, $MAE_k = M^{-1} \sum_{m=1}^M |\varsigma_{m,k} - \hat{\sigma}_m^2|$, $MAPE_k = M^{-1} \sum_{m=1}^M |(\varsigma_{m,k} - \hat{\sigma}_m^2)/\hat{\sigma}_m^2|$, and $LLE_k = M^{-1} \sum_{m=1}^M [\log(\varsigma_{m,k}) - \log(\hat{\sigma}_m^2)]^2$, where M is the number of forecast data point ($M = 250$). $\varsigma_{m,k}$ denotes the volatility forecast of the portfolio constituted of three stock market indices and generated by model k for day m ; it is defined by Eq. 8. $\hat{\sigma}_m^2$ is the actual portfolio volatility on day m

Table 10 presents the forecast accuracy statistics that consist of the mean of four loss functions: MSE, MAE, MAPE, and LLE. In terms of these criteria and based on symmetric models, we find that DCC model produces smaller values than those produced by CCC and cDCC. In terms of these statistics and basing in asymmetric models, the a-cDCC model produces the smallest values. Moreover, we remarked that all loss functions values produced by asymmetric models are smaller than those calculated by symmetric ones. In summary, we can conclude that, in our forecasting study, asymmetric models produce more accurate volatility forecasts as compared to those models with symmetric conditional volatility.

105.3.3 Application to Value-at-Risk

In this section, we present a methodology allowing us to compute the VaR of diversified portfolio. A portfolio with weight κ_i in stock market index i has return as

$$r_p = \kappa' r_t \tag{13}$$

where $r_t = (r_{UK,t}, r_{US,t}, r_{JP,t})'$ denotes the vector of stock market returns of FTSE 100 ($r_{UK,t}$), S&P 500 ($r_{US,t}$), and NIKKEI 225 ($r_{JP,t}$). $\kappa' = (\kappa_{UK}, \kappa_{US}, \kappa_{JP}) = (0.27, 0.40, 0.33)$ is the weight vector of the three given indices. These weights are computed using the R function *portfolio.optim* of the *PerformanceAnalytics* R package, which computes an efficient portfolio from the given return series in the mean-variance sense. The computed portfolio has the desired expected return and no other portfolio exists, which has the same mean return, but a smaller variance.

The portfolio variances are as follows

$$\varsigma_t = \kappa' H_t \kappa \quad (14)$$

where H_t is the conditional covariance defined in Sect. 105.2.

The multivariate GARCH-based VaR estimates for q -day holding periods are computed as follows:

$$\text{VaR}_{t+l}^k(n, \alpha) = q\kappa' \mu_{t+l} + z_\alpha \sqrt{q} \varsigma_{t+l} \quad (15)$$

where the argument (q) of VaR is used to denote the time horizon, z_α denotes the corresponding quantile, which depends on the chosen distribution. For instance, when computing a 99% VaR using normal distribution, $z_\alpha = 2.33$. $\varsigma_{t+l} = (\kappa' H_{t+l} \kappa)^{1/2}$ is the square root of the daily conditional variance forecast of the portfolio generated from model k (CCC, DCC, cDCC), made at time $t + l$. μ_{t+l} is the conditional mean forecast at time $t + l$, generated from VAR(8) model.

105.3.3.1 Backtesting VaR Measures

In order to analyze our results implied by different time-varying volatilities models, we use the above estimation to compute one-day ahead out-of-sample VaR. We performed a backtesting analysis based on likelihood ratio test (Kupiec 1995; Christoffersen 1998) and dynamic quantile regression test (Engle and Manganelli 2004).

Unconditional Coverage

Kupiec (1995) developed the likelihood ratio test, LR_{uc} , as follows:

Let $n_1 = \sum_{t=1}^{n_0} \mathcal{I}_t$ be the number of days over a n_0 period that the portfolio loss was larger than the VaR estimate, where

$$\mathcal{I}_{t+l} = \begin{cases} 1 & \text{if } r_{t+l} < \text{VaR}_{t+l} \mid \Omega_t \\ 0 & \text{if } r_{t+l} \geq \text{VaR}_{t+l} \mid \Omega_t \end{cases}$$

$n_1 \sim B(n_0, \pi)$ is a binomial variable representing the number of *exceedances* or *exceptions* in the sample of length n_0 . The null hypothesis of the failure probability, π , is tested against the alternative hypothesis that the failure probability differs from π_0 . The null hypothesis for Kupiec (1995) test is $H_0 : \pi = n_1/n_0 = \pi_0$, where π is the expected proportion of exceedances, which equals the desired coverage level π_0 (usually equal to 1% and 5%). The LR_{uc} statistic is

$$LR_{uc} = -2 \ln [(1 - \pi^{n_0 - n_1}) \pi^{n_1}] + 2 \ln \left[\left(1 - \frac{n_1}{n_0}\right) \left(\frac{n_1}{n_0}\right)^{n_1} \right] \quad (16)$$

Asymptotically, $LR_{uc} \sim \chi^2(1)$.

Conditional Coverage

Christoffersen (1998) developed a likelihood statistic to test joint assumption of unconditional coverage and independence of failures. He tests the null hypothesis of independence against the alternative of first-order Markov structure of $\{\mathcal{J}_{t+1}\}$. The null hypothesis for Christoffersen (1998) test is $H_0 : \pi_{00} = \pi_{11}$, with transition matrix

$$\Pi = \begin{pmatrix} \pi_{00} & 1 - \pi_{11} \\ 1 - \pi_{11} & \pi_{11} \end{pmatrix}$$

where $\pi_{ii} = p(\mathcal{J}_{t+i} = i | \mathcal{J}_t = i)$, $i = 1, 0$. Let n_{ij} be the number of observations of $\mathcal{J}_{t+1}$ assuming value i followed by j , for $i, j = 0, 1$; and $\pi_{ij} = n_{ij} / \sum_j n_{ij}$ is the corresponding probability. Hence, we have $\hat{\pi}_{01} = n_{01} / (n_{00} + n_{01})$ and $\hat{\pi}_{11} = n_{11} / (n_{10} + n_{11})$. The statistic of the test is given by

$$LR_{cc} = LR_{uc} + LR_{ind} \sim \chi^2(2) \quad (17)$$

where $LR_{ind} = -2 \ln [(1 - \pi)^{n_0 - n_1} \pi^{n_1}] + 2 \ln [(1 - \hat{\pi}_{01})^{\hat{\pi}_{01}} (1 - \hat{\pi}_{11})^{\hat{\pi}_{11}}]$
Asymptotically, $LR_{ind} \sim \chi^2(1)$.

Dynamic Quantile

Engle and Manganelli (2004) proposed the dynamic quantile (DQ) test to correct for the inefficiency in the conditional coverage test of Christoffersen (1998). They defined an indicator function $Hit_t(\alpha) = \mathcal{I}_{\{r_t < \text{VaR}_t(\alpha) | \Omega_{t-1}\}} - \alpha$ to test the VaR of long position as follows:

$$Hit_{t+1}(\alpha) = \begin{cases} 1 - \alpha & \text{if } r_{t+1} < \text{VaR}_{t+1} | \Omega_t \\ -\alpha & \text{else} \end{cases} \quad (18)$$

Engle and Manganelli (2004) suggested to test jointly the following hypothesis:

$$H_0 : \begin{cases} E(Hit_{t+1}) = 0 \\ Hit_{t+1} \text{ is uncorrelated with variables included in the information set.} \end{cases} \quad (1) \quad (2)$$

These two tests (1) and (2) can be done using artificial regression $Hit_{t+1} = X_{t+1}\beta + u_{t+1}$, where X_{t+1} is a $N \times K$ matrix whose first column is a column one and remaining columns are additional explanatory variables. footnote {We include five lags of Hit_t and the current VaR as explanatory variables. Hence, $Hit_t = (\tau, Hit_{t-1}, Hit_{t-2}, Hit_{t-3}, Hit_{t-4}, Hit_{t-5}, \text{VaR}_t(\alpha))$.

Under H_0 , Engle and Manganelli (2004) show that the dynamic quantile test statistic is given by

$$DQ = \frac{\hat{\beta}'_{OLS} X' \hat{X} \hat{\beta}_{OLS}}{\alpha(1 - \alpha)} \sim \chi^2(7) \quad (19)$$

The statistical adequacy of VaR forecasts is obtained by the previous tests. It is well-known that these tests have limited power in distinguishing among various models for VaR. Using these metrics, we cannot conclude whether an adequate model is more accurate than another one. Loss functions represent an alternative approach that can be used to compare models. Lopez (1998) suggested a loss function based on regulatory needs. He proposed measuring the accuracy of VaR forecasts on the basis of distance between observed return, r_t , and forecasted VaR $_t$ values. He defined a penalty variable as follows:

$$LF_{t+1} = \begin{cases} 1 + (r_{t+1} - \text{VaR}_{t+1}|\Omega_t)^2 & \text{if } r_{t+1} < \text{VaR}_{t+1} \mid \Omega_t \\ 0 & \text{if } r_{t+1} \geq \text{VaR}_{t+1} \mid \Omega_t \end{cases}$$

In our study we computed the loss function LF as a sum of LF_{t+1} , with $t = 0, \dots, n_0$. Table 11 depicts the out-of-sample mean daily VaR of the weighted portfolio consisting of the FTSE 100, S&P 500, and NIKKEI 225 stock market returns. We remarked that the a-cDCC model yields the lowest average daily VaR estimates at 1%, 2.5%, 5%, and 10% levels. The backtesting analysis considers a comparison over the last 250 days (from 19 February 2010 to 04 February 2011) and focuses mainly on exceptions or violations, i.e., the number of times in which the portfolio returns underperform the VaR measure, and LR_{uc} , LR_{cc} , and DQ test statistics. We also calculated the failure probability and statistic loss functions suggested by Lopez (1998). Tables 12 and 13 present unconditional, conditional, and dynamic quantile test statistics. The results showed that symmetric and asymmetric models have been rejected by the LR_{uc} , LR_{cc} , and DQ tests. Hence, these models are slow at updating the VaR values when market volatility changes rapidly.

For symmetric models, at 1% significance level, CCC, DCC, and cDCC models provide the same number of violations and failure probabilities. The same remark is shown in the case of asymmetric models. The results in Tables 12 and 13 showed that all

Table 11 Daily VaR forecasts

Model	Mean VaR α -level			
	1%	2.5%	5%	10%
Symmetric models				
CCC	1.48782	1.25373	1.05289	0.82008

Notes: The table presents the evaluation of out-of-sample daily VaR for the weighted portfolio (consisting of three stock market indices) generated by symmetric models. It reports test statistics over last 250 days (19 February 2010 to 03 February 2011). Fail prob.: The failure probability. LR_{uc}: The LR test of unconditional coverage. LR_{ind}: The LR test of independence. LR_{cc}: The joint test of coverage and independence. DQ: The Dynamic Quantile test. LF: The loss function. Values in bold show the selected model for better forecasts

symmetric models produce the lowest number of violations and failure probabilities. For instance, we identify 13 and 23 violations and 5.22% and 9.23% p-values for the DCC model at 1% and 5% level, respectively. While for the asymmetric DCC model, we find 18 and 31 violations and 7.22% and 12.44% p-values at 1% and 5% level, respectively.

As shown in Tables 12 and 13, we also reported the *LF* criterion, which facilitates the selection of optimal VaR model for risk manager. It is clear that CCC and aCCC models provide the lowest *LF* values at 1%, 2.5%, 5%, and 10% levels. For symmetric volatility models, the study identifies the CCC model as the best performing model for a firm, followed by cDCC and DCC models. For the asymmetric volatility models, we identify the aCCC model as the best performing model, followed by DCC and cDCC models. However, we remarked that DCC and cDCC models provide approximately the same performance.

105.4 Wavelet-Based Approach

In this section we employed a new approach called wavelet transform. The wavelet transform has two types of transform, namely, continuous wavelet transform (CWT) and discrete wavelet transform (DWT). Since most of the time series have a finite

Table 13 Summary results for daily VaR diagnostic tests in asymmetric case

	Exceedances	Fail prob. (%)	LR _{uc}	LR _{ind}	LR _{cc}	DQ	LF

Notes: The table presents the evaluation of out-of-sample daily VaR for the weighted portfolio (consisting of three stock market indices) generated by symmetric models. It reports test statistics over last 250 days (19 February 2010 to 03 February 2011). Fail prob.: The failure probability. LR_{uc}: The LR test of unconditional coverage. LR_{ind}: The LR test of independence. LR_{cc}: The joint test of coverage and independence. DQ: The Dynamic Quantile test. LF: The loss function. Values in bold show the selected model for better forecasts

number of observations, the discrete version of wavelet transform is used in finance and economic applications. The wavelet transform decomposes a time series in terms of some elementary functions, called, wavelets; $\psi_{u,\tau}(t) = \frac{1}{\sqrt{\tau}}\psi(\frac{t-u}{\tau})$, where $\frac{1}{\sqrt{\tau}}$ is a normalization factor, u is the translation parameter, and τ is the dilation parameter. $\psi(t)$ must fulfill several conditions (see, Gencay et al. 2002; Percival and Walden 2000): it must have zero mean, $\int_{-\infty}^{+\infty} \psi(t)dt = 0$ its square integrates to unity,

$\int_{-\infty}^{+\infty} \psi^2(t)dt = 1$, and it should also satisfy the admissibility condition, $0 < C_\psi =$

$\int_0^{+\infty} \frac{|\Psi(\lambda)|^2}{\lambda} d\lambda < +\infty$, where $\Psi(\lambda)$ is the Fourier transform of $\psi(t)$, that is $\Psi(\lambda) =$

$\int_{-\infty}^{+\infty} \psi(t)e^{-i\lambda t}dt$. Following the latter condition, we can reconstruct a time series $x(t)$.

We used a discrete wavelet transform (DWT), more specifically, we adopted the maximal overlap discrete wavelet transform (MODWT). We use the MODWT because we can align perfectly the details from the decomposition with the original time series. In comparison with the DWT, no phase shift will result in the MODWT (Gencay et al. 2002). For more information about the MODWT, please refer to Percival and Walden (2000), and Gencay et al. (2002). in a Multi-resolution Analysis

(MRA) framework. For more details, see Mallat (1989) and Percival and Walden (2000).

In our study, we sample the daily stock market returns at different scale j as follows: D_1 (2–4 days), D_2 (4–8 days), D_3 (8–16 days), D_4 (16–32 days), D_5 (32–64 days), D_6 (64–128 days), D_7 (128–256 days), D_8 (256–512 days)¹. We used Daubechies Least Asymmetric wavelet transformation of length $L = 8$ via $LA(L)$ to obtain multi-scale decomposition of the return series. The MRA yields an additive decomposition through MODWT given by

$$\begin{aligned} X(t) &= \sum_k \tilde{S}_{j,k} \phi_{j,k}(t) + \sum_j \sum_k \tilde{d}_{j,k} \psi_{j,k}(t), \quad j = 1, \dots, J \\ &= S_J(t) + D_J(t) + D_{J-1}(t) + \dots + D_1(t) \end{aligned} \quad (20)$$

where $S_J(t)$ refers to the smooth series and it represent the approximation that captures the long memory term properties, $D_j(t)$, $j = 1, \dots, J$ refers to detail series, which represent the contribution of frequency j to the original series.

The wavelet detail, $D_j(t)$, captures local fluctuations over the whole period of time series at each scale, while the wavelet smooth, $S_J(t)$, gives an approximation of the original series at scale J .

After computing the MODWT crystals (details and smooths) for every stock market return, and from the decomposed series ($D_1, \dots, D_8, S_8$) we classify the short-, medium-, and long-term series as follows: Short term = $D_1 + D_2 + D_3$; Medium term = $D_4 + D_5 + D_6$; Long term = $D_7 + D_8 + S_8$. This choice of time-horizon decomposition is used to classify three types of investors or traders, such as short-, medium-, and long-term ones, i.e., to analyze the behavior of investors among different time-horizons. Here the highest frequency component Short term, $D_1 + D_2 + D_3$, represents the short-term variations due to shocks occurring at a timescale of 2–16 days, it provides daily and weekly spillovers, the next component Medium term, $D_4 + D_5 + D_6$, represents the mid-term variations at timescale of 32 to 128 days, it defines the monthly and quarterly spillovers, and the third component Long term, $D_7 + D_8 + S_8$, represents the long-term variations of 256 days and more; it provides the annual spillovers. The main advantage of this classification is to decompose the risk and the volatility spillovers into three investment horizons. Therefore, we focus in three sub-spillovers. All market participants, such as regulators, traders, and investors, who trade in stock markets (in our study, the UK, USA, and Japan stock markets) make decisions over different timescales. In fact, due to the different decision-making timescales among investors, the time-varying volatilities and correlations of stock market indices will vary over the different timescales associated with those horizons (investment strategies).

In order to analyze the co-movements in returns and volatilities (the analysis is based on new time series: Short-, Medium-, and Long-term) between the three

¹ We decompose our time series up to scale 8 (scale $J \leq \log_2[(T-1)/(L-1)+1]$, where T is the number of observations of stock market returns ($T = 2112$), and L is the length of the wavelet filter $LA(8)$). We used the *wavelets* R package for the MODWT.

markets defined before and to investigate the dynamics and spillover effects, we applied a trivariate dynamic conditional correlation (CCC, DCC, and cDCC) model. We proceed with the same specifications presented in Sect. 105.2.3 to model the conditional mean and the conditional variances; we fitted a VAR(1)-MGARCH(1,1) to the three new series as follows:

$$\begin{cases} X_t = c_0 + AX_{t-1} + v_t \\ v_t = D_t z_t \end{cases} \quad (21)$$

where $X_t = (FTSE - Short_t, S \& P500 - Short_t, NIKKEI - Short_t)'$, c_0 is a (3×1) vector of constants, A is (3×3) coefficient matrix, v_t is (3×1) vector of error term from the mean equations of decomposed series, and z_t refers to a (3×1) vector of independently and identically distributed errors.

To ensure the stationarity of our reconstructed series (Short term, Medium term, and Long-term series), we applied the ADF and KPSS tests to our decomposed data. As shown in Table 14 all test statistics are statistically significant at 1% level, therefore indicating stationarity.

Table 15 presents estimates from two types of conditional volatility regressions: (i) a univariate GARCH model, and (ii) a univariate EGARCH model for each market and at each timescale. A GARCH(1,1) model and EGARCH(1,1) model proved adequate for capturing conditional heteroskedasticity. As shown in Table 15 the univariate GARCH models display more statistically significant coefficients than a univariate EGARCH one. In terms of GARCH model, the α and β coefficients (ARCH and GARCH effects, respectively) are positive and statistically significant in all stock markets, indicating highly persistent volatility dynamics in short-term horizon (lower scales/higher frequencies).

The timescale constant conditional correlations among the three stock market returns from the CCC model are summarized in Table 16. The results indicate that the highest constant correlation between markets is shown in medium-term horizon, which corresponds to monthly and quarterly time horizons. Therefore, the co-movements between the three markets are higher in medium horizon than co-movements in short or long horizons. For instance, the correlations between the

Table 14 Unit root tests of wavelet components

	FTSE 100		S&P 500		NIKKEI 225	
	ADF	KPSS	ADF	KPSS	ADF	KPSS
Short-term	-42.986*	0.006*	-46.451*	0.019*	-43.018*	0.008*
Medium-term	-54.386*	0.016*	-52.996*	0.013*	-49.944*	0.004*
Long-term	-33.796*	0.520*	-34.725*	0.486*	-47.833*	0.648*

Notes: The table reports the results of the augmented Dickey-Fuller (Dickey and Fuller 1979) and Kwiatkowski–Phillips–Schmidt–Shin (Kwiatkowski et al. 1992) tests. The KPSS test contains a constant and not a time trend, while the ADF test without constant and trend. The null hypothesis of ADF test is that a time series contains a unit root, $I(1)$ process, whereas the KPSS test has the null hypothesis of stationarity, $I(0)$ process. * indicate the rejection of the unit root null at 1% significance level

Table 15 Univariate GARCH(1,1) estimates for different time horizons

	ω	α	β	γ	Log-Likelihood	AIC

S&P 500		−0.0608	1.0209*	2.2234*	2953.6	−2.7932
NIKKEI 225		−0.0485	1.0232*	2.2854*	2008.5	−1.8982

Notes: The table summarizes the estimated coefficients produced by the univariate GARCH(1,1) model for short- and medium-term horizon series and EGARCH(1,1) model for long-term horizon series. The univariate variance estimates are introduced as inputs in the estimation process of the CCC, DCC, and cDCC models. The estimated coefficient ω denotes the constant term, α and β are the ARCH and GARCH terms, respectively, in the conditional variance equations, γ is the asymmetric parameter. The above estimates are for the sample period of 02 January 2003 to 04 February 2011. Significance levels at 1%, 5%, and 10% are denoted by *, **, and ***, respectively. Log-likelihood is the logarithm maximum likelihood function value. AIC is the Akaike information criterion

Table 16 CCC estimates under wavelet series

	Short-term			Medium-term			Long-term		
	FTSE 100	S&P 500	NIKKE 225	FTSE 100	S&P 500	NIKKE 225	FTSE 100	S&P 500	NIKKE 225

Long-term	0.831890 (0.0242) *	0.167528 (0.0244) *	43,104.5	−40.8247

Notes: This table reports the estimates parameters of DCC and cDCC models. Significance levels at 1%, 5%, and 10% are denoted by *, **, and ***, respectively. Log-likelihood is the logarithm maximum likelihood function value. AIC is the Akaike information criterion

$\theta_1 + \theta_2$ close to unity for the two models and at each scale, implying high persistent volatility in short-, medium- and long-term horizons. Based on DCC model, the degree of persistence, $\theta_1 + \theta_2$, are 0.997, 0.894, and 0.995 for short, medium, and long term, respectively. Based on cDCC model the degree of persistence is 0.997, 0.995, and 0.999 for the short, medium, and long terms, respectively. The short run persistence of shocks on dynamic conditional correlations is the greatest for high scales (0.594 and 0.831), while the largest long run persistence of shocks to conditional correlations is 0.997 (0.004 + 0.993) for low scales. We remark also that the short run persistence shocks increase by scales, while the long run persistence shocks decrease among scales.

The scale spillover effect in volatility provides strong persistence for all components (Short term, Medium term, and Long term); this phenomenon result from the trading of heterogeneous group of investors. In fact, at finest scales (Short term component), market participants are hedging strategists, speculators, and market makers. Therefore, they trade the three markets (the UK, USA, and Japan) simultaneously. Kim and In (2003) showed that speculators and market makers intensively trade to realize a quick profit (or minimize loss) over short timescales. In the intermediate scales (mid-horizon; Medium term component), the main traders are international portfolio managers who mainly follow index tracking trading strategies. Kim and In (2003) showed that trades typically occurs on a weekly to monthly basis, with little attention paid to daily prices. At high scales (Long-term component), the main traders are central banks, which operate on long-term horizons and often consider long-term economic fundamentals for their strategy.

The forecasting performance of the CCC, DCC, and cDCC models at each scale is evaluated by comparing the four statistical loss functions defined in Sect. 105.3.2. This forecasting study is based on recursive out-of-sample one-day ahead forecast of variance-covariance matrix of dynamic conditional models at each time horizon, i.e., Short-, Medium- and Long-term components. The “wavelet” volatility models are estimated based on 1863 observations corresponding to the period 02 January 2003 to 19 February 2010. The variables used in the models are: Short-, Medium-, and

Table 18 One-day out-of-sample volatility forecasts performance for different time horizons

	Forecast loss function			
	RMSE	MAE	MAPE	LLE
Panel A: Short-term				
CCC	1.488636	0.725253	5.076901	8.356644
DCC	1.488659	0.723788	5.050991	8.336478
cDCC	1.489430	0.7181159	4.958577	8.273333
Panel B: Medium-term

DCC	0.139241	0.082996	1.001749	24.865190
cDCC	0.139241	0.082996	1.001749	24.864380
Panel C: Long-term				
CCC	0.015626	0.012123	0.999986	73.91793
DCC	0.015626	0.012123	0.999986	73.91789
cDCC	0.015626	0.012123	0.999986	73.91788

Notes: The table summarizes the four loss metrics estimates at different time horizons. The RMSE,

MAE, MAPE, and LLE are defined as: $RMSE_k(j) = \sqrt{M^{-1} \sum_{m=1}^M (\zeta_{m,k}(j) - \hat{\sigma}_m^2(j))^2}$, $MAE_k(j) = M^{-1} \sum_{m=1}^M |\zeta_{m,k}(j) - \hat{\sigma}_m^2(j)|$, $MAPE_k(j) = M^{-1} \sum_{m=1}^M |(\zeta_{m,k}(j) - \hat{\sigma}_m^2(j)) / \hat{\sigma}_m^2(j)|$ and $LLE_k(j) = M^{-1} \sum_{m=1}^M [\log(\zeta_{m,k}(j)) - \log(\hat{\sigma}_m^2(j))]^2$, where $\zeta_{m,k}(j)$ denotes the wavelet volatility forecast generated by model k for the day m and scale j and $\hat{\sigma}_m^2(j)$ is the actual portfolio volatility on day m and scale j .

Long-term components. We compare the accuracy of wavelet volatility forecasts based on:

$$\begin{aligned}
 RMSE_k(j) &= \left\{ \frac{1}{M} \sum_{m=1}^M (\zeta_{m,k}(j) - \hat{\sigma}_m^2(j))^2 \right\}^{1/2} \\
 MAE_k(j) &= \frac{1}{M} \sum_{m=1}^M |\zeta_{m,k}(j) - \hat{\sigma}_m^2(j)| \\
 MAPE_k(j) &= \frac{1}{M} \sum_{m=1}^M \left| \frac{\zeta_{m,k}(j) - \hat{\sigma}_m^2(j)}{\hat{\sigma}_m^2(j)} \right| \\
 LLE_k(j) &= \frac{1}{M} \sum_{m=1}^M [\log(\zeta_{m,k}(j)) - \log(\hat{\sigma}_m^2(j))]^2
 \end{aligned}$$

where $\zeta_{m,k}(j)$ is the wavelet volatility forecast generated by model k for day m and scale j and $\hat{\sigma}_m^2(j)$ is the actual volatility on day m at scale j . The actual wavelet volatility is not observable; therefore we define three proxies of $\hat{\sigma}_m^2(j)$, such as: (Short-Term)², (Medium-Term)², and (Long-Term)², for the short-term horizon, medium-term horizon, and long-term horizon, respectively.

Table 19 Daily WVaR forecasts

	Mean WVaR α -level			
	1%	2.5%	5%	10%

Notes: The table presents the out-of-sample daily VaR of the weighted portfolio across wavelet scales. We used quantile for normal distribution

Table 18 summarizes the results of the one-day out-of-sample volatility forecast loss functions. We observe that, at low scales (Short-term component) and in terms of MAE, MAPE, and LLE criteria, the cDCC model provides better volatility forecasts, it has lower loss function values than CCC and DCC models. While, at intermediate scales (Medium-term component) and high scales (Long-term component), the three dynamic conditional correlation models show similar accuracy in one-day out-of-sample forecasts (the values of RMSE, MAE, and MAPE are equals).

Table 19 presents mean WVaR estimates for each of the dynamic conditional correlation models under 99%, 97.5%, 95%, and 90% confidence levels over the out-of-sample period from 22 February 2010, to 04 February 2011. This basic statistic can be shown as the preliminary understanding of average performance during the forecasting period before the implementation of backtesting tests and market risk loss criteria. As shown in Table 19, the WVaR estimates produced by the cDCC model at short-term horizon (low scales or high frequencies) are smaller than those of CCC and DCC models in 99%, 97.5%, 95%, and 90% confidence levels. For instance, at 99% confidence level, the average WVaR is 1.7455 for the cDCC model, while those of CCC and DCC are 1.7684 and 1.7641, respectively. We remark also that WVaR at medium-term horizon (intermediate scales) and long-term horizon (high scales or low frequencies) produced by the three models are equals, for each confidence level, 99%, 97.5%, 95%, and 90%. However, the mean WVaR decreases from lower scales to higher ones, such that, Short-term component (low scales/high frequencies) provides high WVaR estimates, followed by Medium-term (intermediate scales) component and Long-term (high scales/low frequencies) component, at all confidence levels.

To accurately compare the forecasting ability of the mentioned models in terms of WVaR,²

backtesting diagnostic tests: unconditional coverage of Kupiec (1995), conditional coverage of Christoffersen (1998), and dynamic quantile of Engle and Manganelli (2004) are introduced and used for determining the accuracy of wavelet model-based VaR measurements. We also used the regularity loss function of Lopez (1998) based on wavelet market risk (WVaR) defined before. It is defined in wavelet case as follows:

$$LF_{t+1}(j) = \begin{cases} 1 + (d_{t+1} - \text{VaR}_{t+1}(j)|\Omega_t)^2 & \text{if } d_{t+1} < \text{VaR}_{t+1}(j) | \Omega_t \\ 0 & \text{if } d_{t+1} \geq \text{VaR}_{t+1}(j) | \Omega_t \end{cases} \quad (22)$$

The statistical adequacy of the WVaR forecasts computed by the three dynamic conditional correlation models is obtained by the backtesting procedure described before: we will characterize the model as an adequate one for the volatility forecasting, if the null hypothesis cannot be rejected. The rejection of the null hypothesis indicates that the computed VaR estimates are not sufficiently accurate. Table 20 presents the summary backtesting statistics for the daily WVaR forecasts of wavelet return series. In terms of LR_{ucs} , LR_{ind} , LR_{cc} , and DQ statistics, the null hypothesis is rejected at 1%, 2.5%, and 5% significance level. According to these metrics, we cannot conclude whether an adequate multivariate model is more accurate than another one. The abovementioned backtesting tests focused on examining the accuracy of failure frequency and the independence of the failure process for VaR models. However, there are a large number of VaR models that can pass these statistical evaluation tests. How do risk managers choose among alternative VaR models? Which model will generate fewer regulatory capital requirements and induce less opportunity cost of capital? To answer these questions, we used a regulatory loss function related to market risk. Column 9 of Table 20 shows the mean loss function values. A WVaR model is preferred to another one, if it yields a lower averaging loss criterion value: $LF(j)$, defined as the sum of $LF_t(j)$, that is, $LF(j) = \sum_{t=1}^{n_0} LF_t(j)$. At 99%, 97.5%, and 95% confidence levels, $LF(j)$ statistic indicates that DCC and cDCC models provide strong WVaR performance (smaller $LF(j)$ values) than CCC model. We can note also that the three dynamic conditional correlation models have the same WVaR performance at medium-term (intermediate scales) and long-term (high scales) horizons for 99%, 97.5%, and 95% confidence levels.

²The multivariate GARCH-based WVaR estimate for one-day ahead forecasts are defined as follows:

$\text{VaR}_{t+m}^k(j) = \kappa' d_{t+m} + z_\alpha \zeta_{t+m}(j)$ where z_α denotes the normal quantile, $\kappa' d_{t+m}$ is the wavelet mean one-day ahead forecast estimate computed by forecasting VAR(1) based on wavelet components series. The wavelet weighted portfolio return is $d_t^{Pff} = \kappa' d_t$: $d_t = (d_{UK,t}, d_{US,t}, d_{JP,t})'$ denotes the vector of wavelet return components of FTSE 100 ($d_{UK,t}$), S&P 500 ($d_{US,t}$), and NIKKEI 225 ($d_{JP,t}$), $\kappa' = (\kappa_{UK}, \kappa_{US}, \kappa_{JP})$ is the vector of weights in the portfolio. $\zeta_t(j) = \kappa' H_t(j) \kappa$, where $H_t(j)$ is the wavelet conditional variance-covariance matrix defined in Sect. 105.2.3. Briefly, the wavelet conditional mean and wavelet conditional variance-covariance estimates are calculated from forecasting the model defined in Eq. 21.

Notes: The table presents the evaluation of out-of-sample daily WVaR for the wavelet details. It reports test statistics over the last 250 days (19 February 2010 to 03 February 2011). Exceedance: The term “exceedance” refers to an instance when portfolio losses are greater than corresponding VaR estimates in the backtest. In the literature, the terms “breaches” and “violations” are also used when referring to “exceedances.” Fail. prob.: The failure probability. LR_{uc}: The LR test of unconditional coverage. LR_{ind}: The LR test of independence. LR_{cc}: The joint test of coverage and independence. DQ: The Dynamic Quantile test. LF(j): The loss function. The respective critical values of LR_{uc} and LR_{cc} statistics at 5% significance level are 3.84 and 5.99

105.5 Conclusion

The empirical analysis in this chapter examined the co-movements and spillover effects in the stock market returns of three developed countries: the UK, USA, and Japan for the period 01 January 2003 to 04 February 2011. Three multivariate conditional correlation volatility models were used, namely, CCC model of Bollerslev (1990), DCC model of Engle (2002), and cDCC model of Aielli (2008). Empirical results show that multivariate estimates were significant for all returns in the CCC, DCC, and cDCC models. However, these models showed evidence of volatility spillovers and asymmetric effects of negative and positive shocks of equal magnitude on the conditional variances. The statistical significance of DCC and cDCC estimates indicates that the conditional correlations were dynamic. In fact, the variance-covariance analysis produced useful information on the dynamic correlations between the three developed markets, and for each pairwise series, the dynamic conditional correlations vary considerably from their respective constant correlations, implying the absence of any constant correlation between the stock markets under study. The empirical findings showed that the UK and US markets were highly correlated since the end of 2007 (the beginning of subprime crisis), followed by the UK and Japan markets and US and Japan markets. These results confirm the presence of spillover effects between pairwise stock market returns. The chapter also compared one-day ahead conditional volatility forecasts from the dynamic conditional correlation models used in the study, using 250 one-day out-of-sample forecasts, and showed that asymmetric cDCC model is preferred over the other models, according to the four used statistical loss metrics: mean squared error, mean absolute error, mean absolute percentage error, and logarithm loss error.

The chapter also combined the wavelet analysis and multivariate conditional volatility models to analyze the co-movements and volatility spillover effects in a multi-scale framework. Unlike the traditional multivariate dynamic conditional correlation volatility models, the wavelet-based dynamic conditional correlation approach allows one to decompose the spillover effect and co-movement into many sub-spillovers and sub-co-movements on various timescales according to heterogeneous groups of traders and investors. However, wavelet analysis helps investors to uncover the complex pattern of return and volatility spillovers on their own horizon and make a good hedging strategy on their risk. The findings of wavelet analysis show that multivariate estimates were significant for all wavelet time series. Moreover, wavelet-based multivariate models highlight volatility spillovers on the conditional variance for all stock markets under study. In fact, the wavelet study successfully decomposes the total spillover into sub-spillovers, respectively, for short-, mid-, and long-term horizons. The out-of-sample forecasts over wavelet scales are evaluated using four statistical loss functions and one-day ahead wavelet VaR (WVaR) forecast accuracy. The out-of-sample forecast results showed that high scales (Long-term component) provide smaller statistical loss metrics values than lower scales (Short-term component).

Cash Conversion Cycle and Corporate Performance: Global Evidence

106

Chong-Chuo Chang

Abstract

Previous studies have seldom explored issues regarding liquidity management; hence, we conduct a global empirical analysis of the relationship between the cash conversion cycle (CCC) and corporate performance by adopting enterprises from different countries as samples. We observe a negative relationship between the CCC and firm's profitability and value, supporting that an aggressive working capital policy can enhance corporate performance; however, this effect reduces or reverses when firms exist at the lower CCC level. Results remain identical after considering endogenous problems, changes in macroeconomic environments, economic development status, financial crises, corporate governance, and financial constraints.

106.1 Introduction

Finance theory discussion is generally related to one of the following categories: capital budgeting, capital structure, dividend policy, or working capital management (WCM). Although WCM is vital because of its impact on a firm's profitability and risk, and consequently its value (Smith 1980), it has received less attention than the other aforementioned categories. Jose et al. (1996) indicate that the day-to-day management of a firm's short-term assets and liabilities plays a crucial role in its success. Therefore, although WCM is short-term financial management, it often becomes a genuine source of profit. Kroes and Manikas (2014) suggest that cash flow management is a critical element of a firm's operational strategies. Working capital investment involves a trade-off between profitability and risk, and the balance between both factors is essential. Firms may have an optimal level of working capital that maximizes their value (Deloof 2003; Howorth and Westhead 2003). Decisions that can increase profitability can also increase risk; conversely, decisions that focus on risk reduction may reduce potential profitability (Filbeck and Krueger 2005; García-Teruel and Martínez-Solano 2007; Boisjoly et al. 2020; Sensini and Vazquez 2021). Tong and Wei (2011), He and Xiong (2012), Wang (2019), and Jalal and Khaksari (2020) also highlight the importance of WCM. De Vito and Gómez (2020) find that specifically during the COVID-19 pandemic, average firms with partial operating flexibility would exhaust their cash holdings in approximately two years when the environment is highly unfavorable. Therefore, during such a financial crisis, using firms' assets and liabilities efficiently is one of the appropriate solutions to mitigate financial problems (Zimon and Tarighi 2021).

Related literature suggests that an aggressive WCM policy can enhance a firm's performance. If the accounts receivable collection period is too long, the firm may face the risk of liquidity and payment recovery. Similarly, the firm may lose its inventory-carrying cost if the inventory conversion period is excessively increased. Increasing the payable deferral period may result in reduced payment stress. In addition, maintaining a high level of working capital leads to an opportunity cost if the firm relinquishes more profitable investments. Therefore, several studies have indicated that a reduced cash conversion cycle (CCC) can improve operating performance. For example, Hager (1976), Kamath (1989), Jose et al. (1996), Shin and Soenen (1998), Wang (2002), Deloof (2003), García-Teruel and Martínez-Solano (2007), Raheman and Nasr (2007), Uyar (2009), Baños-Caballero et al. (2012), Lee (2015), Oseifuah and Gyekye (2016), and Lin and Lin (2021) all indicate that an aggressive liquidity policy can enhance a firm's profitability and value. Furthermore, Soenen (1993) documented that a long CCC might be a primary reason for bankruptcy.

Other related studies have suggested a different viewpoint; that is, a firm's performance can be improved by a conservative WCM policy. Baños-Caballero et al. (2010), and Manikas and Patel (2016) asserted that a longer CCC may increase a firm's sales and profitability for several reasons: first, a firm can increase its sales by extending a higher trade credit that helps the firm to strengthen its relationships

with its customers (Ng et al. 1999). Second, larger inventories can prevent interruptions in the production process and loss of business because of the scarcity of products. In terms of accounts payables, companies may take advantage of crucial discounts for early payments if they reduce supplier financing (Ng et al. 1999; Wilner 2000). According to Czyzewski and Hicks (1992), firms with abundant cash can produce higher than average returns on assets. Afza and Nazir (2008) observe a negative relationship between a firm's profitability measures and the aggressiveness of its working capital investment; a firm yields negative returns if an aggressive working capital policy is adopted.

Based on the aforementioned findings, empirical studies on liquidity management have yielded mixed results. We conclude that the reason for this mixed result is that these studies have not conducted sufficiently thorough examinations and have not considered changes in macroeconomic environments, economic development status, financial crises, corporate governance, financial constraints, and endogeneity problems. Smith (1987), Blinder and Maccini (1991), Carpenter et al. (1994), Kashyap et al. (1994), and Michaelas et al. (1999) all indicate that changes in macroeconomic environments influence corporate liquidity. Klapper (2006) observes that the economic development status influences a business' accounts receivable by changing the credit policy. According to Céspedes et al. (2010), undeveloped financial markets and economies are volatile and allow few financing options for firms, which may influence decisions related to WCM. Campello et al. (2010) suggest that financial crises affect financial constraints and unconstrained corporate liquidity management.

The divergence in corporate governance, financial constraints, and endogeneity problems may also influence the relationship between liquidity and firm performance. Hail and Leuz (2006) observe that firms in countries with strong legal protection for investors tend to enjoy lower equity costs than firms in countries with weak legal protection for investors do. Chen et al. (2009) document that firms with strong firm-level corporate governance have lower capital costs, particularly those in countries with a weak legal protection. Shleifer and Wolfenzon (2002), Almeida et al. (2011), and Kusnadi and Wei (2011) all indicate that corporate governance influences capital costs and the changes in a firm's cash management policy. Riddiough and Wu (2009) identify substantial differences between the investment and liquidity management policies of firms and found that more (less) financially constrained firms exhibit high (low) investment and liquidity management sensitivity to variables that are measures of financial market friction. Ang and Smedema (2011) observe that firms do not always prepare for future recession because of financial constraints and low quantities of cash. According to Petersen and Rajan (1997), Shin and Soenen (1998), Opler et al. (1999), Wang (2002), Chiou et al. (2006), Bates et al. (2009), and Baños-Caballero et al. (2010), a firm's profitability and value also influence the WCM. The relationship between the CCC and corporate performance may suffer from endogeneity problems.

In the present study, we conducted a global empirical analysis of enterprises from different countries to investigate the relationship between WCM and firm's performance. We adopted the CCC as a proxy for WCM. To obtain robust results, we

considered endogenous problems, changes in macroeconomic environments, economic development status, financial crises, corporate governance, and financial constraints. The empirical results indicate that the CCC exhibits a negative relationship with firm's profitability and value, supporting that an aggressive working capital policy can enhance corporate performance; however, this effect reduces or reverses when firms exist at the lower CCC level. The results hold after accounting for various robustness checks.

The remainder of this chapter is arranged as follows: Sect. 106.2 describes the data and methodology; Sect. 106.3 presents the main results; and Sects. 106.4 and 106.5 consider endogeneity and robustness checks. The findings are summarized in Sect. 106.6.

106.2 Data and Methodology

106.2.1 Data

In this study, we conducted a global empirical analysis of the relationship between the CCC and corporate performance by adopting enterprises from different countries as samples. We apply financial statements and the market value of sample enterprises obtained from the Compustat Global Vantage database for the period of 1994–2011. Macroeconomic data are obtained from the World Bank database. We exclude firms with any segment in the financial industry (SIC 6000–6999) or the utility industry (SIC 4900–4999). To mitigate the effects of outliers and errors in the data, we omit the top and bottom one percentiles of all regression variables and firms with negative total assets, liabilities, and operating revenue account balances. The final sample includes 46 countries, 31,612 companies, and 266,547 firm-year observations.

106.2.2 Methodology

Following Soenen (1993), Deloof (2003), Padachi (2006), García-Teruel and Martínez-Solano (2007), and Baños-Caballero et al. (2010), we adopt the CCC as a proxy for WCM and a pooled ordinary least squares regression model to investigate the relationship between the CCC and corporate performance by adopting enterprises from different countries as samples. The specifications of the model are as follows:

$$\begin{aligned} IndAdjROA_{i,t} = & \beta_0 + \beta_1 IndAdjCCC_{i,t} + \beta_2 IndAdjCCC_{i,t} \times LowCCC_{i,t} \\ & + \beta_3 SIZE_{i,t} + \beta_4 DIV_{i,t} + \beta_5 CAPEXP_{i,t} + \beta_6 LEV_{i,t} + \beta_7 LagROA_{i,t} \\ & + \beta_8 RDR_{i,t} + \beta_9 STDROA_{i,t} + \beta_{10} MB_{i,t} + Industry\ dummies \\ & + Country\ dummies + Year\ dummies + \varepsilon_{i,t} \end{aligned}$$

(1)

$$\begin{aligned}
IndAdjTobin's\ Q_{i,t} = & \beta_0 + \beta_1 IndAdjCCC_{i,t} + \beta_2 IndAdjCCC_{i,t} \times LowCCC_{i,t} \\
& + \beta_3 SIZE_{i,t} + \beta_4 DIV_{i,t} + \beta_5 CAPEXP_{i,t} + \beta_6 LEV_{i,t} \\
& + \beta_7 LagROA_{i,t} + \beta_8 RDR_{i,t} + \beta_9 STDROA_{i,t} \\
& + Industry\ dummies + Country\ dummies \\
& + Year\ dummies + \varepsilon_{i,t}
\end{aligned} \tag{2}$$

where i denotes the firm, and t denotes the year. The CCC is calculated by adding the number of days of accounts receivable to the number of days of inventory and subtracting the number of days of accounts payable. The number of days of accounts receivable is calculated as the average accounts receivable divided by revenue per day. The number of days of inventory is calculated as the average inventory divided by the cost of goods sold per day. The number of days of accounts payable is calculated as the average accounts payable divided by the cost of goods sold per day. A shorter (longer) CCC indicates less (more) time between the outlay of cash and cash recovery, indicating that a firm is more likely to adopt an aggressive (conservative) WCM policy. The industry-adjusted CCC (*IndAdjCCC*) is calculated by subtracting the CCC from the industry median CCC in the corresponding year. We employ Fama-French 49-industry classification to group firms into industries. Following Aktas et al. (2015), we added an interaction term between the industry-adjusted CCC dummy and the industry-adjusted CCC ($IndAdjCCC \times LowCCC$) in the model. The industry-adjusted CCC dummy variable (*LowCCC*) equals 1 if the industry-adjusted CCC is negative and 0 otherwise. Return on assets (ROA) is a variable calculated by dividing the net income by the total assets. Tobin's Q is the ratio of the market value of equity added to the book value of debt, divided by the book value of the total assets.¹ *IndAdjROA* and *IndAdjTobin's Q* are the industry-adjusted ROA and Tobin's Q, respectively. *IndAdjROA* (*IndAdjTobin's Q*) is the ROA (Tobin's Q) subtracted from the industry median ROA (Tobin's Q) in the corresponding year.²

In accordance with related literature, we consider a set of control variables. Firm size (*Size*) is defined as the natural logarithm of the market value of equity (Core et al. 2006). Payout ratio (*DIV*) is defined as the ratio of dividends divided by the operating revenues (Lie 2005). *CAPEXP* denotes the ratio of capital expenditure and other investments divided by the total assets (McConnell and Muscarella 1985). Leverage (*LEV*) is defined as the ratio of the total debt divided by the total assets (Cho 1998; González 2013; Lin and Fu 2017; Pombo and Taborda 2017). *LagROA*

¹However, Peters and Taylor (2017) indicate that the OLS regressions exist two problems. The slopes on Tobin's Q are biased due to measurement error in Tobin's Q. Moreover, the OLS R^2 depends not just on how well Tobin's Q explains investment, but also on how well Tobin's Q proxies explain the true, unobservable Tobin's Q. To deal with these problems, Peters and Taylor (2017) reestimate the investment models using the Erickson et al. (2014) cumulant estimator, and their new Tobin's Q proxy is closer to the true Tobin's Q.

²We also perform regressions for dependent variable ROA and Tobin's Q (independent variable CCC), and obtain similar results. To save space, the results of dependent variable ROA and Tobin's Q (independent variable CCC) are not tabulated.

denotes the ROA of the previous year (Kim 2005; Lskavyan and Spatareanu 2006). *RDR* is the ratio of research and development expenditure divided by the total assets (Agrawal and Knoeber 1996; Morck et al. 1988; Doong et al. 2011). *STDROA* is the standard deviation of the ROA over the preceding 5-year period (Core et al. 1999). *MB* denotes the ratio of the market value of equity divided by the book value of equity (Core et al. 2006). We also account for time-invariant industry heterogeneity, time-invariant country heterogeneity, and time trends with a vector of industry-fixed effects, country-fixed effects, and year dummies (*Industry dummies*, *Country dummies*, and *Year dummies*, respectively). *Industry dummies*, *Country dummies*, and *Year dummies* denote the different industries, countries, and years presented in our sample, respectively. We also adjusted the standard errors for heteroskedasticity and autocorrelation using Newey and West (1987) correction.

106.3 Empirical Results

106.3.1 Preliminary Findings

106.3.1.1 Sample Description

Our sample includes 46 countries, 31,612 companies, and 266,547 firm-year observations (Table 1). The average CCC (*IndAdjCCC*) is 82.14 (12.20) days, and the average ROA, *IndAdjROA*, Tobin's *Q*, and *IndAdjTobin's Q* are 0.60%, −1.96%, 1.50, and 0.21, respectively. Japan and the United States exhibit the highest and second highest firm-year observations, accounting for 19.19% and 17.45% of the total sample size, respectively. Different countries exhibit various CCC levels. Greece exhibits the highest CCC, with a mean of 161.75 days, whereas Jordan exhibits the lowest CCC, with a mean of 21.07 days.

In accordance with Fama and French (1997), we also classified firms into 43 industries. Business services, electronic equipment, and retail are the industries with the three highest firm-year observations, accounting for 10.07%, 5.81%, and 5.60% of the total sample size, respectively (Table 2). Shipbuilding, tobacco products, and defense exhibit the lowest firm-year observations, accounting for 0.29%, 0.11%, and 0.08% of the total sample size, respectively. Different industries exhibit various CCC levels. Medical equipment exhibits the highest CCCs, for which ROA, *IndAdjROA*, Tobin's *Q*, and *IndAdjTobin's Q* are −4.16%, −6.07%, 2.31, and 0.43, respectively. Restaurants, hotels, and motels exhibit the lowest CCCs, for which ROA, *IndAdjROA*, Tobin's *Q*, and *IndAdjTobin's Q* are 2.51%, −0.67%, 1.42, and 0.16, respectively.

106.3.1.2 Regression Results for Each Country

Table 3 illustrates the relationship between the CCC and corporate performance for each country. In most countries, the CCC exhibits a negative relationship with firm performance. The CCCs of 40 countries, accounting for 86.96% of the total number of countries, exhibit negative relationships with industry-adjusted ROAs. Among these countries, the *IndAdjCCC* coefficients of 33 countries, accounting for 71.73% of all countries, attain significant levels. Moreover, the findings indicate that the

Table 1 Sample distribution, corporate performance, and CCC by country. This table presents the sample distribution and the mean values of ROA, *IndAdjROA*, Tobin's Q, *IndAdjTobin's Q*, CCC, and *IndAdjCCC* classified by country. ROA is a variable calculated by dividing the net income by the total assets. Tobin's Q is the ratio of the market value of equity added to the book value of debt, divided by the book value of the total assets. The CCC is calculated by adding the number of days of accounts receivable to the number of days of inventory and subtracting the number of days of accounts payable. *IndAdjROA*, *IndAdjTobin's Q*, and *IndAdjCCC* are industry-adjusted ROA, Tobin's Q, and CCC, respectively

Table 2 Sample distribution, corporate performance, and CCC by industry. This table presents the sample distribution and the mean values of ROA, *IndAdjROA*, Tobin's *Q*, *IndAdjTobin's Q*, CCC, and *IndAdjCCC* classified by industry. In accordance with Fama and French (1997), we classified firms into 43 industries. ROA is a variable calculated by dividing the net income by the total assets. Tobin's *Q* is the ratio of the market value of equity added to the book value of debt, divided by the book value of the total assets. The CCC is calculated by adding the number of days of accounts receivable to the number of days of inventory and subtracting the number of days of accounts payable. *IndAdjROA*, *IndAdjTobin's Q*, and *IndAdjCCC* are industry-adjusted ROA, Tobin's *Q*, and CCC, respectively

Table 3 The relationship between the CCC and corporate performance for each country.

This table presents the pooled ordinary least squares (OLS) method estimation results for the relationship between the CCC and corporate performance for each country. All regressions include an intercept, country dummies, and year dummies (unreported). The dependent variables are industry-adjusted ROA (*IndAdjROA*) ($\times 10^2$) and industry-adjusted Tobin's Q (*IndAdjTobin's Q*) ($\times 10^2$), respectively, which *IndAdjROA*(*IndAdjTobin's Q*) is the ROA (Tobin's Q) subtracted from the industry median ROA (Tobin's Q) in the corresponding year. ROA is a variable calculated by dividing the net income by the total assets. Tobin's Q is the ratio of the market value of equity added to the book value of debt, divided by the book value of the total assets. The independent variable, the industry-adjusted CCC (*IndAdjCCC*) is calculated by subtracting the CCC from the industry median CCC in the corresponding year. The CCC is calculated by adding the number of days of accounts receivable to the number of days of inventory and subtracting the number of days of accounts payable. Newey–West heteroskedasticity and autocorrelation-robust standard errors are reported in parentheses. ***, **, and * represent 1%, 5%, and 10% significance levels, respectively

CCCs of 31 countries, accounting for 67.39% of all countries, exhibit negative relationships with industry-adjusted Tobin's Q . Among these countries, the *IndAdjCCC* coefficients of 20 countries, accounting for 43.48% of all countries, attain significant levels. Among all countries, the CCC of Sweden exhibits the most significant effect on the *IndAdjROA*, for which the coefficient of *IndAdjCCC* is -0.0361 at a 1% significance level. The CCC of the United States exhibits the most significant negative effect on *IndAdjTobin's Q*, for which the coefficient of *IndAdjCCC* is -0.2370 at a 1% significance level.

106.3.1.3 Regression Results for Each Industry

Table 4 illustrates the relationship between the CCC and corporate performance for each industry. In most industries, the CCC exhibits a negative relationship with firm performance. The CCCs of 40 industries, accounting for 93.02% of the total number of industries, exhibit negative relationships with *IndAdjROA*. Among these industries, the *IndAdjCCC* coefficients of 36 industries, accounting for 83.72% of all industries, attain significant levels. Moreover, the results indicate that the CCCs of 31 industries, accounting for 72.09% of all industries, exhibit negative relationships with industry-adjusted Tobin's Q . Among these industries, the *IndAdjCCC* coefficients of 19 industries, accounting for 44.19% of all industries, attain significant levels. Among the various industries, the CCC of the candy and soda industry exhibits the most significant effect on the *IndAdjROA*, for which the coefficient of *IndAdjCCC* is -0.0363 at a 1% significance level. The CCC of personal services exhibits the most significant effect on *IndAdjTobin's Q*, for which the coefficient of *IndAdjCCC* is -0.1630 at a 1% significance level.

Table 4 The relationship between the CCC and corporate performance for each industry.

This table presents the pooled ordinary least squares (OLS) method estimation results for the relationship between the CCC and corporate performance for each industry. All regressions include an intercept, industry dummies, and year dummies (unreported). The dependent variables are industry-adjusted ROA (*IndAdjROA*) ($\times 10^2$) and industry-adjusted Tobin's Q (*IndAdjTobin's Q*) ($\times 10^2$), respectively, which *IndAdjROA*(*IndAdjTobin's Q*) is the ROA (Tobin's Q) subtracted from the industry median ROA (Tobin's Q) in the corresponding year. ROA is a variable calculated by dividing the net income by the total assets. Tobin's Q is the ratio of the market value of equity added to the book value of debt, divided by the book value of the total assets. The independent variable, the industry-adjusted CCC (*IndAdjCCC*) is calculated by subtracting the CCC from the industry median CCC in the corresponding year. The CCC is calculated by adding the number of days of accounts receivable to the number of days of inventory and subtracting the number of days of accounts payable. Newey–West heteroskedasticity and autocorrelation-robust standard errors are reported in parentheses. ***, **, and * represent 1%, 5%, and 10% significance levels, respectively

106.3.1.4 Differences in Corporate Performance Between High- and Low-CCC Firms

Table 5 illustrates the differences in corporate performance between firms that implement aggressive policies and those that implement conservative policies for WCM. We classify firms into two groups based on the median CCC (*IndAdjCCC*): low-CCC (*low-IndAdjCCC*) firms (below the median CCC [*IndAdjCCC*]; the aggressive liquidity policy group), and high-CCC (*high-IndAdjCCC*) firms (above the median of CCC [*IndAdjCCC*]; the conservative liquidity policy group). The mean and median variations are assessed using the t-test and the Wilcoxon rank-sum test. Based on various performance indicators, low-CCC (*low-IndAdjCCC*) firms exhibit higher mean and median values, both of which attain significant levels. The results indicate that firms with lower CCCs exhibit higher corporate performance; for example, the difference in the *IndAdjROA* mean (median) between *low-IndAdjCCC* firms and *high-IndAdjCCC* firms is 0.0096 (0.0017), both of which are statistically significant at a 1% significance level. The difference in *IndAdjTobin's Q* mean (median) between *low-IndAdjCCC* firms and *high-IndAdjCCC* firms is 0.0675 (0.0272), both of which are statistically significant at a 1% significance level.

106.3.2 Regression Results

After controlling for industry-fixed effects, country-fixed effects, year dummies, and related control variables, the results indicate that the *IndAdjCCC* for all regression models exhibits significantly negative relationships with *IndAdjROA* and *IndAdjTobin's Q* at a 5% significance level or better (Table 6). Therefore, firms can shorten their CCCs to increase profitability and value. These findings support that an aggressive liquidity policy can enhance a firm's operating performance and value. By contrast, a

Table 5 Difference in corporate performance between high- and low-CCC firms. This table presents the differences in corporate performance between high- and low-CCC firms. We compare the difference in the mean and median between the two samples based on the median CCC (*IndAdjCCC*): low-CCC/low-*IndAdjCCC* firms (below the median of *CCC/IndAdjCCC*), and high-CCC/high-*IndAdjCCC* firms (above the median of *CCC/IndAdjCCC*). ROA is a variable calculated by dividing the net income by the total assets. Tobin's Q is the ratio of the market value of equity added to the book value of debt, divided by the book value of the total assets. The CCC is calculated by adding the number of days of accounts receivable to the number of days of inventory and subtracting the number of days of accounts payable. *IndAdjROA*, *IndAdjTobin's Q*, and *IndAdjCCC* are industry-adjusted ROA, Tobin's Q, and CCC, respectively. Differences in the mean and median are assessed using the t-test and the Wilcoxon rank-sum test. ***, **, and * represent 1%, 5%, and 10% significance levels, respectively

Panel A. The sample firms are classified into two groups based on CCC				
		Low CCC firms	High CCC firms	The difference of mean and median
<i>IndAdjROA</i>	Mean	0.0023	-0.0022	0.0045***
	Median	0.0076	0.0067	0.0010***
<i>IndAdjTobin's Q</i>	Mean	0.0357	-0.0342	0.0699***
	Median	-0.0849	-0.1189	0.0340***
Panel B. The sample firms are classified into two groups based on <i>IndAdjCCC</i>				
		Low <i>IndAdjCCC</i> firms	High <i>IndAdjCCC</i> firms	The difference of mean and median
<i>IndAdjROA</i>	Mean	0.0042	-0.0055	0.0096***
	Median	0.0079	0.0062	0.0017***
<i>IndAdjTobin's Q</i>	Mean	0.0292	-0.0383	0.0675***
	Median	-0.0943	-0.1215	0.0272***

conservative WCM policy can harm a firm's performance. Moreover, the results indicate that the interaction term (*IndAdjCCC* $\times$ *LowCCC*) is significantly positive at a 1% significance level, suggesting that the negative relationships between CCC and the firm's performance diminish or reverse when the industry-adjusted CCC is below 0. This finding indicates that firms can shorten their CCC to increase profitability and value; however, this effect reduces or reverses when firms exist at the lower CCC level. The sum of the coefficients of the interaction term (*IndAdjCCC* $\times$ *LowCCC*) and *IndAdjCCC* for *IndAdjTobin's Q* is positive. From this result, we can infer that CCC has a significantly positive relationship with firm value for extremely low CCC firms.³

Table 6 also indicates that *Size* exhibits significantly positive relationships with *IndAdjROA* and *IndAdjTobin's Q*, implying that larger firms exhibit higher

³ We also test whether the relation between ROA (Tobin's Q) and CCC for low CCC and high CCC firms is different. We divide the sample countries into two groups based on the CCC industry median. The results indicate that the *IndAdjCCC* for high CCC firms (i.e., value is above industry median) exhibit significantly negative relationships with *IndAdjROA* and *IndAdjTobin's Q* at a 5% significance level or better. However, the results show that the *IndAdjCCC* for low CCC firms (i.e., value is below industry median) exhibit significantly positive (negative) relationships with *IndAdjTobin's Q* (*IndAdjROA*). These findings support the results of the interaction term.

Table 6 The relationship between the CCC and corporate performance for all countries. This table presents the pooled ordinary least squares (OLS) method estimation results for the relationship between the CCC and corporate performance for all countries. All regressions include an intercept, industry dummies, country dummies, and year dummies (unreported). The dependent variables are industry-adjusted ROA (*IndAdjROA*) ($\times 10^2$) and industry-adjusted Tobin's Q (*IndAdjTobin's Q*) ($\times 10^2$), respectively, which *IndAdjROA*(*IndAdjTobin's Q*) is the ROA (Tobin's Q) subtracted from the industry median ROA (Tobin's Q) in the corresponding year. ROA is a variable calculated by dividing the net income by the total assets. Tobin's Q is the ratio of the market value of equity added to the book value of debt, divided by the book value of the total assets. The independent variable, the industry-adjusted CCC (*IndAdjCCC*) is calculated by subtracting the CCC from the industry median CCC in the corresponding year. The CCC is calculated by adding the number of days of accounts receivable to the number of days of inventory and subtracting the number of days of accounts payable. The interaction term (*IndAdjCCC* $\times$ *LowCCC*) is calculated by multiplying the industry-adjusted CCC dummy (*LowCCC*) and industry-adjusted CCC (*IndAdjCCC*). The industry-adjusted CCC dummy variable (*LowCCC*) equals 1, if the industry-adjusted CCC is negative and 0 otherwise. Firm size (*Size*) is defined as the natural logarithm of the market value of equity. Payout ratio (*DIV*) is defined as the ratio of dividends divided by the operating revenues. *CAPEXP* denotes the ratio of capital expenditure and other investments divided by the total assets. Leverage (*LEV*) is defined as the ratio of the total debt divided by the total assets. *LagROA* denotes the ROA of the previous year. *RDR* is the ratio of research and development expenditure divided by the total assets. *STDROA* is the standard deviation of the ROA over the preceding 5-year period. *MB* denotes the ratio of the market value of equity divided by the book value of equity. Newey–West heteroskedasticity and autocorrelation-robust standard errors are reported in parentheses. ***, **, and * represent 1%, 5%, and 10% significance levels, respectively

<i>F-value</i>	689.27***	683.65***	292.70***	252.16***

performance. *DIV* exhibits significantly positive relationships with the two types of firm performance variables. The coefficients of *CAPEXP* (*LagROA*) for *IndAdjROA* and *IndAdjTobin's Q* are significantly positive at a 1% significance level, suggesting that higher capital expenditure (previous ROA) can increase a firm's performance. *LEV* exhibits a significantly negative association with performance measures, denoting that an increase in financial leverage may reduce a firm's performance. *STDROA* exhibits a significantly negative relationship with *IndAdjROA*, but a positive relationship with *IndAdjTobin's Q*. *RDR* exhibits a negative relationship with *IndAdjROA* but is expected to increase a firm's value. Thus, *RDR* exhibits a positive relationship with *IndAdjTobin's Q*. The coefficients of *MB* for *IndAdjROA* are positive and statistically significant at a 1% significance level, implying that growth firms (i.e., high *MB* firms) achieve high profitability.

106.4 Endogeneity

According to Petersen and Rajan (1997), Shin and Soenen (1998), Opler et al. (1999), Wang (2002), Chiou et al. (2006), Bates et al. (2009), and Baños-Caballero et al. (2010), a firm's profitability and value can influence the WCM. We adopt the following two approaches to address endogeneity problems: a three-stage least squares (3SLS) method and the generalized method of moments (GMM).

106.4.1 Three-Stage Least Squares

To control for the potential effects of profitability and value on the CCC, we estimate two pairs of equations simultaneously using a 3SLS procedure: Eqs. (3) and (4) and Eqs. (5) and (6):

$$\begin{aligned}
IndAdjROA_{i,t} = & \beta_0 + \beta_1 IndAdjCCC_{i,t} + \beta_2 IndAdjCCC_{i,t} \times LowCCC_{i,t} \\
& + \beta_3 SIZE_{i,t} + \beta_4 DIV_{i,t} + \beta_5 CAPEXP_{i,t} + \beta_6 LEV_{i,t} + \beta_7 LagROA_{i,t} \\
& + \beta_8 RDR_{i,t} + \beta_9 STDROA_{i,t} + \beta_{10} MB_{i,t} + Industry\ dummies \\
& + Country\ dummies + Year\ dummies + \varepsilon_{i,t}
\end{aligned}
\tag{3}$$

$$\begin{aligned}
IndAdjCCC_{i,t} = & \beta_0 + \beta_1 IndAdjROA_{i,t} + \beta_2 SIZE_{i,t} + \beta_3 LEV_{i,t} + \beta_4 SG_{i,t} \\
& + \beta_5 STDSALES_{i,t} + \beta_6 CF_{i,t} + \beta_7 FA_{i,t} + \beta_8 DISTRESS_{i,t} \\
& + Industry\ dummies + Country\ dummies + Year\ dummies + \varepsilon_{i,t}
\end{aligned}
\tag{4}$$

$$\begin{aligned}
IndAdjTobin's\ Q_{i,t} = & \beta_0 + \beta_1 IndAdjCCC_{i,t} + \beta_2 IndAdjCCC_{i,t} \times LowCCC_{i,t} \\
& + \beta_3 SIZE_{i,t} + \beta_4 DIV_{i,t} + \beta_5 CAPEXP_{i,t} + \beta_6 LEV_{i,t} + \beta_7 LagROA_{i,t} \\
& + \beta_8 RDR_{i,t} + \beta_9 STDROA_{i,t} + Industry\ dummies \\
& + Country\ dummies + Year\ dummies + \varepsilon_{i,t}
\end{aligned}
\tag{5}$$

$$\begin{aligned}
IndAdjCCC_{i,t} = & \beta_0 + \beta_1 IndAdjTobin's\ Q_{i,t} + \beta_2 SIZE_{i,t} + \beta_3 LEV_{i,t} \\
& + \beta_4 SG_{i,t} + \beta_5 STDSALES_{i,t} + \beta_6 CF_{i,t} + \beta_7 FA_{i,t} \\
& + \beta_8 DISTRESS_{i,t} + Industry\ dummies + Country\ dummies \\
& + Year\ dummies + \varepsilon_{i,t}
\end{aligned}
\tag{6}$$

In accordance with Myers and Majluf (1984), Emery (1987), Whited (1992), Fazzari and Petersen (1993), Petersen and Rajan (1997), Chiou et al. (2006), Kieschnich et al. (2006), Cuñat (2007), Uyar (2009), Molina and Preve (2009), Baños-Caballero et al. (2010), and Hill et al. (2010), we set the control variables in Eqs. (4) and (6) to include *Size*, *SG*, *LEV*, *STDSALES*, *CF*, *FA*, *DISTRESS*, *Industry dummies*, *Country dummies*, and *Year dummies*. *Size* is defined as the natural logarithm of the market value of equity; *SG* represents the percentage changes in operating revenues in the previous year. *STDSALES* represents the standard deviation of operating revenue over the preceding 5-year period. *LEV* is defined as the ratio of the total debt divided by the total assets. *CF* represents the ratio of the net income added to depreciation divided by the total assets. *FA* is calculated as the ratio of tangible fixed assets to total assets. *DISTRESS* is equal to 1 if a firm fulfills the definition of financial distress, proposed by Molina and Preve (2009) and is 0 otherwise.⁴

⁴In accordance with Molina and Preve (2009), a firm must satisfy two criteria to be classified as financially distressed. First, a coverage ratio is calculated as the operating income before depreciation divided by an interest expense of less than one for 2 consecutive years or less than 0.80 in any given year. Second, a firm is considered overleveraged if its leverage ratio is in the top two deciles of the leverage ratio of its industry in a given year.

Table 7 The relationship between corporate performance and the CCC: 3SLS method of estimation. This table presents the 3SLS estimation results for the relationship between the CCC and corporate performance for all countries. All regressions include an intercept, industry dummies, country dummies, and year dummies (unreported). The dependent variables are industry-adjusted ROA (*IndAdjROA*) and industry-adjusted Tobin's Q (*IndAdjTobin's Q*), respectively, which *IndAdjROA(IndAdjTobin's Q)* is the ROA (Tobin's Q) subtracted from the industry median ROA (Tobin's Q) in the corresponding year. ROA is a variable calculated by dividing the net income by the total assets. Tobin's Q is the ratio of the market value of equity added to the book value of debt, divided by the book value of the total assets. The independent variable, the industry-adjusted CCC (*IndAdjCCC*) is calculated by subtracting the CCC from the industry median CCC in the corresponding year. The CCC is calculated by adding the number of days of accounts receivable to the number of days of inventory and subtracting the number of days of accounts payable. The interaction term (*IndAdjCCC* $\times$ *LowCCC*) is calculated by multiplying the industry-adjusted CCC dummy (*LowCCC*) and industry-adjusted CCC (*IndAdjCCC*). The industry-adjusted CCC dummy variable (*LowCCC*) equals 1 if the industry-adjusted CCC is negative and 0 otherwise. *Size*, *DIV*, *CAPEXP*, *LEV*, *LagROA*, *RDR*, *STDROA*, and *MB* are defined in Table 6. *SG* represents the percentage changes in operating revenues in the previous year. *STDSALES* represents the standard deviation of operating revenues over the preceding 5-year period. *CF* represents the ratio of the net income added to depreciation divided by the total assets. *FA* is calculated as the ratio of tangible fixed assets to total assets. *DISTRESS* is equal to 1 if a firm fulfills the definition of financial distress proposed by Molina and Preve (2009) and is 0 otherwise. Standard errors are reported in parentheses. ***, **, and * represent 1%, 5%, and 10% significance levels, respectively

<i>Adjusted R²</i>	0.0051	0.0351	0.0059	0.0401
<i>F-value</i>	10.68***	71.17***	12.15***	80.43***

The results of 3SLS estimation indicate that *IndAdjCCC* continues to exhibit significantly negative relationships with *IndAdjROA* and *IndAdjTobin's Q* at a 1% significance level, and the coefficient of the interaction term *IndAdjCCC* $\times$ *LowCCC* remains significantly positive (Table 7). These results support that aggressive WCM policy can enhance corporate performance.⁵ However, the negative relationships between CCC and the firm's performance diminish or reverse when the industry-adjusted CCC is below 0. Column (2) also indicates that *IndAdjROA* exhibits a significantly positive relationship with *IndAdjCCC*, suggesting that firms with higher returns on assets have higher CCCs.

106.4.2 Generalized Method of Moments

To robustly avoid endogeneity problems, we apply the GMM methodology of Arellano and Bond (1991). They suggest applying the differences as the first step and using suitable lagged levels of dependent variables as instruments to control endogeneity as the second step. The results indicate that the *IndAdjCCC* (*IndAdjCCC* $\times$ *LowCCC*) exhibits significantly negative (positive) relationships with the two types of firm performance variables at a 1% significance level. These

⁵We also perform regressions for dependent variable ROA and Tobin's Q (independent variable CCC), and obtain similar results. We do not tabulate the results of dependent variable ROA and Tobin's Q (independent variable CCC).

findings imply that a shortened working cycle can increase firm performance, and this effect reduces or reverses when firms exist at the lower CCC level.⁶

106.5 Robustness Checks

106.5.1 Macroeconomic Environment

Existing literature indicates that macroeconomic changes influence the WCM policy and liquidity. Michaelas et al. (1999) suggest that small businesses rely more heavily on short-term financing, rendering them more sensitive to macroeconomic changes. Smith (1987) argues that the state of the economy influences the level of accounts receivable. Blinder and Maccini (1991) observe that recessions are related to severe inventory reductions. Hence, the influence of the CCC on a firm's performance may differ under the circumstances of economic boom or economic recession. In accordance with Blinder and Maccini (1991), Michaelas et al. (1999), and Booth et al. (2001), we adopt *GDPG* and *INFLATION* to divide the sample firms into two groups based on the macroeconomic variable median for each year (above/below the median), namely, the high *GDPG* (*INFLATION*) group and the low *GDPG* (*INFLATION*) group. We subsequently rerun Eqs. (1) and (2) to control the influence of macroeconomic changes on CCC. *GDPG* denotes the annual growth rate of real per capita GDP. *INFLATION* is the annual growth rate of the consumer price index.

After controlling changes in macroeconomic factors, our conclusion remains unchanged. *IndAdjCCC* (*IndAdjCCC* $\times$ *LowCCC*) exhibits significantly negative (positive) relationships with *IndAdjROA* and *IndAdjTobin's Q* in both high and low *GDPG* groups. Moreover, *IndAdjCCC* (*IndAdjCCC* $\times$ *LowCCC*) exhibits a significantly negative (positive) relationship with *IndAdjROA* in both high and low *INFLATION* groups. The results support that an aggressive operating WCM policy can increase a firm's performance, and this effect diminishes or reverses when firms exist at the lower CCC level.⁷

106.5.2 Economic Development Status

Klapper (2006) observes that the economic development status influences a business' accounts receivable by changing the credit policy. Céspedes et al. (2010) indicate that debt markets in Latin American are small and inefficient, allowing firms only limited debt options such as long-term bonds. Moreover, debt costs are

⁶We also perform regressions for dependent variable ROA and Tobin's Q (independent variable CCC), and obtain similar results. We do not tabulate the results of dependent variable ROA and Tobin's Q (independent variable CCC).

⁷We also perform regressions for dependent variable ROA and Tobin's Q (independent variable CCC), and obtain similar results. In the described robustness checks, to save space, we do not tabulate the results of dependent variable ROA and Tobin's Q (independent variable CCC).

high for average firms in the region. Consequently, the influence of the CCC on firm performance can vary between developed and developing economies.

To control this scenario, we divide the sample countries into two groups: developed economies and developing economies and rerun Eqs. (1) and (2). The economic development status (developed economies versus developing economies) is classified according to the World Bank.⁸ The results illustrate the relationship between *IndAdjCCC* and a firm's performance for both developed and developing economies. For both, the coefficients of *IndAdjCCC* for *IndAdjROA* and *IndAdjTobin's Q* remain significantly negative, indicating that the CCCs exhibit negative relationships with profitability and value.⁹ Moreover, the results indicate that the interaction term (*IndAdjCCC* $\times$ *LowCCC*) is significantly positive at the 1% level, suggesting that the negative relationships between CCC and the firm's performance diminish or reverse when the industry-adjusted CCC is below 0.

106.5.3 Financial Crises

Campello et al. (2010) surveyed 1050 Chief Financial Officers in 39 countries in North America, Europe, and Asia to directly assess whether the officers' respective firms were credit-constrained during the global financial crisis of 2008. They observed that during the crisis, financially constrained firms planned to cut investment, technology, marketing, and employment at a higher rate than financially unconstrained firms did. They also indicate that constrained firms were forced to employ a sizeable portion of their cash savings during the crisis, and to significantly cut their planned dividend distributions.

The influence of CCCs on firm performance can be different between financial crisis and nonfinancial crisis periods. We divide the sample countries into two groups: financial crisis period and nonfinancial crisis period and rerun Eqs. (1) and (2). The financial crisis period denotes the period during which a country experiences a banking or currency crisis, for which the dates are provided by Reinhart and Rogoff (2011). The results still support that an aggressive WCM policy can increase firm performance; however, this effect reduces or reverses when firms exist at the lower CCC level.¹⁰

⁸We also use alternative classifications from the Human Development Index of the United Nations Development Program and the International Monetary Fund. The results are similar.

⁹We also perform regressions for dependent variable ROA and Tobin's Q (independent variable CCC), and obtain similar results. In the described robustness checks, to save space, we do not tabulate the results of dependent variable ROA and Tobin's Q (independent variable CCC).

¹⁰We also perform regressions for dependent variable ROA and Tobin's Q (independent variable CCC), and obtain similar results. In the described robustness checks, to save space, we do not tabulate the results of dependent variable ROA and Tobin's Q (independent variable CCC).

106.5.4 Corporate Governance

Hail and Leuz (2006) observe that firms in countries with strong legal protection for investors tend to enjoy lower equity costs than firms in countries with weak legal protection for investors do. Chen et al. (2009) documented that firms with strong firm-level corporate governance have lower capital costs, particularly those in countries with weak legal protection. Shleifer and Wolfenzon (2002), Almeida et al. (2011), Kusunadi and Wei (2011), and Kuan et al. (2012) all indicate that corporate governance influences capital costs and the changes in a firm's cash management policy.

To control for the effects of divergence in corporate governance on the relationship between liquidity and firm performance, we divided the sample countries into two groups based on the corporate governance variable median (above and below the median): the high level of anti-self-dealing (anti-director) index group and the low level of anti-self-dealing (anti-director) index group. We rerun Eqs. (1) and (2). The anti-self-dealing and anti-director exhibit high numbers, and both indicate strong investor protection. The anti-self-dealing index and the anti-director index were constructed by Djankov et al. (2008). These indices measure minority shareholder protection against the actions of the controlling shareholder that may hurt the shareholder value at the country level. The results provide evidence of the negative relationship between the CCC and firm performance classified by corporate governance, indicating that firms can shorten their CCC to improve performance.¹¹ However, the negative relationships between CCC and the firm's performance diminish or reverse when the industry-adjusted CCC is below 0.

106.5.5 Financial Constraints

Riddiough and Wu (2009) identify substantial differences between the investment and liquidity management policies of firms and found that more (less) financially constrained firms exhibit high (low) investment and liquidity management sensitivity to variables that are measures of financial market friction. Ang and Smedema (2011) observe that firms do not always prepare for future recession because of financial constraints and low quantities of cash.

To control the financially constrained effect on the relationship between the CCC and firm performance, we divided the sample firms into two groups: the financially constrained group and the financially unconstrained group and rerun Eqs. (1) and (2). Luo (2011) and Lin et al. (2013) suggest that larger firms are generally viewed as less financially constrained than smaller ones are. Fazzari et al. (1988) and Tsai (2014) argue that unconstrained firms are more likely to exhibit higher payout

¹¹ We also perform regressions for dependent variable ROA and Tobin's Q (independent variable CCC), and obtain similar results. In the described robustness checks, to save space, the results of the dependent variable ROA and Tobin's Q (independent variable CCC) are not tabulated.

ratios than constrained firms are. For each country and year, we classify firms into two groups based on the median firm size and dividend payout: small or low dividend payout firms (below the median) are classified as the financially constrained group, whereas large or high dividend payout firms (above the median) are classified as the financially unconstrained group. The results indicate that in both the financially constrained and financially unconstrained groups, *IndAdjCCC* ($IndAdjCCC \times LowCCC$) exhibits significantly negative (positive) relationships with two types of firm performance variables, thereby supporting that an aggressive liquidity management policy can enhance firm performance, and this effect reduces or reverses when firms exist at the lower CCC level.¹²

106.6 Conclusion

WCM is crucial for a firm's operating performance and corporate value. However, most existing literature on corporate finance has discussed issues regarding the relationship between long-term financial decisions, such as capital structure and capital expenditure, and corporate performance. Previous studies have seldom explored issues regarding liquidity management; hence, we conducted a global empirical analysis of the relationship between the cash conversion cycle (CCC) and corporate performance by adopting enterprises from different countries as samples.

Our sample consists of 46 countries, 31,612 companies, and 266,547 firm-year observations for the period of 1994–2011. The results indicate that industry-adjusted CCCs exhibit significantly negative relationships with industry-adjusted ROAs and industry-adjusted Tobin's Q, and that the negative relationships diminish or reverse when industry-adjusted CCC is below 0. This finding indicates that firms can shorten their CCC to increase profitability and value; however, this effect reduces or reverses when firms exist at the lower CCC level. Furthermore, the results remain unchanged after accounting for endogeneity and controlling for changes in macroeconomic environments, economic development status, financial crises, corporate governance, and financial constraints.

The CCC of WCM is a widely used metric for gauging the effectiveness of a firm's management and the intrinsic need for external financing (Wang 2019). Jalal and Khaksari (2020) suggest that short-term financial management is one of the three most important responsibilities of corporate financial managers, along with capital budgeting and long-term financing activities. Our study contributes to understanding the relationship between CCCs and firm performance, which can consequently help firms establish financial policies. Therefore, WCM is vital because of its impact on

¹² We also perform regressions for dependent variable ROA and Tobin's Q (independent variable CCC), and obtain similar results. In the described robustness checks, to save space, we do not tabulate the results of dependent variable ROA and Tobin's Q (independent variable CCC).

firm performance. The results also can help multinational companies to determine allocation proportions for short-term assets and capital.

How Consistent Are the Judges of Portfolio Performance?

107

Matthew Brigida, Chin W. Yang, and Ken Hung

Abstract

This analysis tests whether the rank ordering of a set of portfolios, with varying number of assets, differs depending on the performance measure used. To test this hypothesis, we construct a Friedman test over 4950 portfolios (50 portfolios for each portfolios sizes 2–100) of S&P 500 stocks. We find that while measures may differ in their sensitivity to portfolio size, all measures consistently prefer larger portfolios. Therefore, the rank ordering of a set of portfolios of various sizes is consistent across performance measures.

107.1 Introduction

The goal of this analysis is to compare the rankings of four popular portfolio performance measures as portfolio size increases. These measures considered are the Sharpe ratio (Sharpe [1966]), information ratio (Goodwin [1988]), Treynor ratio (Treynor [1965]), and Jensen's alpha (Jensen [1969]). Note, these are four unique measures – they are not linear transformations of each other.

This analysis is intended to assist practitioners (portfolio managers and other investment professionals) when ranking portfolios of differing sizes. Specifically, it will give them a better understanding of how a varying number of assets in a set of potential portfolios will affect the rank ordering of the set provided by each performance measure. Thus, given a set of portfolios of differing sizes, this analysis will answer the question: Is the rank ordering of this set of portfolios dependent on the performance measure used?

Note our focus on ranks and not the value of the performance measure. First, values of one performance measure cannot be compared to another. Moreover, for practical purposes, it is the ranking of the portfolios which matters, and not the comparative values of the performance measures. So to compare the behavior of various measures, we compare the respective rankings they provide, and test whether these rankings are statistically different among performance measures.

Previous studies have shown portfolio managers may trade in such way as to increase the value of performance measures, despite not having any private information. For example, Ferson and Siegel (2001) and Lhabitabt (2000) use separate methods to increase the value of a portfolio's Sharpe ratio. We do not consider such trading strategies, since the portfolio manager is using the measures as a way to rank portfolios for potential investment.

107.2 Construction

Our dataset consists of daily log returns for every stock in the S&P 500 index, as well as returns for major indices themselves (S&P 500, Wilshire 5000, Dow Jones Industrial Average, etc.) over the 3 years beginning January 2010 and ending December 2012. The log returns were calculated using stock price data from interactive brokers.

First, we created 50 random portfolios of size two from the set of stocks in the S&P 500. We then calculate each performance measure for each of the 50 random portfolios. We repeat this procedure for portfolio sizes up to 100. This gives us the performance measure values for each of the 50 random portfolios for each portfolio size 2–100 (4950 portfolios).

We then rank the 4950 portfolios using each measure. So for each performance measure we have a ranking of the random portfolios from 1 to 4950, where 1 denoted the portfolio with the highest ranking (most preferred). Letting $r_{n,i}$ denote the rank of the i^{th} portfolio of size n (where $2 \leq n \leq 50$). Then $r_{n,i}$ is an integer between 1 and 4950 inclusive.

Lastly for each portfolio size we sum the ranks of the portfolios of that size (for each n denote this as $\varphi_n = \sum_{i=1}^{50} r_{n,i}$). So for all 99 portfolio sizes we have a sum of the rankings of the 50 random portfolios of that size (φ_n) for each portfolio measure.

This methodology allows us to compare how each portfolio measure ranking changes as the portfolio size changes. A plot of the sum of each ranking (φ_n) for each measure, over the 99 portfolio sizes, is in Fig. 1 below. Figure 1 also contains a linear trendline showing how each portfolio measure is affected by increasing portfolio size.

The figure shows that the Sharpe and information ratios are more sensitive to portfolio size than the Treynor ratio and Jensen’s alpha. We see that, on average, φ_n is 493 and 330 less than φ_n for the Sharpe and information ratios, respectively. This compares with 27 and 15 for the Treynor ratio and Jensen’s alpha, respectively.

Note that a decrease in φ_n means an increase in rank (because for each portfolio measure the highest value has rank 1 and lowest value rank 4950). Thus, our results so far are evidence that Sharpe and information ratios have a tendency to give a higher rank to larger portfolios. The Treynor ratio and Jensen’s alpha have the same tendency, though to a much less degree.

Fig. 1 Sum of portfolio rankings over portfolio sizes 1–100 with trendlines. The negative slope of each trendline shows that each portfolio measure tends to rank larger portfolios higher

107.3 The Friedman Test

In this section we will formally test whether the portfolio measures form consistent rankings of the portfolios. We may think of each portfolio measure as a judge, and each portfolio as a contestant. We wish to test whether each judge will rank the contestants consistently across portfolio sizes. Or rather, we are testing whether a particular judge has a bias toward large, or small, portfolios.

To test this we will use the Friedman test (Friedman 1937, 1939, 1940) which is designed to test whether judges' ranking are consistent with one another. A classic example is to test whether n judges rank k wines consistently. In our case the n judges are our portfolio measures, and the k wines are our 4950 portfolios. Note, the Friedman test is nonparametric, which is necessary given nonnormality of some performance measures.

To conduct the Friedman test we sum the sum of rankings over each portfolio measure, for each portfolio size. For example, consider the 3 stock portfolio size in Table 1 below. We sum each column across the performance measures, and have a sum of $151,887 + 135,609 + 116,304 + 105,176 = 508,976$. For each portfolio size we denote this value as ϖ_n .

The null hypothesis is that the average ranking is equal across all portfolio sizes, that is, $\varpi_2 = \varpi_3 = \dots = \varpi_{100}$. Under this null hypothesis our test statistic $Q = \frac{12S}{nk\lambda^2(n\lambda+1)} X_{n-1}^2$, where n is the number of portfolios (here 99), k is the number of performance measures (here 4), λ is the number of repetitions (here 50), and $S = \sum_{w_i=2}^{100} \varpi_i^2 - \frac{k^n \lambda^2 (n\lambda+1)^2}{4}$.

If we reject the null of the Friedman test, this is evidence that the judges consistently rank the contestants. Conversely if we cannot reject the null this is evidence that the rankings are inconsistent.

107.3.1 Results

Using the Friedman test, from portfolio size 2–100, we reject the null at the less than 0.1% level of significance (the test statistic $Q = 462.67$). This is evidence that all judges are on average ranking the portfolios consistently, that is, all judges consistently prefer larger portfolios. Further, the null hypothesis is also rejected if the test is run over any set of 10 consecutive portfolio sizes.

Table 1 Structure of Friedman test

Measure/portfolio size	2	3	4	...	100
Sharpe ratio	171,463	151,887	142,251	...	104,580
Information ratio	147,382	135,609	131,635	...	108,492
Treynor ratio	118,937	116,304	129,489	...	116,066
Jensen's alpha	114,552	105,176	122,702	...	119,816
ϖ_n	552,334	508,976	526,077	...	448,954

107.4 Conclusion

Our four portfolio measures are consistent in their preference for larger portfolios, i.e., the measures are affected by portfolio size, but in a consistent manner. They only differ in their sensitivities to portfolio size. That is, the portfolio rankings provided by the Sharpe and information ratios afford a greater preference for larger portfolios than do the Treynor ratio and Jensen's alpha.

In sum, however, the answer to our question posed above is: On average, the rank ordering of a given set of portfolios of differing numbers of assets is not dependent on the performance measure used. That is, while these are four unique measures, each of the performance measures is in itself adequate.

Risk Aversion and the Value of Information for Investors

108

Richard E. Kihlstrom

Abstract

The chapter provides a selective survey of the literature relating risk aversion to the value of information. The focus is on several papers, Cabrales et al. (*American Economic Review* 103:360–77, 2013; *Journal of Economic Theory* 170:266–288, 2017) and Losq and Sobti (Demand for information and risk aversion: Some results in a portfolio choice context, unpublished working paper, McGill University, 1985) in which more risk averse investors are shown to put a lower value on information. The intuition for this result suggested by the CARA case considered by Losq and Sobti (Demand for information and risk aversion: Some results in a portfolio choice context, unpublished working paper, McGill University, 1985) is the more conservative investment strategies chosen by highly risk averse investors. The argument used in Losq and Sobti (Demand for information and risk aversion: Some results in a portfolio choice context, unpublished working paper, McGill University, 1985) is quite specific to the CARA case. In Cabrales et al. (*American Economic Review* 103:360–77, 2013; *Journal of Economic Theory* 170:266–288, 2017), the result is a consequence of the assumptions that imply uninformed investors bear no risk. When the investor bears no risk, information acquisition is a risky investment. These results are related to a gambling example provided by a 2001 literature survey in Gollier (*The economics of risk and time*. MIT Press, 2001). The chapter concludes with several CRRA examples that suggest the CARA results can be extended. There is also a digression on the point made in Cabrales et al. (*American Economic Review* 103:360–77, 2013) on the role of entropy in this literature.

108.1 Introduction

Are more risk averse investors willing to pay more for information? Intuition would seem to suggest they are. Two recent papers by Cabrales, Gossner, and Serrano in the *American Economic Review* (Cabrales et al. 2013) and *Journal of Economic Theory* (Cabrales et al. 2017) consider this question and arrive at the opposite result, although under quite special circumstances. These papers are among the latest contributions to the literature that studies the effect of risk aversion on the value of information. This literature has a long but sporadic history that began soon after the introduction of the Arrow-Pratt measures of absolute and relative risk aversion in Arrow (1965), and Pratt (1964). In Chap. 24 of Gollier (2001), Gollier provided a discussion of the state of this literature as of 2001. This chapter is a very selective updated survey that is partially motivated by the Cabrales et al. contributions.

The *American Economic Review* paper by Cabrales, Gossner, and Serrano focused on the place of entropy in this literature. The subsequent paper by the same authors extended the results of the *American Economic Review* paper. The crucial feature of the Cabrales et al. setting is that all risk averse, uninformed investors choose not to take risk. The Cabrales et al. result was partially anticipated by Gollier who, in his 2001 survey, presented an example of a risk averse gambler who also values information less when he is more risk averse. Gollier also obtained this result for the case in which the gambler was so risk averse that he chooses not to gamble when he is uninformed. Gollier went on to note, however, that if the gambler is not very risk averse, he will gamble when he is uninformed and, in such a case, he values information more when he becomes somewhat more risk averse, in contrast to the Cabrales et al. result.

A second motivation for this chapter is to describe some results that had been obtained in an unpublished and, therefore, underappreciated paper written by Losq and Sobti (1985). That paper considered the portfolio problem faced by an investor who maximizes the expected value of a utility function that exhibits constant absolute risk aversion (CARA). In that setting Losq and Sobti also demonstrated that, under general conditions, more risk averse investors value information less. This is a result that, as Gollier's survey discusses, had been obtained after 1985 by other papers. The other papers that obtained this result were, however, only able to do so by also assuming that the distribution of returns was normal, an assumption not required by Losq and Sobti.

108.1.1 Outline of the Chapter

We begin with a brief discussion of the Cabrales et al. main result. We digress to discuss the economic conditions Cabrales et al. describe under which the expression

for the value of information is a ratio of certainty equivalents computed using entropy. They note, in particular, that entropy arises in the expression for the investor's maximum expected utility when the investor's utility function has a CRRA of one. In a 1962 *Annals of Mathematical Statistics* paper, DeGroot (1962) treated (negative) entropy as an example of an "uncertainty function" and obtained generalized versions of the information provided by an experiment using uncertainty functions. DeGroot's paper was a follow-up to a 1956 *Annals of Mathematical Statistics* paper (Lindley 1956) in which Lindley had used entropy to describe the information provided by an experiment. We are motivated by DeGroot's interpretation to derive the "uncertainty functions" other than entropy that arise as the investor's maximum expected utility when the investor's utility function is in the CRRA class, but with a level of relative risk aversion other than one. We then use these uncertainty functions to compute the value of information in the economic setting considered by Cabrales et al.

The discussion then moves on to the Losq-Sobti result for the case of CARA utility functions. When Arrow and Pratt introduced their measures of risk aversion, they noted that an expected utility maximizing investor who simply chooses between a safe and risky asset invests less in the risky asset if his risk aversion measure increases. Losq and Sobti note the strong sense in which this is true for investors whose utility functions are CARA. They describe an explicit relationship between the absolute risk aversion measure and the investor's risky asset position. This relationship forms the basis for their demonstration that an increase in risk aversion reduces the value of information. So Losq and Sobti's analysis suggests that the more cautious investment strategy followed by the more risk averse CARA investors results in information being less important and, hence, less valuable for these investors. This interpretation is consistent with Gollier's example in which a gambler is unable to "gamble more or less cautiously." He either gambles or he does not. In that example, in the range of risk aversion levels for which the uninformed choice is to gamble, the value of information about the gambling outcome increases with risk aversion.

In an attempt to begin an investigation of the extent to which the intuition gained from the CARA case can be extended, we conclude the chapter by considering some examples in which the utility function is in the CRRA class. In contrast to the CARA case, there is no explicit relationship for the CRRA class between the relative risk aversion measure and the investor's risky asset position. We are, thus, motivated to limit attention to numerical examples. The numerical results obtained for the examples prove to be consistent with the intuition developed from the CARA case and Gollier's gambling example. Specifically, we note that, when the CRRA investors are not faced with borrowing or lending constraints that prevent them from behaving more aggressively when they are less risk averse, they value information more when they are less risk averse. When borrowing and/or lending constraints are imposed we do find ranges of the relative risk aversion measure over which less risk averse investors value information less. But on those ranges, the borrowing and/or lending constraints do prevent more aggressive behavior by less risk averse investors.

108.1.2 Some Clarifying Remarks

First, we should note that, throughout the discussion, we assume that investors maximize expected utility. The risk aversion measures considered are the usual Arrow-Pratt absolute and relative measures for utility functions of a single variable, final wealth. The discussion takes place in a static, partial equilibrium setting. This means that asset prices do not change when the investor becomes informed; we are not discussing “rational expectations.” We will make further comments on this point as the discussion proceeds.

108.2 A General Framework

This section describes the general framework that we use to introduce the definition of the value of information used in this chapter. This general framework is given different interpretations as we proceed with our discussion.

We treat the investor’s problem as a general decision problem in which the investor chooses a portfolio $c = \hat{c}(u, p, W, \mu)$ where

$$\hat{c}(u, p, W, \mu) = \arg \max_{c \in C(p, W)} \sum_{x \in X} u(I(x, c)) \mu(x)$$

and where x is the state of the world that determines the return to an investment in the risky assets. The state of the world, x , is the realization of a random variable, $\tilde{x}$, that (for ease of exposition and without loss of generality) takes values in a finite set X . The probability of $\tilde{x} = x$ is denoted by $\mu(x)$, and

$$\Pr(\tilde{x} \in X) = 1.$$

We use $I(x, c)$ to denote the investor’s final wealth when he invests in the portfolio c and the state of the world is x . The investor’s utility function of I is $u(I)$ which is assumed to be strictly concave. The investor’s initial wealth is W and p denotes the vector of asset prices. The set of possible portfolios is the investor’s wealth constraint, $C(p, W)$.

Remark 2 *Because, for each portfolio choice, c , expected utility is a linear function of μ , the function*

$$\varphi(u, p, W, \mu) = \max_{c \in C(p, W)} \sum_{x \in X} u(I(x, c)) \mu(x)$$

is a convex function of μ .

We now introduce the possibility that the investor can observe a signal $\tilde{s}$ that is correlated with $\tilde{x}$ and can make use of the information about $\tilde{x}$ provided by this

observation to make a better portfolio choice. The sample space of $\tilde{s}$ is denoted by S . We denote the unconditional distribution of $\tilde{x}$ by μ_0 . For each $s \in S$, let μ_s be the conditional distribution of $\tilde{x}$ given that $\tilde{s} = s$. When he has observed $\tilde{s} = s$, the investor chooses,

$$\hat{c}(u, p, W, \mu_s) = \arg \max_{c \in C(p, W)} \sum_{x \in X} u(I(x, c)) \mu_s(x).$$

Conditional on having observed that $\tilde{s} = s$, the investor's expected utility is

$$\varphi(u, p, W, \mu_s) = \arg \max_{c \in C(p, W)} \sum_{x \in X} u(I(x, c)) \mu_s(x).$$

It must be emphasized that, even after the investor observes that $\tilde{s} = s$, the prices remain unchanged; they are the same as they were when the investor was uninformed. This is what we meant earlier when we noted that we were discussing a "partial equilibrium setting" and not considering "rational expectations." In the rational expectations literature prices do change when investors become informed.

Once he knows that he will observe $\tilde{s}$ before choosing c , but has not yet observed it, the *ex ante* expected utility of information is

$$E\varphi(u, p, W, \mu_s),$$

where, of course, the unconditional distribution of $\tilde{s}$ is used to compute the expectation. Because $\varphi(u, p, W, \mu)$ is a convex function of μ , Jensen's inequality implies that

$$E\varphi(u, p, W, \mu_s) \geq \varphi(u, p, W, E\mu_s). \quad (1)$$

Since

$$E\mu_s = \mu_0,$$

(1) asserts that

$$E\varphi(u, p, W, \mu_s) \geq \varphi(u, p, W, \mu_0).$$

This means that the expected value of making an informed decision exceeds the expected utility of making the decision without information.

The argument just presented that the expected utility of making an informed decision exceeds the expected utility of making an uninformed decision is rather old. It appeared in an unpublished RAND Research Memorandum (Bonnenblust and Sherman 1949) in 1949. Blackwell used it in his paper Blackwell (1953) on the comparison of experiments.

We can now define the value of information, $V = V(u, p, W, \mu_0, \tilde{s})$, as

$$E\varphi(u, p, W - V, \mu_{\tilde{s}}) = \varphi(u, p, W, \mu_0).$$

It will also be useful to define $v = v(u, p, W, \mu_0, \tilde{s}) = \frac{V(u, p, W, \mu_0, \tilde{s})}{W}$, which is simply the value of information as a fraction of wealth.

108.3 An Exposition of the Cabrales et al. Contribution

Cabrales et al. (2013, 2017) showed that, for a very special case,

$$V(u^1, p, W, \mu_0, \tilde{s}) < V(u^2, p, W, \mu_0, \tilde{s})$$

if the utility function u^1 is more risk averse than the utility function u^2 . In Cabrales et al. (2013) they actually discussed and considered the case in which

$$u^2(I) = \log(I).$$

But the result is more general and the same authors generalized it in Cabrales et al. (2017).

108.3.1 The Setting

In Cabrales et al. (2013, 2017) markets are assumed to be complete and an additional assumption was made about asset prices. This additional assumption implies that any risk averse uninformed investor takes no risk. We exposit their results by assuming a market for Arrow-Debreu contingent claims. A contingent claim that pays \$1 in state x and nothing in any other state has a price p_x . In this case, the investor's budget set is

$$C(p, W) = \left\{ c \in R_n : \sum_{x \in X} p_x c_x = W \right\}$$

The assumption that implies any risk averse uninformed investor takes no risk is that, for all x , $p_x = \mu_0(x)$. They referred to this as the assumption of "risk-neutral pricing," but this assumption is stronger than what is usually referred to as "risk-neutral pricing." It might more accurately be referred to as "actuarially fair pricing." It effectively means that asset prices are determined in a market in which the marginal investor is risk neutral and for whom the probability distribution of the states is μ_0 . When the value of information is computed, it is assumed that the prices remain $p = \mu_0(\cdot)$ after the investor becomes informed. It is quite easy to see that, for any strictly concave utility function u ,

$$\widehat{c}(u, p = \mu_o, W, \mu_o) = W$$

and

$$\varphi(u, p = \mu_0, W, \mu_0) = u(W).$$

Thus, an investor who maximizes the expected value of u chooses to hold only the riskless asset and bears no risk.

108.3.2 Risk Aversion and Information Value in This Setting

Cabrales et al. show that

$$V(u^1, p = \mu_0, W, \mu_0, \widetilde{s}) < V(u^2, p = \mu_0, W, \mu_0, \widetilde{s})$$

if u^1 is more risk averse than u^2 . The acquisition of information in the Cabrales et al. setting is analogous to the acquisition of a valuable but risky investment opportunity. The proof of their result is the same as the proof of the well-known result that a more risk averse investor will put a lower value on such an opportunity.

Although the uninformed investor chooses not to bear risk when $p = \mu_0$, he does choose to bear risk when he becomes informed and his beliefs are updated so that $\mu_s \neq \mu_0$, but the prices are unchanged so that $p = \mu_0$. This is what makes information acquisition effectively the same as an investment in a profitable risky investment. The more risk averse investor is more averse to the risks he chooses to take on learning that $\mu_s \neq \mu_0$. These risks are compounded by the fact that, *ex ante*, the investor faces the risks of fluctuations in the conditional distribution μ_s .

108.3.3 Entropy and the Value of Information

In the discussion to follow we will not impose the assumption that

$$p = \mu_0(\cdot).$$

So we do not impose restrictions on the vector of contingent claims prices. When the utility function is

$$u(I) = \log(I),$$

the optimal portfolio of contingent claims is $\widehat{c}$, where

$$\widehat{c}_x(u, p, W, \mu) = \frac{\mu(x)W}{p_x}.$$

Thus,

$$\begin{aligned} \varphi(u, p, W, \mu) \\ = \sum_{x \in X} \log(\mu(x))\mu(x) - \sum_{x \in X} \log(p_x)\mu(x) + \log(W) \end{aligned}$$

It will be noted that the first term in this expression is the negative of entropy, a concave function of μ .

In this case,

$$\begin{aligned} E\varphi(u, p, W, \mu_s^-) &= E \left[\sum_{x \in X} \log(\mu_s^-(x))\mu_s^-(x) \right] \\ &\quad - \sum_{x \in X} \log(p_x)E\mu_s^-(x) + \log(W) \end{aligned}$$

where

$$\sum_{x \in X} \log(p_x)E\mu_s^-(x) = \sum_{x \in X} \log(p_x)\mu_0(x)$$

The value of information as a fraction of wealth, $v = \frac{V}{W}$, is the solution of

$$E\varphi(u, p, W(1-v), \mu_s^-) = \varphi(u, p, W, \mu_0)$$

which simplifies to

$$\begin{aligned} &\log(1-v) \\ &= \sum_{x \in X} \log(\mu_0)\mu_0(x) - E \left[\sum_{x \in X} \log(\mu_s^-)\mu_s^-(x) \right]. \end{aligned}$$

So, in the log utility case

$$v = 1 - \left(\frac{\exp \sum_{x \in X} \log(\mu_0)\mu_0(x)}{\exp E \left[\sum_{x \in X} \log(\mu_s^-)\mu_s^-(x) \right]} \right)$$

Note that the exponent in the denominator is simply the expected negative entropy of the possible posterior (conditional) distributions and the exponent in the numerator is the negative entropy of the prior (unconditional) distribution. Note also that v is independent of the price vector p and of wealth, W .

108.3.4 CRRA Utility and Information Value

In the preceding section we noted that, when

$$u(I) = \log(I),$$

and the relative risk aversion is, therefore, constant and equal to one, the function $\varphi(u, p, W(1 - v), \mu)$ is essentially the convex function that is the negative of entropy. We now derive the function φ for CRRA utility functions $u(c)$ for which the relative risk aversion is not one, that is, we now suppose that

$$u(c) = \frac{c^{1-\gamma}}{1-\gamma},$$

where γ positive and unequal to one. We continue to analyze the value of information in the complete market setting described above.

In that case, the optimal demand for state x contingent claims is

$$\hat{c}_x(\gamma, p, W, \mu) = \frac{W \left[\frac{\mu(x)}{p_x} \right]^{\frac{1}{\gamma}}}{\sum_{x' \in X} \left[\frac{\mu(x')}{p_{x'}} \right]^{\frac{1}{\gamma}} p_{x'}}$$

and

$$\varphi(\gamma, p, W, \mu) = \frac{W^{1-\gamma}}{(1-\gamma)} \psi(\gamma, p, \mu)$$

where

$$\begin{aligned} \psi(\gamma, p, \mu) &= \left(\sum_{x \in X} \left[\frac{\mu(x)}{p_x} \right]^{\frac{1-\gamma}{\gamma}} \mu(x) \right)^{\gamma} \\ &= \left(\sum_{x \in X} p_x^{\frac{\gamma-1}{\gamma}} \mu(x)^{\frac{1}{\gamma}} \right)^{\gamma}. \end{aligned}$$

When $\gamma > 1$, φ equals a negative constant times the concave “uncertainty function” ψ . The value of information as a fraction of wealth solves

$$(1 - v)^{1-\gamma} E\psi(\gamma, p, \mu_s) = \psi(\gamma, p, \mu_0)$$

and

$$v(\gamma, p, \mu_0, \tilde{s}) = 1 - \frac{[\psi(\gamma, p, \mu_0)]^{\frac{1}{1-\gamma}}}{[E\psi(\gamma, p, \mu_s)]^{\frac{1}{1-\gamma}}}$$

where

$$\psi(\gamma, p, \mu) = \left(\sum_{x \in X} p_x^{\frac{\gamma-1}{\gamma}} \mu(x)^{\frac{1}{\gamma}} \right)^{\gamma}.$$

108.4 The CARA Case

While the CRRA utility functions have become the most widely used class of utility functions in the finance literature of recent years, the CARA class is commonly used in the theoretical market microstructure literature. As noted in the introduction, a 1985 unpublished paper (Losq and Sobti 1985) written by Losq and Sobti assumed constant absolute risk aversion and studied the impact of risk aversion on the value of information. They demonstrated that more risk averse investors facing a general portfolio problem value information less. While this is the same conclusion obtained by Cabrales et al., the logic of the argument used to obtain the result is quite different and the setting of the portfolio problem is more general. In this section, we exposit their result and attempt to clarify the underlying intuition.

108.4.1 The Simple Portfolio Problem

We assume that an investor, with absolute risk aversion α , can invest in a safe and risky asset and we now use c to denote the amount invested in the risky asset. We will assume that the investor cannot sell short or borrow to invest and we have $p = 1$. So the constraint set is

$$C(W) = \{0 \leq c \leq W\}.$$

The return on the safe asset is one and the excess return on the risky asset is x . We continue to assume that, x , is the realization of a random variable, $\tilde{x}$, that (for ease of exposition and without loss of generality) takes values in a finite set X . We continue to use $\mu(x)$ to denote the probability of $\tilde{x} = x$. No other distributional assumptions are imposed.

These assumptions imply that

$$\begin{aligned} \varphi(\alpha, W, \mu) &\equiv \varphi(u^\alpha, W, \mu) \\ &= \max_{0 \leq c \leq W} \sum_{x \in X} -\exp[-\alpha(W + cx)]\mu(x) \end{aligned}$$

The amount the investor invests in the risky asset is

$$\begin{aligned} \hat{c}(\alpha, W, \mu) &= \arg \max_{c \in [0, W]} -(\exp[-\alpha W]) \left[\sum_{x \in X} (\exp[-\alpha cx])\mu(x) \right] \\ &= \arg \max_{c \in [0, W]} -\sum_{x \in X} (\exp[-\alpha cx])\mu(x) \end{aligned}$$

So $\hat{c}(\alpha, W, \mu)$ is independent W and we can write $\hat{c}(\alpha, W, \mu)$ as $\hat{c}(\alpha, \mu)$. We should emphasize that this assumes that

$$\arg \max_{c \in [0, W]} - \sum_{x \in X} (\exp [-acx]) \mu(x) < W.$$

Of course, if this condition fails, $\widehat{c}(\alpha, W, \mu) = W$. So we are assuming an interior solution.

In fact, when we have an interior solution to the portfolio problem,

$$\widehat{c}(\alpha, \mu) = \frac{\widehat{c}(\alpha = 1, \mu)}{\alpha}$$

and the investor's maximum utility is simply

$$\begin{aligned} \varphi(\alpha, W, \mu) &= \max_{c \in [0, W]} - (\exp [-\alpha W]) \sum_{x \in X} (\exp [-acx]) \mu(x) \\ &= -(\exp [-\alpha W]) \psi(\mu) \end{aligned}$$

where

$$-\psi(\mu) = \max_{c \in [0, W]} - \sum_{x \in X} (\exp [-cx]) \mu(x).$$

The important feature of this expression is that the function ψ is independent of α !

At this point, we introduce the possibility that the investor can observe a signal $\tilde{s}$ that is correlated with $\tilde{x}$ and make use of the information about $\tilde{x}$ provided by his observation of $\tilde{s}$ to make a better decision. Again S is the sample space of $\tilde{s}$. For each $s \in S$, let μ_s be the conditional (posterior) distribution of $\tilde{x}$ given that $\tilde{s} = s$. When the investor has observed $\tilde{s} = s$, he invests

$$\widehat{c}(\alpha, \mu_s) = \frac{\widehat{c}(\alpha = 1, \mu_s)}{\alpha}$$

in the risky asset and his expected utility is

$$\psi(\alpha, W, \mu_s) = -(\exp [-\alpha W]) \psi(\mu_s)$$

Again we emphasize that this again assumes an interior solution.

The equation defining the value of information, $V = V(\alpha, W, \mu_0, \tilde{s})$,

$$E\varphi(\alpha, W - V, \mu_s) = \varphi(\alpha, W, \mu_0),$$

becomes

$$(\exp [-\alpha(W - V)]) E\psi(\mu_s) = (\exp [-\alpha W]) \psi(\mu_0).$$

Since

$$0 > -E\psi(\mu_s) \geq -\psi(\mu_0),$$

the value of information is

$$V(\alpha, W, \mu_0, \tilde{s}) = \frac{\log\left(\frac{\psi(\mu_0)}{E\psi(\mu_s)}\right)}{\alpha} \geq 0.$$

Note that $V(\alpha, W, \mu_0, \tilde{s})$ is decreasing in the absolute risk aversion measure α and is independent of wealth, W .

Also, the value of information as a fraction of wealth

$$v(\alpha, W, \mu_0, \tilde{s}) = \frac{V(\alpha, W, \mu_0, \tilde{s})}{W} = \frac{\log\left(\frac{\psi(\mu_0)}{E\psi(\mu_s)}\right)}{\alpha W}$$

is decreasing in wealth while the relative risk aversion, αI , is increasing. This follows from the observation that $V(\alpha, W, \mu_0, \tilde{s})$ is independent of W .

The fact that

$$\hat{c}(\alpha, \mu) = \frac{\hat{c}(\alpha = 1, \mu)}{\alpha}$$

means that a more risk averse investor simply holds a portfolio in which his investment in the risky asset is scaled back to account for his higher aversion to risk. This observation holds because we are assuming that, for all relevant μ ,

$$\hat{c}(\alpha, \mu) = \frac{\hat{c}(\alpha = 1, \mu)}{\alpha} < W.$$

When α is small enough

$$\frac{\hat{c}(\alpha = 1, \mu)}{\alpha}$$

can exceed W and in that case

$$\hat{c}(\alpha, \mu) = W$$

and the above argument fails to apply.

Since a more risk averse investor scales back his investment in the risky asset, the impact on utility of the optimal exposure to the excess return of the risky asset is

$$\alpha \hat{c}(\alpha, \mu)x = \hat{c}(1, \mu)x$$

for all levels of risk aversion α and for all possible distributions μ , whether they be the prior μ_0 or a posterior μ_s . This effectively means that the benefits of being informed are the same for all CARA investors regardless of how risk averse they are. More risk averse CARA investors with α higher do put a higher value on the cost of acquiring information.

Throughout the discussion, we have emphasized the fact that the investor's optimal investment in the risky asset is less than his wealth. If for some level of risk aversion this were not true it would be true for less risk averse investors. In that case, less risk averse investors would not, because of the wealth constraint invest more aggressively than, at least some, more risk averse investors and the Losq-Sobti argument would not apply. In the next section, we will focus on this issue explicitly.

108.5 The CRRA Case and the Simple Portfolio Problem

In this section, we return to the case in which the investor's utility function is in the CRRA class. In our earlier discussion of this case we focused on the complete market setting and the value of information when the investor chooses a portfolio of contingent claims in a complete market setting. In this section, we focus on the simple portfolio problem discussed by Losq and Sobti.

When an investor with relative risk aversion $\gamma > 0$ can invest in a safe and risky asset it is convenient to let c be the fraction of wealth invested in the risky asset. We will exposit the argument for the case in which $\gamma \neq 1$.

We will initially assume that the investor cannot sell short or borrow to invest and we have $p = 1$. So, initially, the constraint set is

$$C(W) = \{0 \leq c \leq 1\}.$$

At certain points in the discussion it will be important to consider the case in which the restrictions against short selling and borrowing will be ignored and c will be allowed to be negative or to exceed one. In fact, the cases in which the constraints are ignored play a central role in the discussion.

As in the CARA case, the return on the safe asset is one and the excess return on the risky asset is x . These assumptions imply that

$$\begin{aligned} \varphi(\gamma, W, \mu) &\equiv \varphi(u', W, \mu) \\ &= \max_{0 \leq c \leq 1} \frac{W^{1-\gamma}}{(1-\gamma)} \sum_{x \in X} (1+cx)^{1-\gamma} \mu(x) \\ &= W^{1-\gamma} \psi(\gamma, \mu) \end{aligned}$$

where

$$\psi(\gamma, \mu) = \max_{0 \leq c \leq 1} \sum_{x \in X} \frac{(1-cx)^{1-\gamma}}{(1-\gamma)} \mu(x)$$

is independent of W . When the borrowing and short selling prohibitions are ignored the same equations hold but c is not restricted to lie in the interval $[0,1]$.

The equation

$$E\varphi(\gamma, W(1-v), \mu_s^-) = \varphi(\gamma, W, \mu_0)$$

defining the value of information, $v = v(\gamma, E, \mu_0, \tilde{s})$ as a fraction of wealth now becomes

$$(1-v)^{1-\gamma} E\psi(\gamma, \mu_s^-) = \psi(\gamma, \mu_0).$$

So

$$v(\gamma, \mu_0, \tilde{s}) = 1 - \frac{[\psi(\gamma, \mu_0)]^{\frac{1}{1-\gamma}}}{[E\psi(\gamma, \mu_s)]^{\frac{1}{1-\gamma}}},$$

which is independent of wealth, W . Note that, in this case, the absolute risk aversion, γ/I , is decreasing in I while the value of information $v(\gamma, W, \mu_0, \tilde{s}) = v(\gamma, \mu_0, \tilde{s})W$ is increasing in W .

108.5.1 Some Examples

We now consider several simple examples in which there are only two possible excess returns. So $X = \{x_1, x_2\}$. Since we have two assets, this is a case of complete markets. We then introduce the possibility that the investor can observe a prediction, $s \in S = \{s_1, s_2\}$ of the return before making his portfolio choice. An observation of $\tilde{s} = s_i$ is interpreted as a prediction that $\tilde{x}$ will equal x_i in the sense that the probability of observing $\tilde{s} = s_i$ conditional on the return being x_i , $\Pr(s_i|x_i)$, exceeds one-half. For a range of relative risk aversion measures γ between 2.5 and 10.55 we compute $v(\gamma, \mu_0, \tilde{s})$, the fraction of wealth the investor would pay for the opportunity to make his portfolio choice after observing the prediction.

We let

$$X = \{x_1 = .24, x_2 = -.1\}$$

and

$$\mu_0(x_1) = .48.$$

So

$$(E_0\tilde{x}, \sigma_0\tilde{x}) = (.0632, .1699).$$

This mean and standard deviation are close to those reported for 1889–1978 in Table 1 of Mehra and Prescott (1985).

108.5.1.1 The First Example

In this example, the prediction is not particularly reliable in the sense that

$$\Pr(s_1|x_1) = \Pr(s_2|x_2) = .55.$$

The posterior when $\tilde{s} = s_1$ has been observed is

$$\langle \mu_{s_1}(x_1), \mu_{s_1}(x_2) \rangle = \langle .5301, .4699 \rangle.$$

So

$$(E[\tilde{x}|s_1], \sigma_{s_1}\tilde{x}) = (.0802, .1697).$$

Also, the posterior when $\tilde{s} = s_2$ has been observed is

$$\langle \mu_{s_2}(x_1), \mu_{s_2}(x_2) \rangle = \langle .4303, .5697 \rangle$$

So

$$(E[\tilde{x}|s_2], \sigma_{s_2}\tilde{x}) = (.0463, .1683).$$

Since the information provided by the prediction is not very reliable, the posterior moments are close to the prior moments. In the case of a prediction of a low return, the expected return remains positive and, as a consequence the investment in the risky asset, $\hat{c}$ also remains positive. The graph in Fig. 1 plots $v(\gamma, \mu_0, \tilde{s})$, for a range of relative risk aversion measures γ between 2.5 and 10.55.

The values of v are in the range of 0.04% to 0.15%. Most significantly, when γ is between 2.5 and 3.1, $v(\gamma, \mu_0, \tilde{s})$ is an increasing function of relative and, hence, absolute risk aversion. It turns out to be important to note that, for the γ values in this range, the investor holds only the risky asset when there is a prediction of a high return. So in that range, there is a corner solution.

To highlight the importance of the corner solution in this example, we can solve the portfolio problem allowing the investor to borrow and to choose c above one. In that case, he will indeed choose c to be above one when $\gamma < 3.1$ and there is a prediction of a high return. For this case, Fig. 2 plots $v(\gamma, \mu_0, \tilde{s})$, for the range of relative risk aversion measures γ between 2.5 and 10.55.

As illustrated in Fig. 2, we see that when c can be chosen to be above one, the value of information, $v(\gamma, \mu_0, \tilde{s})$, is everywhere a decreasing function of relative risk aversion and there is no range in which $v(\gamma, \mu_0, \tilde{s})$ is an increasing function of risk aversion.

108.5.1.2 The Second Example

In this example, the prediction is more reliable in the sense that

Fig. 1 First Example, No Borrowing or Short Sales

Fig. 2 First Example, Borrowing and Short Sales Permitted

$$\Pr(s_1|x_1) = \Pr(s_2|x_2) = .75.$$

The posterior when $\tilde{s} = s_1$ has been observed is

$$\langle \mu_{s_1}(x_1), \mu_{s_1}(x_2) \rangle = \langle .7347, .2653 \rangle.$$

So

$$(E[\tilde{x}|s_1], \sigma_{s_1}\tilde{x}) = (.1498, .1501).$$

Also

$$\langle \mu_{s_2}(x_1), \mu_{s_2}(x_2) \rangle = \langle .2353, .7647 \rangle.$$

So

$$(E[\tilde{x}|s_2], \sigma_{s_2}\tilde{x}) = (-.02, .1442).$$

In this case, the prediction of a low return implies a negative expected excess return and, as a consequence, any risk averse investor holds only the riskless asset. So there is a corner solution. Figure 3 plots $v(\gamma, \mu_0, \tilde{s})$, for a range of relative risk aversion measures γ between 2.5 and 10.55.

These v values are in the range of 1% to 2.6%. In this case, when γ is between 2.5 and 3.5, $v(\gamma, \mu_0, \tilde{s})$ is an increasing function of relative and, hence, absolute risk aversion. Again it should be noted that for the γ values in this range, the investor holds only the risky asset when there is a prediction of a high return. So again we have a corner solution.

Again, it turns out that the result that $v(\gamma, \mu_0, \tilde{s})$ is an increasing function of relative risk aversion for a range of γ 's depends crucially on the fact that, in that range, the investor's optimal portfolio is a corner solution. If we ignore the constraints and allow the investor to borrow and sell short, he will borrow when there is a prediction of a high return and sell short when the return prediction is low. In that case $v(\gamma, \mu_0, \tilde{s})$ is a decreasing function of relative risk aversion over the entire range of γ from 2.5 to 10.55. For this case, Fig. 4 plots $v(\gamma, \mu_0, \tilde{s})$, for the range of relative risk aversion measures γ between 2.5 and 10.55.

108.5.1.3 A Third Example

This example is motivated by the fact that, in the first two examples, the uninformed investors all invested positive amounts in the riskless asset and as risk aversion increased the fraction of wealth invested in the risky asset declined. In the final example, we raise the unconditional probability of $\tilde{x} = x_1$ to

$$\mu_0(x_1) = .6.$$

Fig. 3 Second Example, No Borrowing or Short Sales

Fig. 4 Second Example, Borrowing and Short Sales Permitted

Then

$$(E_0\tilde{x}, \sigma_0\tilde{x}) = (.104, .1665).$$

In this case, the uninformed investors with γ between 2.5 and 3.95 all choose not to invest in the riskless asset. As risk aversion increases in this range these investors do not behave more cautiously and the fraction of wealth invested in the risky asset does not decline.

Again suppose that the prediction is more reliable in the sense that

$$\Pr(s_1|x_1) = \Pr(s_2|x_2) = .75$$

The posterior when $\tilde{s} = s_1$ has been observed is

$$\langle \mu_{s_1}(x_1), \mu_{s_1}(x_2) \rangle = \langle .82, .18 \rangle.$$

So

$$(E[\tilde{x}|s_1], \sigma_{s_1}\tilde{x}) = (.1782, .1311).$$

In response to this reliable good news, the investors with γ between 2.5 and 7.4 all choose not to invest in the riskless asset.

The posterior when $\tilde{s} = s_2$ has been observed is

$$\langle \mu_{s_2}(x_1), \mu_{s_2}(x_2) \rangle = \langle .33, .67 \rangle.$$

So

$$(E[\tilde{x}|s_2], \sigma_{s_2}\tilde{x}) = (.013, .1603).$$

In response to this reliable bad news, investors at all levels of γ between 2.5 and 10.55 choose to invest over 78% of their wealth in the riskless asset.

Figure 5 plots $v(\gamma, \mu_0, \tilde{s})$, for a range of relative risk aversion measures γ between 2.5 and 10.55. These v values are in the range of 0.9% to 2%. In this case, when γ is between 2.5 and 5.45, $v(\gamma, \mu_0, \tilde{s})$ is an increasing function of relative and, hence, absolute risk aversion. It should again be noted that for the γ values in this range, the investor holds only the risky asset when there is a prediction of a high return. The investors who choose not to invest in the riskless asset when they are uninformed, viz., those with γ between 2.5 and 3.95, are in this range.

Once again, it turns out that the result that $v(\gamma, \mu_0, \tilde{s})$ is an increasing function of relative risk aversion for a range of γ 's depends crucially on the fact that in that range the investor's optimal portfolio is a corner solution. If we ignore the constraints and allow the investor to borrow and sell short, he will when it is optimal. In that case $v(\gamma, \mu_0, \tilde{s})$ is a decreasing function of relative risk aversion. For this case, Fig. 6 plots $v(\gamma, \mu_0, \tilde{s})$, for the range of relative risk aversion measures γ between 2.5 and 10.55. Note that for the least risk averse investor $v = 5.3\%$ and for the most risk averse $v = 1.2\%$.

108.6 Concluding Remarks

The somewhat surprising result that a risk aversion increase reduces the value of information is rather general. Why does it happen? The answers are different when the uninformed investor chooses to face no risk and when he does choose to face risk. An uninformed investor who chooses not to bear risk and who can acquire information effectively has the opportunity to make a risky investment. More risk averse investors put a lower value on risky investment opportunities.

In the CARA case we considered, the uninformed investor does choose to face risk. In the CARA case, a more risk averse investor scales back his exposure to risk

Fig. 5 Third Example, No Borrowing or Short Sales

Fig. 6 Third Example, Borrowing and Short Sales Permitted

to such an extent that the impact of his increased risk aversion is completely eliminated. The more cautious behavior of the more risk averse investor means that he has no more need for information than the less risk averse investor. Caution effectively reduces the need for information. Alternatively, one could say that less risk averse investors use information more aggressively and that makes it more valuable.

In the simple CRRA examples for which we computed the value of information there were ranges of the relative risk aversion measure on which the value of information did rise with risk aversion. But in those ranges, the investor's optimal portfolio was constrained to be a corner solution. That effectively meant that increases in risk aversion did not imply more cautious behavior. The investor did not, as in the CARA case, scale back his investment in the risky asset as he became more risk averse. In all of the examples, when the borrowing and lending constraints were ignored, increases in risk aversion always implied more cautious optimal behavior on the part of the investor and the increases in risk aversion did lower the value of information. This suggests that, in a portfolio setting, when a more risk averse investor is able to invest more cautiously than a less risk averse investor, information will be less valuable. This observation is consistent with the gambling example considered by Gollier in his 2001 survey in Chap. 24 of Gollier (2001). In the Gollier example, the potential gambler either gambles or he does not. The size of the gamble is fixed. More risk averse gamblers cannot gamble less aggressively. In that example the least risk averse gamblers do gamble and the least risk averse among them put the lowest value on information.

A Fuzzy Real Option Valuation Approach To Capital Budgeting Under Uncertainty Environment **109**

Shin-Yun Wang and Cheng-Few Lee

Abstract

The information needed for capital budgeting is generally not known with certainty. The sources of uncertainty may be the net cash inflows, the life of the project, or the discount rate. We propose a capital budgeting model under uncertainty environment in which the concept of probability is employed in describing fuzzy events and cash flow information can be specified as a special type of fuzzy numbers. The present worth of each fuzzy project cash flow can be subsequently estimated. At the same time, to select fuzzy projects and determine the optimal decision time under limited capital budget, we offer an example to analyze the results of the capital budgeting problem under uncertainty using a fuzzy real option valuation.

109.1 Introduction

Large investments are capital projects of strategic importance which often have a long economic life cycle. They are characterized by many unknowns that are hard to foresee at their initial planning stage. Hence, the outcome of these investments may change during their long economic life, and the changes can be crucial since the larger the investments are, the more strategic importance they usually have. However, the information needed for capital budgeting is generally not known with certainty. Therefore, capital budgeting procedures under uncertainty remain to be further developed. The sources of uncertainty may be the net cash inflow, the life of the project, the cash flow volatility, and/or the discount rate.

In practice, precise information concerning future investment projects is rarely available. Hence, a decision maker does not have exact knowledge concerning future investment opportunities. Extensive studies have been undertaken to consider the capital budgeting problems under risk. Traditional approaches to capital budgeting are based on the premise that probability theory is necessary and sufficient to deal with the uncertainty that underlies the estimates of required parameters. However, it is argued that in many circumstances this premise is invalid since the principal sources of uncertainty are often nonrandom in nature and are related to the fuzziness rather than the frequency of data. In order to capture and quantify correctly the underlying uncertainty present in nonstatistical situations, the theory of possibility, an extension of the theory of fuzzy sets introduced by Zadeh (1965), can be used.

In the real world, the data sometimes cannot be recorded or collected precisely. For instance, if we ask a group of economists to predict the economic growth rate in the next year, their statements may be something like “approximately 3%,” “should be 3–5%,” “may be below 6%,” etc. All of these statements can be characterized as fuzzy sets. Suppose that we introduce a selection procedure which will determine the probability that each economist will be selected, then for each possible selection, their statements are fuzzy sets. Similarly, in a capital budgeting model under uncertainty, the cash flow information can be specified as a special type of fuzzy number (triangular fuzzy numbers). Zadeh (1965), Dubois and Prade (1988), and Carlsson and Fuller (2002) have investigated the usefulness of the fuzzy set theory in decision-making under uncertainty. Other studies involving decision-making use fuzzy modeling (Cabrer et al. 2009; Hu and Li 2009; Rao and Peng 2009), and fuzzy data mining (Hu and Tseng 2009; Peng et al. 2008). The fuzzy capital budgeting approaches allow cash flow estimates to be treated as fuzzy numbers, and in certain situations, fuzzy cash flows can better reflect the uncertainty in the project (Wang and Hwang 2010).

In this chapter, we integrate fuzzy versions of the neoclassical capital budgeting methods and real option valuation. In Sect. 109.2, we will discuss methods for capital budgeting and investment decision-making. Section 109.3 derives the fuzzy real option method. Section 109.4 gives a numerical example to compare and analyze the results of the capital budgeting problem using a fuzzy real option valuation. Conclusions are in Sect. 109.5.

109.2 Methods for Capital Budgeting and Investment Decision-Making

Capital budgeting methods based on the discounted cash flow (DCF) have been the primary instruments for investment decision-making. The most commonly used DCF-based method is the net present value (NPV). Under static circumstances, DCF-based methods provide reliable results. However, the real-world situations are seldom static. Especially in cases of large investments with long economic lives, the static DCF-based methods fail to present a highly reliable picture of the profitability and possibilities offered by the investment project. As DCF-based methods have been the best thing available, they have rooted to management practices during years of use.

Although there are many enhancements to the original formulae, the underlying unsatisfactory assumptions still exist. Hence, modified models are used which include the risk-adjusted discount-rate method and the certainty-equivalent method. The risk-adjusted discount-rate method simply extends the cash-flow valuation model under certainty to the uncertainty case. The advantage of this method is that the valuation model gives us a formula that explicitly considers the uncertainty associated with future cash flows. Although the model does not specify exactly what constitutes the risk of the cash flows, it can be used to develop and explore the relationships among the variables of asset-valuation models. On the other hand, the disadvantages of the risk-adjusted discount-rate model are clear. The value of risk-adjusted discount rate is only a subjective estimate, which could well differ from person to person. Therefore, an objective determination of the value of a risky investment project will be almost impossible by simply applying this method.

While the risk-adjusted discount-rate method provides a means for adjusting the basic riskless discount-rate, an alternative method, the certainty-equivalent method, adjusts the estimated value of the uncertain cash flows. The underlying rationale is that, given a risky cash flow, the decision maker will evaluate this risky cash flow by attaching an expected utility to that cash flow, which utility estimate being hypothesized to be equal to the utility derived from some certain amount. If a decision maker performs this process for each cash flow, a series of certainty equivalents for the risky flows can be obtained. These two models should yield the same value for a given stream of cash flows. However, Robichek and Myers (1966) show that the risk-adjusted discount-rate method tends to lump together the pure rate of interest, a risk premium, and time (through the compounding process), while the certainty-equivalent approach keeps risk and the pure rate of interest separate. This separation gives an advantage to the certainty-equivalent method.

Some economic factors, such as competition, inflation, consumer preferences, technological development, and labor market conditions are a few of them that make it impossible to foretell the future. Consequently, the economic life, revenues, and costs of investment projects are less than certain. With risk, a firm is no longer indifferent between two investment proposals having same internal rates of return or net present values. Three related stochastic methods have been useful in capital-budgeting decisions which are the probability distribution, decision tree, and simulation methods.

These methods have explicitly utilized the concepts of probability distributions and statistical distributions to carry out the analysis. If there is only a single accept-reject decision at the outset of the project, then a decision maker can use either statistical-distribution methods or simulation methods. If investment opportunities involve a sequence of decisions over time, a decision-tree method can be used to perform the analysis. Decision-tree is an analytical technique used in sequential decisions, where various decision points are studied in relation to subsequent chance events. This technique enables one to choose among alternatives in an objective and consistent manner. Simulation is another approach to confronting the problems of capital budgeting under uncertainty. Because uncertainty associated with capital budgeting is not restricted to one or two variables, every variable relevant in the capital-budgeting decision can be viewed as a random variable. Facing so many random variables, it may be impossible to obtain tractable results from an economic model. Simulation is a useful tool designed to deal with this problem and is the closest we can get to modeling in cases of uncertainty. However, if risk reduction is a consideration, then the real option is a better alternative. The real option approach also supports the determination of the timing for the investment and offers a comprehensive way of presenting a value of possibilities opened by the project, which can be further enhanced with frequently updated fuzzy cash flows.

The real option approach is a methodology that calculates the value of an investment with techniques originally developed for valuation of financial options. This gives the possibility to take into consideration the managerial flexibility to take action during the lifetime of an investment. The term real option was first introduced in an article about corporate borrowing by Myers and Turnbull (1977). Since then, there has been a growing literature to describe the different theoretical aspects of real options (Kulatilaka and Marcus 1988; Dixit and Pindyck 1994; Trigeorgis 1995), as well as the managerial and strategic implications and applications of real options (Bowman and Hurry 1993; Luehrman 1998; Amram and Kulatilaka 1999). A number of case-based articles are also available to give further insight into real-world application (Kulatilaka 1993; Nichols 1994; Micalizzi 1999).

109.3 A Fuzzy Real Option Valuation

109.3.1 Real Option Valuation

Real option means the possibility to either choose for or against making an investment decision without binding oneself up front. The real option rule is that one should invest today only if the net present value is high enough to compensate for giving up the value of the option to wait. While ongoing evaluation effort is structured around key decision points or triggered by changes in the business environment, it is a process in which the valuation is not intended to provide a definite answer, but rather to provide decision makers an ongoing dialogue about the project (Dahlberg and Porter 2000; Zeng and Zhang 2011).

In real options, the options involve real assets. Real options can be valued using the analogue option theories that have been developed for financial options, although they are not the same thing. Real options deal with strategic decisions of a company where degrees of freedom are limited to the capabilities of the company. In these strategic decisions, different stakeholders play a role, especially if the resources needed for an investment are significant and thereby the continuity of the company is at stake. Hence, it is quite different from traditional discounted cash flow investment approaches. Making decisions based upon the traditional methods is very hard when there is uncertainty about the exact outcome of the investment. In particular, since traditional methods ignore the value of flexibility and discount heavily for external uncertainty involved, many interesting innovative activities and projects are cancelled because of the uncertainties.

Thinking in real options is based on the Black-Scholes model in financial options. The option-pricing theory stipulates that one should invest today only if the net present value is high enough to compensate for giving up the value of the option to wait. Because the option to invest loses its value when the investment is irreversibly made, this loss is an opportunity cost of investing. In order to obtain the real option value (ROV) from the cash flow, the detail and inference process are explained below. Following the binomial model, we can compute the value of a real option as

$$ROV = F_0 B(n \geq a|T, p) - K(1+r)^{-T} B(n \geq a|T, p'), \quad (1)$$

where p is the cash flow up probability such that

$$p = \frac{(1+r-d)}{u-d}, p' = \frac{u}{1+r} p. \quad (2)$$

ROV denotes the current real option value; F_0 is the value of expected cash flows; $B(n \geq a|T, p)$ is the cumulative probability of having an in-the-money option (i.e., $n \geq a$), where the probabilities are the certainty-equivalent probabilities determined by the risk-free hedge portfolio; and $K(1+r)^{-T}$ is the discounted initial cash outflow. The option expires at time T , and r is the risk-free rate (see Copeland and Antikarov 2001 for details).

109.3.2 Probability of Fuzzy Events

The concept of probability is employed in describing fuzzy events and in using sample information to make statistical inferences (Lee et al. 2005a). An event is an experimental outcome that may or may not occur. The probability of a fuzzy event is used to measure the chance, the degree of compatibility, or degree of truth.

109.3.3 Prior Probability of Fuzzy Events

In the ROV (real option value) under uncertainty, the distributions of the primary variables are assessed subjectively. Therefore, a manager faces the problem of implicit fuzziness. It is difficult to measure the impreciseness with the concept of probability (Zadeh 1965; Tanaka and Asai 1984) because probability is used to measure randomness. Randomness is relevant to the occurrence or nonoccurrence of an event, while fuzziness is relevant to the degree of an event (Bellman and Zadeh 1970). According to the definition given by Zadeh (1965), a fuzzy set is used to describe the set of an event without clear boundaries. The membership function $\mu_{\tilde{A}} : X \rightarrow [0, 1]$ expresses the fuzzy set $\tilde{A}$ in set X where if element $x \in X$, then $\mu_{\tilde{A}}(x) \in [0, 1]$ expresses the grade of membership x (also, the degree of compatibility or degree of truth) of X in $\tilde{A}$, which maps X to the membership space. The greater the value of $\mu_{\tilde{A}}(x)$ is, the higher the grade of membership of x belongs to $\tilde{A}$. According to Zadeh (1968), when there is no extrasample information, the prior probability $P(\tilde{A})$ of fuzzy event $\tilde{A}$ can be defined as

$$P(\tilde{A}) = \sum_{i=1}^I \mu_{\tilde{A}}(x_i) \cdot P(x_i). \quad (3)$$

109.3.4 Posterior Probability of Fuzzy Events

Let $X = \{x_1, x_2, \dots, x_m\}$ be the sample information space. In S_k state, if the prior probability $P(x_j|S_k)$ of acquiring sample information x_j is known, then the posterior probability of acquiring sample information x_j is

$$P(S_k|x_j) = \frac{P(x_j|S_k) \cdot P(S_k)}{P(x_j)}. \quad (4)$$

One could evaluate the sample information acquired through this method. However, it still involves the subjective opinion of managers. On the other hand, the posterior probability of the sample information with fuzziness can be calculated as shown in the following. Let sample information space be $X = \{x_1, x_2, \dots, x_m\}$, let $\{x_r\}$, $r = 1, 2, \dots, m$ be an independent event, and let $\tilde{M} = \{\tilde{M}_1, \tilde{M}_2, \dots, \tilde{M}_J\}$ be the concept of fuzzy sample information. The posterior probability $P(S_k|\tilde{M}_j)$ is calculated in accordance with Bayes' rule after deriving $\tilde{M}_j$.

$$P(S_k|\tilde{M}_j) = \frac{P(\tilde{M}_j|S_k) \cdot P(S_k)}{P(\tilde{M}_j)},$$

where

$$P(\tilde{M}_j|S_k) = \sum_{r=1}^m P(x_r|S_k) \cdot \mu_{\tilde{M}_j}(x_r),$$

$$P(\tilde{M}_j) = \sum_{r=1}^m P(x_r) \cdot \mu_{\tilde{M}_j}(x_r),$$

therefore

$$P(S_k|\tilde{M}_j) = \frac{\sum_{r=1}^m P(x_r|S_k) \cdot \mu_{\tilde{M}_j}(x_r) \cdot P(S_k)}{\sum_{r=1}^m P(x_r) \cdot \mu_{\tilde{M}_j}(x_r)}. \quad (5)$$

When fuzzy sample information exists, the occurrence probability of state S_k can be described using the above formula. Therefore, the concept of “fuzzy” to describe the ROV under fuzzy environment should be brought into the picture.

When the range of the membership function is improved to $\{0, 1\}$, then $\tilde{A}$ will be transformed to a crisp set A . The $\mu_{\tilde{A}}$ will be transformed into C_A (characteristic function). This kind of transformation in the ROV means that the estimates of the primary variable cash flows, risk-rate, and the volatility of cash flow (F , R , σ) are without fuzziness, that is, $\mu_{\tilde{A}}(x_i) = 1$ or 0 . Under these circumstances, $\mu_{\tilde{A}}(x) = C_A(x) = 1$ if $x \in A$, or $\mu_{\tilde{A}}(x_i) = 0$, if $x \notin A$. Therefore, the probability for the occurrence of fuzzy event $\tilde{A}$ can be defined as

$$P(\tilde{A}) = \sum_{i=1}^I \mu_{\tilde{A}}(x_i) \cdot P(x_i) = \sum_{i=1}^I C_A(x_i) \cdot P(x_i) = P(A). \quad (6)$$

According to the traditional probabilistic ROV, the decision space faced by a manager is $B = \{S, D, P(S_i), ROV(d_j, S_i)\}$. Therefore, under state S_i and sample information x_r , the expected fuzzy real option value $\{FROV(d_j^*|x_r)\}$ of the optimal alternative is defined as

$$FROV(d_j^*|x_r) = \min_j \left\{ \sum_{i=1}^I ROV(d_j, S_i) \cdot P(S_i|x_r) \right\}$$

$$= \bigwedge_{j=1}^J \sum_{i=1}^I ROV(d_j, S_i) \cdot P(S_i|x_r). \quad (7)$$

When dealing with the actual ROV issues, a company not only faces a fuzzy sample information space but also stays in a fuzzy state space. For example, a manager forecasts future risk-free interest rate in accordance with the classification

of “booming economy,” “fair economy,” or “recession.” The definitions of “booming economy,” “fair economy,” and “recession” depend on the manager’s subjective opinion. Therefore, the state space encountered by the manager also involves implicit fuzziness. Besides, the actions that the manager plans to take will cause the cash flow structure to fluctuate. Moreover, due to the company’s environment, timing of the decision-making, and the inability to give it a trial, it is virtually impossible to sit and wait for a longtime for the collection of perfect information. Under these circumstances, the alternative adopted by the manager for ROV under uncertainty contains fuzziness. In summary, the ROV, which a manager actually deals with, is in a fuzzy state with fuzzy sample information and fuzzy action. As a result, the company can be defined with fuzzy decision space $\tilde{B} = \{\tilde{F}, \tilde{A}, P(\tilde{S}), ROV(\tilde{A}, \tilde{S})\}$, in which $\tilde{S} = \{\tilde{S}_1, \tilde{S}_2, \dots, \tilde{S}_K\}$ stands for fuzzy state set; $\tilde{S}_k, k = 1, 2, \dots, K$ stands for a fuzzy set in S ; and $S = \{S_1, S_2, \dots, S_I\}$ stands for the state set. $S_i, i = 1, 2, \dots, I$ stands for a state of the state set. $\tilde{A} = \{\tilde{A}_1, \tilde{A}_2, \dots, \tilde{A}_N\}$ stands for fuzzy action set; $\tilde{A}_n, n = 1, 2, \dots, N$ stands for a fuzzy action set in D ; $D = \{d_1, d_2, \dots, d_J\}$ stands for action set; and $d_j, j = 1, 2, \dots, J$ stands for an action or alternative available for the company. $P(\tilde{S}_k)$ is the prior probability of $\tilde{S}_k$; $ROV(\tilde{A}, \tilde{S})$ is the evaluation function of $\tilde{A} \times \tilde{S}$. The prior probability of fuzzy state $P(\tilde{S}_k)$ is defined as

$$P(\tilde{S}_k) = \sum_{i=1}^I \mu_{\tilde{F}_k}(S_i) \cdot P(S_i). \quad (8)$$

Let $\tilde{M} = \{\tilde{M}_1, \tilde{M}_2, \dots, \tilde{M}_J\}$ be the fuzzy sample information space in X . $\tilde{M}_j, j = 1, 2, \dots, J$, is the fuzzy sample information; $X = \{x_1, x_2, \dots, x_m\}$ is the sample information space, and $\{x_r\}, r = 1, 2, \dots, m$, is an independent event.

The posterior probability of fuzzy state $\tilde{S}_k$ is defined in accordance with the posterior probability of fuzzy events after the fuzzy sample information $\tilde{M}_j$ is derived as

$$\begin{aligned} P(\tilde{S}_k | \tilde{M}_j) &= \sum_{i=1}^I \mu_{\tilde{S}_k}(S_i) \cdot P(S_i | \tilde{M}_j) \\ &= \sum_{i=1}^I \mu_{\tilde{S}_k}(S_i) \cdot \frac{\sum_{r=1}^m P(x_r | S_i) \cdot \mu_{\tilde{M}_j}(x_r) \cdot P(S_i)}{P(\tilde{M}_j)} \\ &= \frac{\sum_{i=1}^I \sum_{r=1}^m \mu_{\tilde{S}_k}(S_i) \cdot \mu_{\tilde{M}_j}(x_r) \cdot P(x_r | S_i) \cdot P(S_i)}{\sum_{r=1}^m \mu_{\tilde{M}_j}(x_r) \cdot P(x_r)}. \end{aligned} \quad (9)$$

109.3.5 A Fuzzy Real Option Valuation

In this section, we shall introduce a real option rule in a fuzzy setting (Carlsson and Fuller 2003; Dai et al. 2016; Su et al. 2019; Wang and Lee 2010; Ho and Liao 2011; Mao and Wu 2011), where the present value of expected cash flows is estimated by triangular fuzzy numbers. We will also determine the optimal exercise time by using the fuzzy real option valuation. To do so, we first briefly discuss the concept of triangular fuzzy number, followed by the combination of binomial model and triangular fuzzy numbers to form fuzzy decision tree.

As illustrated in Zadeh (1965), $\tilde{A}$ is a convex fuzzy set if and only if its α -level set $\tilde{A}_\alpha = \{x : \mu_{\tilde{A}}(x) \geq \alpha\}$ is a convex set for all α . Therefore, if $\tilde{a}$ is a fuzzy number, then the α -level set $\tilde{a}_\alpha$ is a compact (closed and bounded in $\mathbb{R}$) and convex set; that is, $\tilde{a}$ is a closed interval. The α -level set of $\tilde{a}$ is then denoted by $\tilde{a}_\alpha = [\tilde{a}_\alpha^L, \tilde{a}_\alpha^U]$. A fuzzy number $\tilde{a}$ is said to be nonnegative if $\mu_{\tilde{a}}(x) = 0$ for $x < 0$. It is easy to see that if $\tilde{a}$ is a nonnegative fuzzy number, then $\tilde{a}_\alpha^L$ and $\tilde{a}_\alpha^U$ are all nonnegative real numbers for all $\alpha \in [0, 1]$. The concept of triangular fuzzy number attempts to deal with real problems by possibility. The membership of a triangular fuzzy number is defined as follows (Fig. 1):

$$\mu_{\tilde{A}}(x) = \begin{cases} (x - L)/(M - L) \rightarrow L \leq x \leq M \\ (R - x)/(R - M) \rightarrow M \leq x \leq R \\ \rightarrow \rightarrow \rightarrow 0 \rightarrow \rightarrow \rightarrow \text{otherwise} \end{cases}$$

According to the characteristics of triangular fuzzy numbers and the extension principle put forward by Zadeh (1965), the operational laws of triangular fuzzy numbers, $\tilde{A} = (l_1, m_1, r_1)$ and $\tilde{B} = (l_2, m_2, r_2)$, are as follows:

1. Addition of two fuzzy numbers $\oplus$

$$(l_1, m_1, r_1) \oplus (l_2, m_2, r_2) = (l_1 + l_2, m_1 + m_2, r_1 + r_2)$$

Fig. 1 The membership function of the triangular fuzzy number

2. Subtraction of two fuzzy numbers $\ominus$

$$(l_1, m_1, r_1) \ominus (l_2, m_2, r_2) = (l_1 - r_2, m_1 - m_2, r_1 - l_2)$$

3. Multiplication of two fuzzy numbers $\otimes$

$$(l_1, m_1, r_1) \otimes (l_2, m_2, r_2) \cong (l_1 l_2, m_1 m_2, r_1 r_2)$$

4. Division of two fuzzy numbers $\oslash$

$$(l_1, m_1, r_1) \oslash (l_2, m_2, r_2) \cong (l_1/r_2, m_1/m_2, r_1/l_2)$$

Usually, the present value of expected cash flows cannot be characterized by a single number. But managers are able to estimate the present value of expected cash flows by using triangular possibility distribution of the form $\tilde{F} = [f_l, f_m, f_r]$, i.e., the most likely values of the present value of expected cash flows lie in the f_m (which is the core of the triangular fuzzy number $\tilde{F}$); f_r is the greatest value and f_l is the smallest value for the present value of expected cash flows.

In addition, the values are also influenced by the financial markets such as risk-free interest rate (discount rate) and the volatility of cash inflows. We use historical data to estimate them by using a triangular possibility distribution of the form $\tilde{R} = [r_l, r_m, r_r]$, $\tilde{\sigma} = [\sigma_l, \sigma_m, \sigma_r]$.

The most possible values of risk rate and the volatility of cash inflow lie in the interval r_m and σ_m (which is the core of the triangular fuzzy number $\tilde{R}$ and $\tilde{\sigma}$). r_r is the greatest value and r_l is the smallest value for discount rate, and σ_r is the greatest value and σ_l is the smallest value for the volatility of cash inflows.

The information needed for capital budgeting is generally not known with certainty. The sources of uncertainty may be the net cash inflows, the discount rate, the cash flow volatility, the life of the project, etc. Hence in addition to considering the fuzzy volatility, we also consider the fuzzy cash inflow $\tilde{F}$ and fuzzy interest rate $\tilde{R}$. Under these circumstances, we suggest the use of formulas described in the next section for computing fuzzy real option values.

109.4 N-Step Fuzzy Decision Tree

We now combine binomial model and triangular fuzzy number to form fuzzy decision tree (Lee et al. 2005b). Assume that decision tree will mature (project termination) in a given period and the cash flow is initially set to F ($t = 1$). Cash flows can move up or down in the next period ($t = 2$). There are three possible scenarios in the up movement, $F_{ur}(=ur \cdot F)$, $F_{um}(=um \cdot F)$, or $F_{ul}(=ul \cdot F)$, and three scenarios in the down movement, $F_{dr}(=dr \cdot F)$, $F_{dm}(=dm \cdot F)$, or $F_{dl}(=dl \cdot F)$ depending on volatility. Hence, in each time interval the cash flow moves from its initial value of F to one of the above six new values, F_{ur} , F_{um} , F_{ul} , F_{dr} , F_{dm} , or F_{dl} . These six values are defined as:

F_{ur} : cash flow of up movement under the greatest volatility, $F_{ur} = F_0 \cdot \left[e^{(1+\rho)\sigma\sqrt{\Delta t}} \right]$,

F_{um} : cash flow of up movement under medium volatility, $F_{um} = F_0 \cdot \left[e^{\sigma\sqrt{\Delta t}} \right]$,

F_{ul} : cash flow of up movement under the smallest volatility, $F_{ul} = F_0 \cdot \left[e^{(1-\rho)\sigma\sqrt{\Delta t}} \right]$,

F_{dr} : cash flow of down movement under the greatest volatility, $F_{dr} = F_0 \cdot \left[e^{-(1-\rho)\sigma\sqrt{\Delta t}} \right]$,

F_{dm} : cash flow of down movement under medium volatility, $F_{dm} = F_0 \cdot \left[e^{-\sigma\sqrt{\Delta t}} \right]$,

F_{dl} : cash flow of down movement under the smallest volatility, $F_{dl} = F_0 \cdot \left[e^{-(1+\rho)\sigma\sqrt{\Delta t}} \right]$.

The FROV in maturity are $R\tilde{O}V_{ur} = \max(F_{ur} - X, 0)$, $R\tilde{O}V_{um} = \max(F_{um} - X, 0)$, $R\tilde{O}V_{ul} = \max(F_{ul} - X, 0)$, $R\tilde{O}V_{dr} = \max(F_{dr} - X, 0)$, $R\tilde{O}V_{dm} = \max(F_{dm} - X, 0)$, and $R\tilde{O}V_{dl} = \max(F_{dl} - X, 0)$.

To illustrate the process of obtaining the greatest volatility, we use the replicating portfolio approach found in the financial options. Let

$$mF + B = ROV \quad (10)$$

where m is the number of units of the underlying asset under the greatest volatility and B the amount invested in bonds under the greatest volatility.

Assume we buy m units of underlying asset under the greatest volatility and invest amount B in risky assets (bonds), (r_l, r_m, r_h) ; after one period, the value of portfolio for up movement is: $mF_{ur} + B(1 + r_h) = R\tilde{O}V_{ur}$ and the one for down movement is: $mF_{dl} + B(1 + r_h) = R\tilde{O}V_{dl}$.

where ur is the range of the greatest volatility of "up" movement. The movement from F to $F_{ur}(=ur \cdot F)$ is therefore an "up" movement under the greatest volatility; dl is the range of the greatest volatility of "down" movement. The movement from F to $F_{dl}(=dl \cdot F)$ is therefore a "down" movement under the greatest volatility.

Suppose the value of the portfolio either under up or down movement is equal to the value of the corresponding FROV, we obtain

$$\begin{aligned} m &= \frac{C_{ur} - C_{dl}}{F_{ur} - F_{dl}}, B = \frac{C_{ur} - mF_{ur}}{(1 + r_h)} = \frac{C_{ur} - \left(\frac{C_{ur} - C_{dl}}{F_{ur} - F_{dl}} \right) F_{ur}}{(1 + r_h)} \\ &= \frac{\left(\frac{C_{ur}F_{ur} - C_{ur}F_{dl} - C_{ur}F_{ur} + C_{dl}F_{ur}}{F_{ur} - F_{dl}} \right)}{(1 + r_h)} = \frac{\left(\frac{C_{dl}F_{ur} - C_{ur}F_{dl}}{F_{ur} - F_{dl}} \right)}{(1 + r_h)}, \end{aligned}$$

where $P_u = \frac{(1+r_h)-dl}{ur-dl}$, $P_m = \frac{(1+r_m)-dm}{um-dm}$, $P_d = \frac{(1+r_l)-dr}{ul-dr}$.

The probabilities of three up movements are P_u , P_m , and P_d , while the probabilities of three down movement are $1-P_u$, $1-P_m$, and $1-P_d$, respectively. In the above

equations, $\tilde{R\hat{O}V}_u$, $\tilde{R\hat{O}V}_m$, and $\tilde{R\hat{O}V}_d$ are the right, medium, and the left values of the current fuzzy real option price, respectively. So we can get the FROV under the greatest volatility ($\tilde{R\hat{O}V}_u$) as: $\tilde{R\hat{O}V}_u = e^{-r_l \Delta t} [P_u \cdot \tilde{R\hat{O}V}_{ur} + (1 - P_u) \cdot \tilde{R\hat{O}V}_{dl}]$. Similarly, we also can get the FROV under medium and the smallest volatility as follows: $\tilde{R\hat{O}V}_m = e^{-r_m \Delta t} [P_m \cdot \tilde{R\hat{O}V}_{um} + (1 - P_m) \cdot \tilde{R\hat{O}V}_{dm}]$, $\tilde{R\hat{O}V}_d = e^{-r_h \Delta t} [P_d \cdot \tilde{R\hat{O}V}_{ul} + (1 - P_d) \cdot \tilde{R\hat{O}V}_{dr}]$. The process of fuzzy decision tree can be stated as follows:

- [Step 1]: Estimate ρ and σ value to compute the F_{ur} , F_{um} , F_{ul} , F_{dr} , F_{dm} , and F_{dl} . In other words, $\sigma(1 + \rho)$ is the volatility of the right value of up movement, $\sigma(1 - \rho)$ is the volatility of the left value of up movement, and $F_{ur}(=ur \cdot F)$, $F_{um}(=um \cdot F)$, and $F_{ul}(=ul \cdot F)$ are the degrees of up movement. In the down movement, $-\sigma(1 - \rho)$ is the volatility of the right value of down movement, $-\sigma(1 + \rho)$ is the volatility of the left value of down movement, and $F_{dr}(=dr \cdot F)$, $F_{dm}(=dm \cdot F)$, and $F_{dl}(=dl \cdot F)$ are the degrees of down movement.
- [Step 2]: Compute FROV from the fuzzy cash flow of $t = n$ to the FROV of $t = n$. We use the fuzzy cash flow at $t = n$ and the (nominal) value of fixed costs to compute the FROV. The process is the same with binomial tree model. $FROV_n = \max(F_n - X, 0)$, where F_n is the fuzzy cash flow at time t and X is the (nominal) value of fixed costs.
- [Step 3]: Compute the fuzzy real option price from $t = n$ to $t = n-1$. Now we integrate the fuzzy set with the binomial tree model and use different probabilistic for different volatilities and interest rates. Here, $\tilde{R\hat{O}V}_u$, $\tilde{R\hat{O}V}_m$, and $\tilde{R\hat{O}V}_d$ are the largest, middle, and the smallest values of the fuzzy option price, respectively. Each node of the fuzzy option price has three option prices, not just a single one, as in the binomial tree model. So we replace the fuzzy option prices $\tilde{R\hat{O}V}_{ur}$ and $\tilde{R\hat{O}V}_{dl}$ for the greatest volatility to get $\tilde{R\hat{O}V}_u = e^{-r_l \Delta t} [P_u \cdot \tilde{R\hat{O}V}_{ur} + (1 - P_u) \cdot \tilde{R\hat{O}V}_{dl}]$; $\tilde{R\hat{O}V}_{um}$ and $\tilde{R\hat{O}V}_{dm}$ for the medium volatility to get $\tilde{R\hat{O}V}_m = e^{-r_m \Delta t} [\tilde{R\hat{O}V}_{um} \cdot P_m + \tilde{R\hat{O}V}_{dm} \cdot (1 - P_m)]$; and $\tilde{R\hat{O}V}_{ul}$ and $\tilde{R\hat{O}V}_{dl}$ for the smallest volatility to get $\tilde{R\hat{O}V}_d = e^{-r_h \Delta t} [\tilde{R\hat{O}V}_{ul} \cdot P_d + \tilde{R\hat{O}V}_{dr} \cdot (1 - P_d)]$.
- [Step 4]: Compute the FROV from $t = n-1$ to $t = n-2$. We use the same principle as the calculation of the fuzzy option price from $t = n$ to $t = n-1$ with three fuzzy option prices at $t = n-1$. We still use the same way for the FROV from $t = n$ to $t = n-1$, and the value we get at every node will have multiple FROVs.
- [Step 5]: Compute the fuzzy option price from $t = n-2$ to $t = n-3, \dots, t = 1$. The same principle applies to the FROV from $t = n-1$ to $t = n-2$. For computing one FROV, we shall generalize the probabilistic decision rule for optimal investment strategy to a fuzzy setting: Here, T is the maximum deferral time, and t^* is the time at which investment (exercise the option) is made, $0 \leq t^* \leq T$, for which the option, $\tilde{R\hat{O}V}_{t^*}$, attains its maximum value $\tilde{R\hat{O}V}_{t^*} = \max_{t=0, 1, \dots, T} \tilde{R\hat{O}V}_t$.

However, to find a maximum element from the set $\{\tilde{R\hat{O}V}_0, \tilde{R\hat{O}V}_1, \dots, \tilde{R\hat{O}V}_T\}$ is not an easy task because it involves ranking of triangular fuzzy numbers. In our computerized implementation, we have employed the following function to

determine the expected fuzzy real option values $\{\tilde{R\ddot{O}V}_u, \tilde{R\ddot{O}V}_m, \tilde{R\ddot{O}V}_d\}$ of triangular form:

$$E(\tilde{R\ddot{O}V}_t) = \text{Max}\{[(\tilde{R\ddot{O}V}_u - \tilde{R\ddot{O}V}_d) + (\tilde{R\ddot{O}V}_m - \tilde{R\ddot{O}V}_d)]/3 + \tilde{R\ddot{O}V}_d, 0\},$$

where $\tilde{R\ddot{O}V}_u$, $\tilde{R\ddot{O}V}_m$, and $\tilde{R\ddot{O}V}_d$ are the largest, middle, and the smallest values of the fuzzy real option values, respectively. In the following subsections, we employ an example to describe the application of FROV under uncertainty.

109.4.1 Fuzzy State

Assume that the manager is projecting possible risk rates in the next term for different future outlooks of the economy: “booming,” “fair,” and “recession.” Suppose state set $S = \{S_1, S_2, S_3\}$, where S_i denotes the risk rate of ROV and the set represents a collection of fuzzy states. The probability of risk-rate state can be illustrated in Table 1. For example, when the economy is in the state of “booming,” the probability of a 3% risk rate is 0.6.

109.4.2 Fuzzy Sample Information

While F , K , T , and R can be derived directly from observation, the calculation of σ requires the use of cash flow over some past periods of time. In response to recent cash flow fluctuations, the manager has readjusted the magnitude of fluctuation for the cash flow (σ). Based on historical statistics, σ is revised downward from its current level of 60–40%. Suppose the sample message space $X = \{x_1, x_2, x_3\}$, where x_r , $r = 1, 2, 3$ denotes the cash flow and (x_r) is an independent event. The manager produces estimations based on two basic assumptions of “very high risk-rate growth” and “relatively flat risk-rate growth.” Hence the fuzzy sample message space can be expressed as $\tilde{M} = \{\tilde{M}_1, \tilde{M}_2\}$, where $\tilde{M}_1$ denotes very high risk-rate growth and $\tilde{M}_2$ a relatively flat risk-rate growth. It is also known that historically given S_i , company’s prior probability of the occurrence of x_r is $P(x_r | S_i)$, as shown in Table 2, and the prior probability of the membership function $u_{\tilde{M}_j}(x_r)$ and x_r for fuzzy sample message $\tilde{M}_j$, $j = 1, 2$ is $P(x_r)$, as shown in Table 3.

From the above data, we can get the prior probability and posterior probability shown in Table 4. Then we can compute and analyze the results of FROV, assuming that the initial outlay, K , is \$10,000 and the net cash flows are \$3000, \$5000, and \$7000 associated with each prior probability scenario. The probability and cash flow in fuzzy environment can be simplified as in Table 4.

In Table 4, we consider a project that requires an initial outlay (K) of \$10,000 (column 1). In each of the following time periods, the cash flow (columns 3, 5, and 7) to be received is not known with perfect certainty, but the probabilities associated with each cash flow in each period are assumed to be known (columns 2, 4, and 6),

Table 1 $\mu_{\tilde{F}_k}(S_i)$ and $P(S_i)$

	$S_i(R_i)$		
$\mu_{\tilde{F}_k}(S_i)/P(S_i)$	3%	4%	5%
$\mu_{\tilde{F}_1}(S_i)$	0.6	0.4	0
$\mu_{\tilde{F}_2}(S_i)$	0.2	0.7	0.1
$\mu_{\tilde{F}_3}(S_i)$	0.1	0.4	0.5
$P(S_i)$	0.3	0.5	0.2

Table 2 $P(x_r|S_i)$

		x_r		
S_i	R_i	\$3,000	\$5,000	\$7,000
S_1	3%	0.25	0.3	0.25
S_2	4%	0.5	0.4	0.5
S_3	5%	0.25	0.3	0.25

Table 3 $\mu_{\tilde{M}_j}(x_r)$ and $P(x_r)$

	x_r		
$\tilde{\mu}_{\tilde{M}_j}(x_r)/P(x_r)$	\$3,000	\$5,000	\$7,000
$\tilde{\mu}_{\tilde{M}_1}(x_r)$	0.3	0.2	0.25
$\tilde{\mu}_{\tilde{M}_2}(x_r)$	0.2	0.2	0.25
$P(x_r)$	0.5	0.4	0.5

so that we use triangular fuzzy number to deal with cash flow and probability. We note that columns (4) and (6) are fuzzy conditional-probability figures, where the later periods' expected cash flows depend highly on what occurred in earlier time periods. Given our fuzzy cash flow and fuzzy probability estimates for periods 1, 2, and 3, we find 27 possible fuzzy joint probabilities (column 8), each of which corresponds to a cash-flow series. Thus in the uppermost path, we find the fuzzy joint probability 0.015 being associated with a fuzzy cash flow of \$2000 in period 1, followed by fuzzy cash flows of \$2000 and \$1000 in periods 2 and 3, respectively. This particular path is the worst possible result; in nondiscounted dollar terms, there is a 50% loss on the investment (see Table 5 at $t = 1$). At the other end of the spectrum, we find the best possible outcome offers a return \$12,945 with a fuzzy joint probability of 0.0125 (see Table 5 at $t = 27$). The returns and fuzzy joint probabilities can be calculated similarly for the other 25 possible patterns.

While the primary hurdle in this process is in estimating the fuzzy cash flows and the fuzzy probabilities, we recognize that it is the fuzzy NPV figures we are ultimately interested in. Table 5 gives the fuzzy present value of the fuzzy cash flows and the fuzzy net present value of the project for each fuzzy cash-flow series, where a 4% discount rate was employed. When we multiply each joint probability by the expected net present value associated with that probability, we obtain the expected net present value for the project as a whole to be \$2,517.18.

Based upon the cash flows and standard deviations from Table 5, we use triangular fuzzy number to obtain the $\tilde{F}$ and $\tilde{\sigma}(\tilde{F})$ in Table 6. We then use the discount rate $\tilde{R} = [0.03, 0.04, 0.05]$ to compute the FROV and transform them into the expected fuzzy real option value ($E(\tilde{ROV}_t)$).

Referring to Table 6, we are dealing with a case of uncertainty because the fuzzy probabilities associated with each fuzzy cash flow in each period are not known. According to Table 5, we can compute the standard deviation of fuzzy cash flows and use triangular fuzzy numbers to obtain the interval of fuzzy cash flows (column 2). Similarly, the computation of fuzzy variance of the present value of the expected cash flows uses the same process (column 3). Then based upon $\tilde{F}$ and $\tilde{\sigma}(\tilde{F})$, we can obtain column 4 (FROV). The fuzzy variance of the fuzzy cash flows and fuzzy real option values are triangular fuzzy numbers. Finally, we use the defuzzified fuzzy ranking method to determine the expected fuzzy real option values (column 5). From

where t : time (in years), $\tilde{F}$: fuzzy cash flow, $\tilde{\sigma}(\tilde{F})$: variance of the present value expected fuzzy cash flows, $FROI$: fuzzy real option value, and $E(\tilde{ROV}_t)$: expected fuzzy real option value

Table 6, we know that the FROV will increase with increasing expected fuzzy cash flow estimates. If the fuzzy volatility of cash flow increases, then the FROV will also increase.

In sum, when the environment is uncertain, the manager will face a distribution of future cash flows rather than a single-point estimate of future cash flows in each period. To deal with these uncertain cash flows, we employ the fuzzy real option valuation method. Such valuation method recognizes the importance of uncertainty, which the NPV analysis assumes away. We use the fuzzy real option valuation to compare and analyze the project, then we obtain the expected fuzzy real option values for the project, $\tilde{R\ddot{O}V}_{t^*} = \max_{t=0,1,\dots,T} \tilde{R\ddot{O}V}_t$, where the maximum deferral time is $T = 27$ and the investment decision time (exercise the option) is time t^* ; $0 \leq t^* \leq T$. Generally, the longer the time to maturity, the greater will be the FROV. By using FROV model, we can get the optimal time to abandon the project. In Table 6, it is shown that the optimal time to abandon is $t = 14$ at which $E(\tilde{R\ddot{O}V}_t)$ attends its maximum value.

109.5 Conclusions

The fuzzy capital budgeting approaches allow the cash flows estimate to be fuzzy numbers. Fuzzy cash flows can better reflect the uncertainty in the project. The integration of qualitative information into the process gives better decision support. The fuzzy real option approach also supports the determination of the optimal time to abandon the project, which the traditional method cannot do. The FROV thus offers a comprehensive way of presenting the value of possibilities opened by the project, which is further enhanced with frequently updated fuzzy cash flows. Finally, we would like to stress that advanced decision methods such as real options and fuzzy capital budgeting open the chance to explore the value of flexibility inside and outside a project, and give further insight into the uncertainty of large investments. The uncertainty is genuine, i.e., we simply do not know the exact levels of future cash flows. Without introducing FROV, it would not be possible to formulate this genuine uncertainty. The proposed model that incorporates subjective judgments and statistical uncertainties may give managers a better understanding of the problem when making investment decisions.

The findings of this chapter and their implications for the managerial decision-making can be summarized as follows: (1) The FROV increases with increasing expected cash flows estimates; proactive management can influence this by developing market strategies to enhance the sales and trim the costs; (2) FROV increases with increasing fuzzy volatility; the corporate management can be proactive and find ways to expand to new markets and product innovations as end results of their strategic decisions; (3) the longer the time to maturity, the greater will be the FROV; proactive management can make sure of this development by maintaining protective barriers and maintaining a technological lead; (4) an increase in risk-free rate of returns will increase the FROV, and this can be further enhanced by closely

monitoring changes in interest rates; and (5) the FROV will decrease if value is lost during the postponement of the investment, but this can be countered by either creating business barriers for competitors or by better managing key resources.

Appendix Supplementary Explanation for Fuzzy Set

The Definition of Fuzzy Set

Fuzzy sets have been introduced by Zadeh (1965). What Zadeh proposed is very much a paradigm shift that first gained acceptance in the Far East, and its successful application has ensured its adoption around the world. Fuzzy sets are an extension of classical set theory and are used in fuzzy logic. In classical set theory, the membership of elements in relation to a set is assessed in binary terms according to a crisp condition – an element either belongs or does not belong to the set. By contrast, fuzzy set theory permits the gradual assessment of the membership of elements in relation to a set; this is described with the aid of a membership function valued in the real unit interval $[0, 1]$. Fuzzy sets are an extension of classical set theory since, for a certain universe, a membership function may act as an indicator function, mapping all elements to either 1 or 0, as in the classical notion. Specifically, a fuzzy set is any set that allows its members to have different grades of membership (membership function) in the interval $[0, 1]$. A fuzzy set on a classical set X is defined as follows:

$$\tilde{A} = \{(x, \mu_A(x)) | x \in X\}.$$

Membership Function

The membership function $\mu_A(x)$ quantifies the grade of membership of the elements x to the fundamental set X . An element mapping to the value 0 means that the member is not included in the given set; 1 describes a fully included member. Values strictly between 0 and 1 characterize the fuzzy members.

Fuzzy Logic

Fuzzy logic is a superset of conventional (Boolean) logic that has been extended to handle the concept of partial truth values between “completely true” and “completely false.” As its name suggests, it is the logic underlying modes of reasoning which are approximate rather than exact. The importance of fuzzy logic derives from the fact that most modes of human reasoning and especially common sense reasoning are approximate in nature.

The Operations of Fuzzy Set

After knowing about the characteristic of fuzzy set, we will introduce the operations of fuzzy set. A fuzzy number is a convex, normalized fuzzy set whose membership function is at least segmental continuous and has the functional value $\mu_A(x) = 1$ at precisely one element. This can be likened to the funfair game “guess your weight,” where someone guesses the contestants weight, with closer guesses being more correct, and where the guesser “wins” if they guess near enough to the contestant’s weight, with the actual weight being completely correct (mapping to 1 by the membership function). A fuzzy interval is an uncertain set with a mean interval whose elements possess the membership function value $\mu_A(x) = 1$. As in fuzzy numbers, the membership function must be convex, normalized, and at least segmental continuous.

Defuzzify

When we are through the operations of fuzzy set to get the fuzzy interval, we will convert the fuzzy value into the crisp value. Below are some methods that convert a fuzzy set back into a single crisp (nonfuzzy) value. This is something that is normally done after a fuzzy decision has been made, and the fuzzy result must be used in the real world. For example, if the final fuzzy decision were to adjust the temperature setting on the thermostat a “little higher,” then it would be necessary to convert this “little higher” fuzzy value to the “best” crisp value to actually move the thermostat setting by some real amount.

Fuzzy Decision

After the process of defuzzifying, the next step is to make a fuzzy decision. Fuzzy decision is a model for decision-making in a fuzzy environment, and the object function and constraints are characterized as their membership functions, the intersection of fuzzy constraints, and fuzzy objection function.

Appendix A: Derivation of Dividend Discount Model

A.1 Summation of Infinite Geometric Series

Summation of geometric series can be defined as:

$$S = A + AR + AR^2 + \cdots + AR^{n-1} \quad (\text{A.1})$$

Multiplying both sides of Equation A.1 by R , we obtain

$$RS = AR + AR^2 + \cdots + AR^{n-1} + AR^n \quad (\text{A.2})$$

Subtracting Equation A.1 by Equation A.2, we obtain

$$S - RS = A - AR^n$$

It can be shown

$$S = \frac{A(1 - R^n)}{1 - R} \quad (\text{A.3})$$

If R is smaller than 1, and n approaches to ∞ , then R^n approaches to 0 i.e.,

$$S_{\infty} = A + AR + AR^2 + \cdots + AR^{n-1} + \cdots + AR^{\infty}, \quad (\text{A.4})$$

then,

$$S_{\infty} = \frac{A}{1 - R} \quad (\text{A.5})$$

A.2 Dividend Discount Model

Dividend Discount Model can be defined as:

$$P_0 = \frac{D_1}{1+k} + \frac{D_2}{(1+k)^2} + \frac{D_3}{(1+k)^3} + \dots \quad (\text{A.6})$$

Where P_0 = present value of stock price per share D_t = dividend per share in period t ($t = 1, 2, \dots, n$)

If dividends grow at a constant rate, say g , then, $D_2 = D_1(1+g)$, $D_3 = D_2(1+g) = D_1(1+g)^2$, and so on.

Then, Equation A.6 can be rewritten as:

$$\begin{aligned} P_0 &= \frac{D_1}{1+k} + \frac{D_1(1+g)}{(1+k)^2} + \frac{D_1(1+g)^2}{(1+k)^3} + \dots \text{ or,} \\ P_0 &= \frac{D_1}{1+k} + \frac{D_1}{(1+k)} \times \frac{(1+g)}{(1+k)} + \frac{D_1}{(1+k)} \times \frac{(1+g)^2}{(1+k)^2} + \dots \end{aligned} \quad (\text{A.7})$$

Comparing Equation A.7 with Equation A.4, i.e., $P_0 = S_\infty$, $\frac{D_1}{1+k} = A$, and $\frac{1+g}{1+k} = R$ as in the Equation A.4.

Therefore, if $\frac{1+g}{1+k} < 1$ or if $k > g$, we can use Equation A.5 to find out P_0 i.e.,

$$\begin{aligned} P_0 &= \frac{D_1/(1+k)}{1 - [(1+g)/(1+k)]} \\ &= \frac{D_1/(1+k)}{[1+k - (1+g)]/(1+k)} \\ &= \frac{D_1/(1+k)}{(k-g)/(1+k)} \\ &= \frac{D_1}{k-g} = \frac{D_0(1+g)}{k-g} \end{aligned}$$

Appendix B: Derivation of DOL, DFL and DCL

B.1 DOL

Let P = price per unit

V = variable cost per unit

F = total fixed cost

Q = quantity of goods sold

The definition of DOL can be defined as: DOL (Degree of operating leverage)

$$\begin{aligned}
 &= \frac{\text{Percentage Change in Profits}}{\text{Percentage Change in Sales}} \\
 &= \frac{\Delta \text{EBIT} / \text{EBIT}}{\Delta \text{Sales} / \text{Sales}} \\
 &= \frac{\{[Q(P-V)-F] - [Q'(P-V)-F]\} / [Q(P-V)-F]}{(P \times Q - P \times Q') / (P \times Q)} \\
 &= \frac{[Q(P-V) - Q'(P-V)] / [Q(P-V)-F]}{P(Q-Q') / P \times Q} \\
 &= \frac{(Q-Q')(P-V) / [Q(P-V)-F]}{P(Q-Q') / P \times Q} \\
 &= \frac{\cancel{(Q-Q')}(P-V)}{Q(P-V)-F} \times \frac{P \times Q}{P \cancel{(Q-Q')}} \\
 &= \frac{Q(P-V)}{Q(P-V)-F} \\
 &= \frac{Q(P-V)-F+F}{Q(P-V)-F} = \frac{Q(P-V)-F}{Q(P-V)-F} + \frac{F}{Q(P-V)-F} \\
 &= 1 + \frac{F}{Q(P-V)-F} \\
 &= 1 + \frac{\text{Fixed Costs}}{\text{Profits}}
 \end{aligned}$$

B.2 DFL

$$\left. \begin{array}{l} \text{Let } i = \text{interest rate on} \\ \text{outstanding debt} \\ D = \text{outstanding debt} \end{array} \right\} \begin{array}{l} iD = \text{interest payment} \\ \text{on debt} \end{array}$$

N = the total number of shares outstanding

τ = corporate tax rate

$$EAIT = [Q(P - V) - F - iD](1 - \tau)$$

The definition of DFL can be defined as:

DFL (Degree of financial leverage)

$$\begin{aligned} &= \frac{\Delta \text{EPS/EPS}}{\Delta \text{EBIT/EBIT}} = \frac{(\Delta EAIT/N)/(\text{EAIT}/N)}{\Delta \text{EBIT/EBIT}} \\ &= \frac{\Delta \text{EAIT/EAIT}}{\Delta \text{EBIT/EBIT}} \\ &= \frac{[Q(P - V) - F - iD](1 - \tau) - [Q'(P - V) - F - iD]}{(1 - \tau)[Q(P - V) - F - iD](1 - \tau)} \\ &= \frac{[Q(P - V) - F] - [Q'(P - V) - F]}{[Q(P - V) - F]} \\ &= \frac{[Q(P - V)](1 - \tau) - [Q'(P - V)](1 - \tau)}{[Q(P - V) - F - iD](1 - \tau)} \\ &= \frac{[Q(P - V) - Q'(P - V)]}{[Q(P - V) - F]} \\ &= \frac{[\cancel{Q - Q'}(P - V)](\cancel{1 - \tau})}{[Q(P - V) - F - iD](\cancel{1 - \tau})} \times \frac{Q(P - V) - F}{\cancel{Q - Q'}(P - V)} \\ &= \frac{Q(P - V) - F}{Q(P - V) - F - iD} \left(= \frac{\text{EBIT}}{\text{EBIT} - iD} \right) \end{aligned}$$

B.3 DCL (Degree of Combined Leverage)

$$= \text{DOL} \times \text{DFL}$$

$$= \frac{Q(P - V)}{\cancel{Q(P - V)} - F} \times \frac{\cancel{Q(P - V)} - F}{Q(P - V) - F - iD} = \frac{Q(P - V)}{Q(P - V) - F - iD}$$

Appendix C: Derivation of Crossover Rate

Suppose there are two projects under consideration. Cash flows of project A, B and B – A are as follows:

Period	0	1	2	3
Project A	– 10,500	10,000	1,000	1,000
Project B	– 10,500	1,000	1,000	12,000
Cash flows of B – A	0	– 9,000	0	11,000

Based upon the information the table above we can calculate the NPV of Project A and Project B under different discount rates. The results are presented in Table A.1.

NPV(B) is higher with low discount rates and NPV(A) is higher with high discount rates. This is because the cash flows of project A occur early and those of project B occur later. If we assume a high discount rate, we would favor project A; if a low discount rate is expected, project B will be chosen. In order to make the right choice, we can calculate the crossover rate. If the discount rate is higher than the crossover rate, we should choose project A; if otherwise, we should go for project B.

The crossover rate, R_c , is the rate such that NPV(A) equals to NPV(B).

Suppose the crossover rate is R_c , then

$$\begin{aligned} \text{NPV}(A) = & -10,500 + 10,000/(1 + R_c) + 1,000/(1 + R_c)^2 \\ & + 1,000/(1 + R_c)^3 \end{aligned} \tag{A.8}$$

$$\begin{aligned} \text{NPV}(B) = & -10,500 + 1,000/(1 + R_c) + 1,000/(1 + R_c)^2 \\ & + 12,000/(1 + R_c)^3 \\ = & \text{NPV}(A) \end{aligned} \tag{A.9}$$

Therefore,

$$\begin{aligned} & -10,500 + \frac{10,000}{1 + R_c} + \frac{1,000}{(1 + R_c)^2} + \frac{1,000}{(1 + R_c)^3} \\ = & -10,500 + \frac{1,000}{1 + R_c} + \frac{1,000}{(1 + R_c)^2} + \frac{12,000}{(1 + R_c)^3} \end{aligned}$$

Table A.1 NPV of Project A and B under different discount rates

Discount rate (%)	NPV (Project A)	NPV (Project B)
0	1500.00	3500.00
5	794.68	1725.46
10	168.67	251.31
15	−390.69	−984.10
20	−893.52	−2027.78

Rearranging the above equation (moving all terms on the LHS to the RHS), we obtain Equation A.10

$$\begin{aligned} 0 = & [-10,500 - (-10,500)] + \left[\frac{1,000}{1 + R_c} - \frac{10,000}{1 + R_c} \right] \\ & + \left[\frac{1,000}{(1 + R_c)^2} - \frac{1,000}{(1 + R_c)^2} \right] + \left[\frac{12,000}{(1 + R_c)^3} - \frac{1,000}{(1 + R_c)^3} \right] \end{aligned} \tag{A.10}$$

Solving Equation A.10 by trial and error method for R_c , R_c equals 10.55%.
Using the procedure of calculating internal rate of return (IRR) as discussed in Equations A.8, A.9, and A.10, we calculate the IRR for both Project A and Project B. The IRR for Project A and B are 11.45% and 10.95% respectively. From this information, we have concluded that Project A will perform better than Project B without consideration for change of discount rate. Therefore, the IRR decision rule cannot be used for capital budgeting decisions when there exists an increasing or decreasing net cash inflow. This is so called “The Timing Problem” for using the IRR method for capital budgeting decisions.

Appendix D: Capital Budgeting Decisions with Different Lives

D.1 Mutually Exclusive Investment Projects with Different Lives

The traditional NPV technique may not be the appropriate criterion to select a project from mutually exclusive investment projects, if these projects have different lives. The underlying reason is that, compared with a long-life project, a short-life project can be replicated more quickly in the long run. In order to compare projects with different lives, we compute the NPV of an infinite replication of the investment project. For example, let Projects A and B be two mutually exclusive investment projects with the following cash flows.

Year	Project A	Project B
0	100	100
1	70	50
2	70	50
3		50

By assuming a discount rate of 12%, the traditional NPV of Project A is 18.30 and the NPV of Project B is 20.09. This shows that Project B is a better choice than Project A. However, the NPV with infinite replications for Project A and B should be adjusted into a comparable basis.

In order to compare Projects A and B, we compute the NPV of an infinite stream of constant scale replications. Let $NPV(N, \infty)$ be the NPV of an N -year project with NPV (N), replicated forever. This is exactly the same as an annuity paid at the beginning of the first period and at the end of every N years from that time on. The NPV of the annuity is:

$$NPV(N, \infty) = NPV(N) + \frac{NPV(N)}{(1 + K)^N} + \frac{NPV(N)}{(1 + K)^{2N}} + \cdots$$

In order to obtain a closed-form formula, let $(1/[(1 + K)^N]) = H$. Then we have:

$$NPV(N, t) = NPV(N)(1 + H + H^2 + \cdots + H^t) \tag{A.11}$$

Multiplying both sides by H , this becomes

$$H[NPV(N, t)] = NPV(N)(H + H^2 + \dots + H^t + H^{t+1}) \quad (\text{A.12})$$

Subtracting Equation A.12 from Equation A.11 gives:

$$\begin{aligned} NPV(N, t) - (H)NPV(N, t) &= NPV(N)(1 - H^{t+1}) \\ NPV(N, t) &= \frac{NPV(N)(1 - H^{t+1})}{1 - H} \end{aligned}$$

Taking the limit as the number of replications, t , approaches infinity gives:

$$\begin{aligned} \lim_{t \rightarrow \infty} NPV(N, t) &= NPV(N, \infty) \\ &= NPV \left[\frac{1}{1 - [1/(1 + K)^N]} \right] \\ &= NPV(N) \left[\frac{(1 + K)^N}{(1 + K)^N - 1} \right] \end{aligned} \quad (\text{A.13})$$

Equation A.13 is the NPV of an N -year project replicated at constant scale an infinite number of times. We can use it to compare projects with different lives because when their cash-flow streams are replicated forever, it is as if they had the same (infinite) life.

Based upon Equation A.13, we can calculate the NPV of Projects A and B as follows:

For Project A

$$\begin{aligned} &NPV(2, \infty) \\ &= NPV(2) \left[\frac{(1 + 0.12)^2}{(1 + 0.12)^2 - 1} \right] \\ &= (18.30) \left[\frac{1.2544}{0.2544} \right] \\ &= 90.23 \end{aligned}$$

For Project B

$$\begin{aligned} &NPV(3, \infty) \\ &= NPV(3) \left[\frac{(1 + 0.12)^3}{(1 + 0.12)^3 - 1} \right] \\ &= 20.09 \left[\frac{1.4049}{0.4049} \right] \\ &= 69.71 \end{aligned}$$

Consequently, we would choose to accept Project A over Project B, because, when the cash flows are adjusted for different lives, A provides the greater cash flow.

Alternatively, Equation A.13 can be rewritten as an equivalent annual NPV version as:

$$K \times NPV(N, \infty) = \frac{NPV(N)}{\text{Annuity factor}} \quad (\text{A.14})$$

where the annuity factor is

$$\frac{1 - 1/(1 + K)^N}{K}$$

The decision rule from Equation A.14 is equivalent to the decision rule of Equation A.13.

The different project lives can affect the beta coefficient estimate, as shown by Meyers and Turnbull (1977). For empirical guidance for evaluating capital-investment alternatives with unequal lives, the readers are advised to refer Emery (1982).

D.2 Equivalent Annual Cost

Equation A.14 can be written as:

$$NPV(N) = K \times NPV(N, \infty) \times \text{Annuity Factor} \quad (\text{A.15})$$

Corporate Finance by Ross, Westerfield, and Jaffe (2005, 7th edn, p. 193) has discussed about Equivalent Annual Cost. The Equivalent Annual Cost (C) can be calculated as follows:

$$NPV(N) = C \times \text{Annuity Factor} \quad (\text{A.16})$$

From Equations A.15 and A.16, we obtain

$$C = K \times NPV(N, \infty) \quad (\text{A.17})$$

Assume company A buys a machine that costs \$1,000 and the maintenance expense of \$250 is to be paid at the end of each of the 4 years. To evaluate this investment, we can calculate the present value of the machine. Assuming the discount rate as 10%, we have

$$\begin{aligned} NPV(A) &= 1000 + \frac{250}{1.1} + \frac{250}{(1.1)^2} + \frac{250}{(1.1)^3} + \frac{250}{(1.1)^4} \\ &= 1792.47 \end{aligned} \quad (\text{A.18})$$

Equation A.18 shows that payments of (1,000, 250, 250, 250, 250) are equivalent to a payment of 1792.47 at time 0. Using Equation A.16, we can equate the payment at time 0 of 1792.47 with a 4 year annuity.

$$\begin{aligned} 1792.47 &= C \times A_{0.1}^4 = C \times 3.1699 \\ C &= 565.47 \end{aligned}$$

In this example, following Equation A.13, we can find

$$\begin{aligned} NPV(N, \infty) &= 1749.47 \times (1 + 0.1)^4 / [(1 + 0.1)^4 - 1] \\ &= 5654.71 \end{aligned}$$

Then following the Equation A.17, we obtain

$$C = K \times NPV(N, \infty) = 0.1 \times 5654.71 = 565.47$$

Therefore, the equivalent annual cost C is identical to the equivalent annual NPV as defined in Equation A.14.

Appendix E: Derivation of Minimum-Variance Portfolio

If there is a two security portfolio, its variance can be defined as:

$$\sigma_p^2 = w_D^2 \sigma_D^2 + w_E^2 \sigma_E^2 + 2w_D w_E \text{Cov}(r_D, r_E) \quad (\text{A.19})$$

where r_D and r_E are the rate of return for security D and security E respectively; w_D and w_E are weight associated with security D and E respectively; σ_D^2 and σ_E^2 are variance of security D and E respectively; and $\text{Cov}(r_D, r_E)$ is the covariance between r_D and r_E .

The problem is choosing optimal w_D to minimize the portfolio variance, σ_p^2

$$\underset{w_D}{\text{Min}} \sigma_p^2 \quad (\text{A.20})$$

We can solve the minimization problem by differentiating the σ_p^2 with respect to w_D and setting the derivative equal to 0 i.e., we want to solve

$$\frac{\partial \sigma_p^2}{\partial w_D} = 0 \quad (\text{A.21})$$

Since, $w_D + w_E = 1$ or, $w_E = 1 - w_D$ therefore, the variance, σ_p^2 , can be rewritten as

$$\begin{aligned} \sigma_p^2 &= w_D^2 \sigma_D^2 + w_E^2 \sigma_E^2 + 2w_D w_E \text{Cov}(r_D, r_E) \\ &= w_D^2 \sigma_D^2 + (1 - w_D)^2 \sigma_E^2 + 2w_D(1 - w_D) \text{Cov}(r_D, r_E) \\ &= w_D^2 \sigma_D^2 + \sigma_E^2 - 2w_D \sigma_E^2 + w_D^2 \sigma_E^2 + 2w_D \text{Cov}(r_D, r_E) - 2w_D^2 \text{Cov}(r_D, r_E) \end{aligned}$$

Now, the first order conditions of Equation A.21 can be written as

$$2w_D \sigma_D^2 - 2\sigma_E^2 + 2w_D \sigma_E^2 + 2 \text{Cov}(r_D, r_E) - 4w_D \text{Cov}(r_D, r_E) = 0$$

Rearranging the above equation,

$$\begin{aligned}w_D\sigma_D^2 + w_D\sigma_E^2 - 2w_D\text{Cov}(r_D, r_E) &= \sigma_E^2 - \text{Cov}(r_D, r_E) \\[\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D, r_E)]w_D &= \sigma_E^2 - \text{Cov}(r_D, r_E)\end{aligned}$$

Finally, we have

$$w_D = \frac{\sigma_E^2 - \text{Cov}(r_D, r_E)}{\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D, r_E)}$$

Appendix F: Derivation of an Optimal Weight Portfolio Using the Sharpe Performance Measure

Solution for the weights of the optimal risky portfolio can be found by solving the following maximization problem:

$$\underset{w_D}{\text{Max}} S_p = \frac{E(r_p) - r_f}{\sigma_p}$$

where $E(r_p)$ = expected rates of return for portfolio P

r_f = risk free rates of return

S_p = sharpe performance measure, and

σ_p as defined in Equation A.19 of Appendix 5

We can solve the maximization problem by differentiating the S_p with respect to w_D , and setting the derivative equal to 0 i.e., we want to solve

$$\frac{\partial S_p}{\partial w_D} = 0 \quad (\text{A.22})$$

In the case of two securities, we know that

$$E(r_p) = w_D E(r_D) + w_E E(r_E) \quad (\text{A.23})$$

$$\sigma_p = [w_D^2 \sigma_D^2 + w_E^2 \sigma_E^2 + 2w_D w_E \text{Cov}(r_D, r_E)]^{1/2} \quad (\text{A.24})$$

$$w_D + w_E = 1 \quad (\text{A.25})$$

From above Equations A.23, A.24, and A.25, we can rewrite $E(r_p) - r_f$ and σ_p as:

$$\begin{aligned} E(r_p) - r_f &= w_D E(r_D) + w_E E(r_E) - r_f \\ &= w_D E(r_D) + (1 - w_D) E(r_E) - r_f \\ &\equiv f(w_D) \end{aligned} \quad (\text{A.26})$$

$$\begin{aligned}
\sigma_p &= [w_D^2 \sigma_D^2 + w_E^2 \sigma_E^2 + 2w_D w_E \text{Cov}(r_D, r_E)]^{1/2} \\
&= [w_D^2 \sigma_D^2 + (1 - w_D)^2 \sigma_E^2 + 2w_D(1 - w_D) \text{Cov}(r_D, r_E)]^{1/2} \\
&\equiv g(w_D)
\end{aligned} \tag{A.27}$$

Equation A.22 becomes

$$\begin{aligned}
\frac{\partial S_p}{\partial w_D} &= \frac{\partial [f(w_D)/g(w_D)]}{\partial w_D} \\
&= \frac{f'(w_D)g(w_D) - f(w_D)g'(w_D)}{[g(w_D)]^2} = 0
\end{aligned} \tag{A.28}$$

$$\text{where } f'(w_D) = \frac{\partial f(w_D)}{\partial w_D} = E(r_D) - E(r_E) \tag{A.29}$$

$$\begin{aligned}
g'(w_D) &= \frac{\partial g(w_D)}{\partial w_D} \\
&= \frac{1}{2} \times [w_D^2 \sigma_D^2 + (1 - w_D)^2 \sigma_E^2 + 2w_D(1 - w_D) \text{Cov}(r_D, r_E)]^{1/2-1} \\
&\quad \times [2w_D \sigma_D^2 + 2w_D \sigma_E^2 - 2\sigma_E^2 + 2\text{Cov}(r_D, r_E) - 4w_D \text{Cov}(r_D, r_E)] \\
&= [w_D \sigma_D^2 + w_D \sigma_E^2 - \sigma_E^2 + \text{Cov}(r_D, r_E) - 2w_D \text{Cov}(r_D, r_E)] \\
&\quad \times [w_D^2 \sigma_D^2 + (1 - w_D)^2 \sigma_E^2 + 2w_D(1 - w_D) \text{Cov}(r_D, r_E)]^{-1/2}
\end{aligned} \tag{A.30}$$

From Equation A.28,

$$\begin{aligned}
f'(w_D)g(w_D) - f(w_D)g'(w_D) &= 0, \text{ or} \\
f'(w_D)g(w_D) &= f(w_D)g'(w_D)
\end{aligned} \tag{A.31}$$

Now, plugging $f(w_D)$, $g(w_D)$, $f'(w_D)$, and $g'(w_D)$ [Equations A.26, A.27, A.29, and A.30] into Equation A.31, we have

$$\begin{aligned}
&[E(r_D) - E(r_E)] \\
&\quad \times [w_D^2 \sigma_D^2 + (1 - w_D)^2 \sigma_E^2 + 2w_D(1 - w_D) \text{Cov}(r_D, r_E)]^{1/2} \\
&= [w_D E(r_D) + (1 - w_D) E(r_E) - r_f] \\
&\quad \times [w_D \sigma_D^2 + w_D \sigma_E^2 - \sigma_E^2 + \text{Cov}(r_D, r_E) - 2w_D \text{Cov}(r_D, r_E)] \\
&\quad \times [w_D^2 \sigma_D^2 + (1 - w_D)^2 \sigma_E^2 + 2w_D(1 - w_D) \text{Cov}(r_D, r_E)]^{-1/2}
\end{aligned} \tag{A31}$$

Multiplying by $[w_D^2 \sigma_D^2 + (1 - w_D)^2 \sigma_E^2 + 2w_D(1 - w_D) \text{Cov}(r_D, r_E)]^{1/2}$ on both sides of Equation A.32, we have

$$\begin{aligned}
& [E(r_D) - E(r_E)] \\
& \times \left[w_D^2 \sigma_D^2 + (1 - w_D)^2 \sigma_E^2 + 2w_D(1 - w_D)\text{Cov}(r_D, r_E) \right] \\
& = [w_DE(r_D) + (1 - w_D)E(r_E) - r_f] \\
& \times [w_D \sigma_D^2 + w_D \sigma_E^2 - \sigma_E^2 + \text{Cov}(r_D, r_E) - 2w_D \text{Cov}(r_D, r_E)]
\end{aligned} \tag{A.33}$$

Rearrange all terms on both hand sides of Equation A.33, i.e.,

Left hand side of Equation A.33

$$\begin{aligned}
& [E(r_D) - E(r_E)] \\
& \times \left[w_D^2 \sigma_D^2 + (1 - w_D)^2 \sigma_E^2 + 2w_D(1 - w_D)\text{Cov}(r_D, r_E) \right] \\
& = [E(r_D) - E(r_E)] \\
& \times [w_D^2 \sigma_D^2 + \sigma_E^2 - 2w_D \sigma_E^2 + w_D^2 \sigma_E^2 + 2w_D \text{Cov}(r_D, r_E) - 2w_D^2 \text{Cov}(r_D, r_E)] \\
& = [E(r_D) - E(r_E)] \times \{ w_D^2 [\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D, r_E)] \\
& \quad + 2w_D [\text{Cov}(r_D, r_E) - \sigma_E^2] + \sigma_E^2 \} \\
& = [E(r_D) - E(r_E)] \times \{ w_D^2 [\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D, r_E)] \} \\
& \quad + [E(r_D) - E(r_E)] \times \{ 2w_D [\text{Cov}(r_D, r_E) - \sigma_E^2] \} + [E(r_D) - E(r_E)] \times \sigma_E^2 \\
& = [E(r_D) - E(r_E)] \times [\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D, r_E)] w_D^2 + 2[E(r_D) - E(r_E)] \\
& \quad \times [\text{Cov}(r_D, r_E) - \sigma_E^2] w_D + [E(r_D) - E(r_E)] \times \sigma_E^2
\end{aligned}$$

Right hand side of Equation A.33

$$\begin{aligned}
& [w_DE(r_D) + (1 - w_D)E(r_E) - r_f] \times [w_D \sigma_D^2 + w_D \sigma_E^2 \\
& - \sigma_E^2 + \text{Cov}(r_D, r_E) - 2w_D \text{Cov}(r_D, r_E)] \\
& = [w_DE(r_D) + E(r_E) - w_DE(r_E) - r_f] \times [w_D \sigma_D^2 \\
& \quad + w_D \sigma_E^2 - 2w_D \text{Cov}(r_D, r_E) - \sigma_E^2 + \text{Cov}(r_D, r_E)] \\
& = \{ w_D[E(r_D) - E(r_E)] + [E(r_E) - r_f] \} \times \{ w_D [\sigma_D^2 \\
& \quad + \sigma_E^2 - 2\text{Cov}(r_D, r_E)] + \text{Cov}(r_D, r_E) - \sigma_E^2 \} \\
& = w_D[E(r_D) - E(r_E)] \times w_D [\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D, r_E)] \\
& \quad + w_D[E(r_D) - E(r_E)] \times [\text{Cov}(r_D, r_E) - \sigma_E^2] \\
& \quad + [E(r_E) - r_f] \times w_D [\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D, r_E)] \\
& \quad + [E(r_E) - r_f] \times [\text{Cov}(r_D, r_E) - \sigma_E^2] \\
& = [E(r_D) - E(r_E)] \times [\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D, r_E)] w_D^2 \\
& \quad + [E(r_D) - E(r_E)] \times [\text{Cov}(r_D, r_E) - \sigma_E^2] w_D \\
& \quad + [E(r_E) - r_f] \times [\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D, r_E)] w_D \\
& \quad + [E(r_E) - r_f] \times [\text{Cov}(r_D, r_E) - \sigma_E^2]
\end{aligned}$$

Subtracting

$[E(r_D) - E(r_E)][\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D, r_E)]w_D^2$ and $[E(r_D) - E(r_E)][\text{Cov}(r_D, r_E) - \sigma_E^2]w_D$ from both hand sides of Equation A.33, we have

$$\begin{aligned} & [E(r_D) - E(r_E)] \times [\text{Cov}(r_D, r_E) - \sigma_E^2]w_D + [E(r_D) - E(r_E)] \times \sigma_E^2 \\ &= [E(r_E) - r_f] \times [\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D, r_E)]w_D + [E(r_E) - r_f] \\ & \quad \times [\text{Cov}(r_D, r_E) - \sigma_E^2] \end{aligned} \quad (\text{A.34})$$

Moving all the terms with w_D on one side and leaving the rest terms on the other side from Equation A.34, we have

$$\begin{aligned} & [E(r_D) - E(r_E)] \times \sigma_E^2 - [E(r_E) - r_f] \times [\text{Cov}(r_D, r_E) - \sigma_E^2] \\ &= [E(r_E) - r_f] \times [\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D, r_E)]w_D \\ & \quad - [E(r_D) - E(r_E)] \times [\text{Cov}(r_D, r_E) - \sigma_E^2]w_D \end{aligned} \quad (\text{A.35})$$

Rearrange Equation A.35 in order to solve for w_D , i.e.,

$$\begin{aligned} & [E(r_D) - E(r_E) + E(r_E) - r_f] \times \sigma_E^2 \\ & \quad - [E(r_E) - r_f] \text{Cov}(r_D, r_E) \\ &= \{ [E(r_E) - r_f] \sigma_D^2 + [E(r_E) - r_f] \sigma_E^2 \\ & \quad - [E(r_E) - r_f] [2\text{Cov}(r_D, r_E)] - [E(r_D) \\ & \quad - E(r_E)] \text{Cov}(r_D, r_E) + [E(r_D) - E(r_E)] \sigma_E^2 \} w_D \\ &= \{ [E(r_D) - r_f] \sigma_E^2 + [E(r_E) - r_f] \sigma_D^2 - [E(r_D) - r_f + E(r_E) - r_f] \text{Cov}(r_D, r_E) \} w_D \end{aligned}$$

Finally, we have the optimum weight of security D as

$$\begin{aligned} w_D &= \frac{[E(r_D) - r_f] \sigma_E^2 - [E(r_E) - r_f] \text{Cov}(r_D, r_E)}{[E(r_D) - r_f] \sigma_E^2 + [E(r_E) - r_f] \sigma_D^2} \\ & \quad - [E(r_D) - r_f + E(r_E) - r_f] \text{Cov}(r_D, r_E) \end{aligned}$$

Appendix G: Applications of the Binomial Distribution to Evaluate Call Options

In this appendix, we show how the binomial distribution is combined with some basic finance concepts to generate a model for determining the price of stock options.

G1. What is an Option?

In the most basic sense, an **option** is a contract conveying the right to buy or sell a designated security at a stipulated price. The contract normally expires at a pre-determined date. The most important aspect of an option contract is that the purchaser is under no obligation to buy; it is, indeed, an “option.” This attribute of an option contract distinguishes it from other financial contracts. For instance, whereas the holder of an option may let his or her claim expire unused if he or she so desires, other financial contracts (such as futures and forward contracts) obligate their parties to fulfill certain conditions.

A *call option* gives its owner the right to buy the underlying security, a *put option* the right to sell. The price at which the stock can be bought (for a call option) or sold (for a put option) is known as the exercise price.

G2. The Simple Binomial Option Pricing Model

Before discussing the binomial option model, we must recognize its two major underlying assumptions. First, the binomial approach assumes that trading takes place in discrete time, that is, on a period-by-period basis. Second, it is assumed that the stock price (the price of the underlying asset) can take on only two possible values each period; it can go up or go down.

Say we have a stock whose current price per share S can advance or decline during the next period by a factor of either u (up) or d (down). This price either will increase by the proportion $u - 1 \geq 0$ or will decrease by the proportion $1 - d$, $0 < d < 1$. Therefore, the value S in the next period will be either uS or dS . Next, suppose that a call option exists on this stock with a current price per share of C and an exercise price per share of X and that the option has one period left to maturity.

This option's value at expiration is determined by the price of its underlying stock and the exercise price X . The value is either

$$C_u = \text{Max}(0, uS - X) \quad (\text{A.36})$$

or

$$C_d = \text{Max}(0, dS - X) \quad (\text{A.37})$$

Why is the call worth $\text{Max}(0, uS - X)$ if the stock price is uS ? The option holder is not obliged to purchase the stock at the exercise price of X , so she or he will exercise the option only when it is beneficial to do so. This means the option can never have a negative value. When is it beneficial for the option holder to exercise the option? When the price per share of the stock is greater than the price per share at which he or she can purchase the stock by using the option, which is the exercise price, X . Thus if the stock price uS exceeds the exercise price X , the investor can exercise the option and buy the stock. Then he or she can immediately sell it for uS , making a profit of $uS - X$ (ignoring commission). Likewise, if the stock price declines to dS , the call is worth $\text{Max}(0, dS - X)$.

Also for the moment, we will assume that the risk-free interest rate for both borrowing and lending is equal to r percent over the one time period and that the exercise price of the option is equal to X .

To intuitively grasp the underlying concept of option pricing, we must set up a *risk-free portfolio* – a combination of assets that produces the same return in every state of the world over our chosen investment horizon. The investment horizon is assumed to be one period (the duration of this period can be any length of time, such as an hour, a day, a week, etc.). To do this, we buy h share of the stock and sell the call option at its current price of C . Moreover, we choose the value of h such that our portfolio will yield the same payoff whether the stock goes up or down.

$$h(uS) - C_u = h(dS) - C_d \quad (\text{A.38})$$

By solving for h , we can obtain the number of shares of stock we should buy for each call option we sell.

$$h = \frac{C_u - C_d}{(u - d)S} \quad (\text{A.39})$$

Here h is called the *hedge ratio*. Because our portfolio yields the same return under either of the two possible states for the stock, it is without risk and therefore should yield the risk-free rate of return, r percent, which is equal to the risk-free borrowing and lending rate, the condition must be true; otherwise, it would be possible to earn a risk-free profit without using any money. Therefore, the ending portfolio value must be equal to $(1 + r)$ times the beginning portfolio value, $hS - C$.

$$(1 + r)(hS - C) = h(uS) - C_u = h(dS) - C_d \quad (\text{A.40})$$

Note that S and C represent the beginning values of the stock price and the option price, respectively.

Setting $R = 1 + r$, rearranging to solve for C , and using the value of h from Equation A.39, we get

$$C = \left[\left(\frac{R - d}{u - d} \right) C_u + \left(\frac{u - R}{u - d} \right) C_d \right] / R \quad (\text{A.41})$$

where $d < r < u$. To simplify this equation, we set

$$p = \frac{R - d}{u - d} \text{ so } 1 - p = \left\{ \frac{u - R}{u - d} \right\} \quad (\text{A.42})$$

Thus we get the option's value with one period to expiration

$$C = \frac{pC_u + (1 - p)C_d}{R} \quad (\text{A.43})$$

This is the binomial call option valuation formula in its most basic form. In other words, this is the binomial valuation formula with one period to expiration of the option.

To illustrate the model's qualities, let's plug in the following values, while assuming the option has one period to expiration. Let

$$\begin{aligned} X &= \$100 \\ S &= \$100 \\ U &= (1.10), \text{ so } uS = \$110 \\ D &= (0.90), \text{ so } dS = \$90 \\ R &= 1 + r = 1 + 0.07 = 1.07 \end{aligned}$$

First we need to determine the two possible option values at maturity, as indicated in Table A.2.

Next we calculate the value of p as indicated in Equation A.42.

$$\begin{aligned} p &= \frac{1.07 - 0.90}{1.10 - 0.90} = 0.85 \text{ so } 1 - p = \frac{1.10 - 1.07}{1.10 - 0.90} \\ &= 0.15 \end{aligned}$$

Solving the binomial valuation equation as indicated in Equation A.43, we get

$$\begin{aligned} C &= \frac{0.85(10) + 0.15(0)}{1.07} \\ &= \$7.94 \end{aligned}$$

Table A.2 Possible option value at maturity

Today Stock (S)	Option (C)	Next Period (Maturity)
\$100 C	$uS = \$110$	$C_u = \text{Max}(0, uS - X)$ $= \text{Max}(0, 110 - 100)$ $= \text{Max}(0, 10)$ $= \$10$
	$dS = \$90$	$C_d = \text{Max}(0, dS - X)$ $= \text{Max}(0, 90 - 100)$ $= \text{Max}(0, -10)$ $= \$0$

The correct value for this particular call option today, under the specified conditions, is \$7.94. If the call option does not sell for \$7.94, it will be possible to earn arbitrage profits. That is, it will be possible for the investor to earn a risk-free profit while using none of his or her own money. Clearly, this type of opportunity cannot continue to exist indefinitely.

G3. The Generalized Binomial Option Pricing Model

Suppose we are interested in the case where there is more than one period until the option expires. We can extend the one-period binomial model to consideration of two or more periods.

Because we are assuming that the stock follows a binomial process, from one period to the next it can only go up by a factor of u or go down by a factor of d . After one period the stock's price is either uS or dS . Between the first and second periods, the stock's price can once again go up by u or down by d , so the possible prices for the stock two periods from now are uuS , udS , and ddS . This process is demonstrated in tree diagram (Figure A.1) given in Example A.1 later in this appendix.

Note that the option's price at expiration, two periods from now, is a function of the same relationship that determined its expiration price in the one-period model, more specifically, the call option's maturity value is always

$$C_T = [0, S_T - X]$$

(A.44)

where T designated the maturity date of the option.

To derive the option's price with two periods to go ($T = 2$), it is helpful as an intermediate step to derive the value of C_u and C_d with one period to expiration when the stock price is either uS or dS , respectively.

$$C_u = \frac{pC_{uu} + (1-p)C_{ud}}{R} \quad (\text{A.45})$$

$$C_d = \frac{pC_{du} + (1-p)C_{dd}}{R} \quad (\text{A.46})$$

Equation A.45 tells us that if the value of the option after one period is C_u , the option will be worth either C_{uu} (if the stock price goes up) or C_{ud} (if stock price goes down) after one more period (at its expiration date). Similarly, Equation A.46 shows that the value of the option is C_d after one period, the option will be worth either C_{du} or C_{dd} at the end of the second period. Replacing C_u and C_d in Equation A.43 with their expressions in Equations A.45 and A.46, respectively, we can simplify the resulting equation to yield the two-period equivalent of the one-period binomial pricing formula, which is

$$C = \frac{p^2C_{uu} + 2p(1-p)C_{ud} + (1-p)^2C_{dd}}{R^2} \quad (\text{A.47})$$

In Equation A.47, we used the fact that $C_{ud} = C_{du}$ because the price will be the same in either case.

We know the values of the parameters S and X . If we assume that R , u , and d will remain constant over time, the possible maturity values for the option can be determined exactly. Thus deriving the option's fair value with two periods to maturity is a relatively simple process of working backwards from the possible maturity values.

Using this same procedure of going from a one-period model to a two-period model, we can extend the binomial approach to its more generalized form, with n periods maturity

$$C = \frac{1}{R^n} \sum_{k=0}^n \frac{n!}{k!(n-k)!} p^k (1-p)^{n-k} \text{Max}[0, u^k d^{n-k} S - X] \quad (\text{A.48})$$

To actually get this form of the binomial model, we could extend the two-period model to three periods, then from three periods to four periods, and so on. Equation A.48 would be the result of these efforts. To show how Equation A.48 can be used to assess a call option's value, we modify the example as follows: $S = \$100$, $X = \$100$, $R = 1.07$, $n = 3$, $u = 1.1$ and $d = 0.90$.

First we calculate the value of p from Equation A.42 as 0.85, so $1 - p$ is 0.15. Next we calculate the four possible ending values for the call option after three periods in terms of $\text{Max}[0, u^k d^{n-k} S - X]$.

Fig. A.1 Price path of underlying stock (Source: Rendelman and Bartter, 1979, 1906)

$$C_1 = \left[0, (1.1)^3 (0.90)^0 (100) - 100 \right] = 33.10$$
$$C_2 = \left[0, (1.1)^2 (0.90) (100) - 100 \right] = 8.90$$
$$C_3 = \left[0, (1.1) (0.90)^2 (100) - 100 \right] = 0$$
$$C_4 = \left[0, (1.1)^0 (0.90)^3 (100) - 100 \right] = 0$$

Now we insert these numbers (C_1 , C_2 , C_3 , and C_4) into the model and sum the terms.

$$\begin{aligned}
C &= \frac{1}{(1.07)^3} \left[\frac{3!}{0!3!} (0.85)^0 (0.15)^3 \times 0 \right. \\
&\quad + \frac{3!}{1!2!} (0.85)^1 (0.15)^2 \times 0 \\
&\quad + \frac{3!}{2!1!} (0.85)^2 (0.15)^1 \times 8.90 \\
&\quad \left. + \frac{3!}{3!0!} (0.85)^3 (0.15)^0 \times 33.10 \right] \\
&= \frac{1}{1.225} \left[0 + 0 + \frac{3 \times 2 \times 1}{2 \times 1 \times 1} (0.7225)(0.15)(8.90) \right. \\
&\quad \left. + \frac{3 \times 2 \times 1}{3 \times 2 \times 1 \times 1} \times (0.61413)(1)(33.10) \right] \\
&= \frac{1}{1.225} [(0.32513 \times 8.90) + (0.61413 \times 33.10)] \\
&= \$18.96
\end{aligned}$$

As this example suggests, working out a multiple-period problem by hand with this formula can become laborious as the number of periods increases. Fortunately, programming this model into a computer is not too difficult.

Now let's derive a binomial option pricing model in terms of the cumulative binomial density function. As a first step, we can rewrite Equation A.48 as

$$\begin{aligned}
C &= S \left[\sum_{k=m}^n \frac{n!}{k!(n-k)!} p^k (1-p)^{n-k} \frac{u^k d^{n-k}}{R^n} \right] \\
&\quad - \frac{X}{R^n} \left[\sum_{k=m}^n \frac{n!}{k!(n-k)!} p^k (1-p)^{n-k} \right]
\end{aligned} \tag{A.49}$$

This formula is identical to Equation A.48 except that we have removed the Max operator. In order to remove the Max operator, we need to make $u^k d^{n-k} S - X$ positive, which we can do by changing the counter in the summation from $k = 0$ to $k = m$. What is m ? It is the minimum number of upward stock movements necessary for the option to terminate "in the money" (that is, $u^k d^{n-k} S - X > 0$). How can we interpret Equation A.49? Consider the second term in brackets; it is just a cumulative binomial distribution with parameters of n and p . Likewise, via a small algebraic manipulation we can show that the first term in the brackets is also a cumulative binomial distribution. This can be done by defining $P' \equiv (u/R)p$ and $1 - P' \equiv (d/R)(1 - p)$. Thus

$$p^k (1-p)^{n-k} \frac{u^k d^{n-k}}{R^n} = p'^k (1-p')^{n-k}$$

Therefore the first term in brackets is also a cumulative binomial distribution with parameters of n and p' . Using Equation A.45 in the text, we can write the binomial call option model as

$$C = SB_1(n, p', m) - \frac{X}{R^n} B_2(n, p, m) \quad (\text{A.50})$$

where

$$B_1(n, p', m) = \sum_{k=m}^n C_k^n p'^k (1 - p')^{n-k}$$

$$B_2(n, p, m) = \sum_{k=m}^n C_k^n p^k (1 - p)^{n-k}$$

and m is the minimum amount of time the stock has to go up for the investor to finish *in the money* (that is, for the stock price to become larger than the exercise price).

In this appendix, we showed that by employing the definition of a call option and by making some simplifying assumptions, we could use the binomial distribution to find the value of a call option. In the next chapter, we will show how the binomial distribution is related to the normal distribution and how this relationship can be used to derive one of the most famous valuation equations in finance, the Black-Scholes option pricing model.

Example A.1

A Decision Tree Approach to Analyzing Future Stock Price

By making some simplifying assumptions about how a stock's price can change from one period to the next, it is possible to forecast the future price of the stock by means of a decision tree. To illustrate this point, let's consider the following example.

Suppose the price of Company A's stock is currently \$100. Now let's assume that from one period to the next, the stock can go up by 17.5% or go down by 15%. In addition, let us assume that there is a 50% chance that the stock will go up and a 50% chance that the stock will go down. It is also assumed that the price movement of a stock (or of the stock market) today is completely independent of its movement in the past; in other words, the price will rise or fall today by a random amount. A sequence of these random increases and decreases is known as a **random walk**.

Given this information, we can lay out the paths that the stock's price may take. Figure A.1 shows the possible stock prices for company A for four periods.

Note that in period 1 there are two possible outcomes: the stock can go up in value by 17.5% to \$117.50 or down by 15% to \$85.00. In period 2 there are four possible outcomes. If the stock went up in the first period, it can go up again to \$138.06 or down in the second period to \$99.88. Likewise, if the stock went down in the first period, it can go down again to \$72.25 or up in the second period to \$99.88. Using the same argument, we can trace the path of the stock's price for all four periods.

If we are interested in forecasting the stock's price at the end of period 4, we can find the average price of the stock for the 16 possible outcomes that can occur in period 4.

$$\bar{P} = \frac{\sum_{i=1}^{16} P_i}{16} = \frac{190.61 + 137.89 + \cdots + 52.20}{16} = 105.09$$

We can also find the standard deviation for the stock's return.

$$\begin{aligned}\sigma_P &= \left[\frac{(190.61 - 105.09)^2 + \cdots + (52.20 - 105.09)^2}{16} \right]^{1/2} \\ &= 34.39\end{aligned}$$

$\bar{P}$ and σ_P can be used to predict the future price of stock A.

Appendix H: Derivation of Modigliani and Miller (M&M) Proposition I and II with Taxes

H1. M&M Proposition I with Taxes

Assume that the firms are non-growth companies; the market value of levered firm is equal to the market value of unlevered firm plus the present value of the cost of perpetually total debt.

$$V_L = V_U + \sum_{t=1}^{\infty} \frac{TDk_d}{(1+k_d)^t} = V_U + \frac{TDk_d}{k_d} = V_U + TD \quad (\text{A.51})$$

Where V_L = market value of levered firm, V_U = market value of unlevered firm, T = marginal corporate tax rate, D = total debt, k_d = the cost of debt, and TD = tax shield value.

Alternatively, the market value of levered firm, V_L , can be viewed as the total cash flow to all stakeholders

$$\begin{aligned} & (EBIT - k_d D) \times (1 - T) + k_d D \\ & = EBIT \times (1 - T) + T k_d D \end{aligned} \quad (\text{A.52})$$

The cash flow to all stakeholders is made up of cash flow to stockholders plus cash flow to bondholders. The present value of first term is equal to the market value of unlevered firm, V_U , and the present value of second term is TD . Therefore, $V_L = V_U + TD$.

Miller (1977) modified Eq. A.51 by introducing personal as well as corporate taxes into the model, and obtaining

$$V_L = V_U + \left[1 - \left[\frac{(1-T)(1-T^{PS})}{(1-T^{PD})} \right] \right] D \quad (\text{A.53})$$

Where V_L , V_U , T , and D have been defined in Eq. A.51; T^{PS} and T^{PD} are the personal tax rate on equity income and the personal tax from bond income, respectively. If T^{PS} equals to T^{PD} , then Eq. A.53 can be reduced to M&M Proposition I with taxes.

H2. M&M Proposition II with Taxes

Since market value of levered firm, V_L , is equal to total equity, E , plus total debt, D , and based on M&M proposition I with taxes, the market value of unlevered firm can be derived as

$$V_L = E + D = V_U + TD \Rightarrow V_U = E + (1 - T)D \quad (\text{A.54})$$

The cash flow from each side of balance sheet must equal, therefore

$$\begin{aligned} Ek_e + Dk_d &= V_U k_u + TDk_d \\ &= (E + (1 - T)D)k_u + TDk_d \end{aligned} \quad (\text{A.55})$$

Where E = total equity, D = total debt, k_e = the cost of equity, k_d = the cost of debt, k_u = the cost of unlevered equity, and T = marginal corporate tax rate.

Divide both side by total equity, E , then we can get

$$\begin{aligned} k_e + \frac{D}{E}k_d &= \left(1 + (1 - T)\frac{D}{E}\right)k_u + \frac{D}{E}Tk_d \\ &= k_u + (1 - T)\frac{D}{E}k_u + \frac{D}{E}Tk_d \end{aligned} \quad (\text{A.56})$$

$$\begin{aligned} k_e &= k_u + (1 - T)\frac{D}{E}k_u + \frac{D}{E}Tk_d - \frac{D}{E}k_d \\ &= k_u + (1 - T)\frac{D}{E}k_u - (1 - T)\frac{D}{E}k_d \\ &= k_u + (k_u - k_d)\frac{D}{E}(1 - T) \end{aligned} \quad (\text{A.57})$$

Figure A.2 represents the relationship between the cost of equity with and without taxes, and the cost of unlevered firm. The weighted average cost of capital with taxes will decrease when the ratio of debt to equity increases.

Fig. A.2 The Relationship Between the Cost of Capital and Debt-to-Equity Ratio

Appendix I: Derivation of Capital Market Line (CML)

By geometric theory, triangles R_fPE and R_fM_pD in the Fig. A.3 below are similar and are, therefore, directly proportional,

$$\Delta PR_fE \cong \Delta M_pR_fD \quad (\text{A.58})$$

Therefore,

$$\begin{aligned} \frac{E(R_p) - R_f}{E(R_{M_p}) - R_f} &= \frac{\sigma_p}{\sigma_{M_p}} \\ \Rightarrow (E(R_p) - R_f) &= \frac{\sigma_p}{\sigma_{M_p}} (E(R_{M_p}) - R_f) \\ \Rightarrow E(R_p) &= R_f + [E(R_{M_p}) - R_f] \frac{\sigma_p}{\sigma_{M_p}} \end{aligned} \quad (\text{A.59})$$

Fig. A.3 The Capital Market Line

where R_f = the risk-free rate; R_{M_p} = return on market portfolio M_p ; R_p = return on the portfolio consisting of combinations of the risk-free asset and portfolio M_p ; σ_p and σ_{M_p} = standard deviations of the portfolio and the market; and the operator E denotes expectations.

Appendix J: Derivation of Capital Market Line (SML)

Sharpe (1964) used a general risky asset that did not lie on the CML and dubbed it *I* in Fig. A.4. The combinations of risk and return possible by combining security *I* with the market portfolio, *M*, are shown by figure above. The average return and standard deviation for any *I-M* combination can be approached in the same way as for a two-asset case:

$$E(R_P) = w_i E(R_i) + (1 - w_i) E(R_m) \quad (\text{A.60})$$

$$\sigma_P = [w_i^2 \sigma_i^2 + (1 - w_i)^2 \sigma_m^2 + 2(1 - w_i) w_i \sigma_{im}]^{\frac{1}{2}} \quad (\text{A.61})$$

where w_i represents excess demand for *I* or demand greater than its equilibrium weight in portfolio *M*, and σ_{im} is the covariance of *i* and *m*.

The change in mean and standard deviation as the proportion w_i changes are the partial derivatives

$$\frac{\partial E(R_P)}{\partial w_i} = E(R_i) - E(R_m) \quad (\text{A.62})$$

$$\frac{\partial(\sigma_P)}{\partial w_i} = \frac{1}{2} [w_i^2 \sigma_i^2 + (1 - w_i)^2 \sigma_m^2 + 2w_i(1 - w_i) \sigma_{im}]^{-\frac{1}{2}} (2w_i \sigma_i^2 - 2\sigma_m^2 + 2w_i \sigma_m^2 + 2\sigma_{im} - 4w_i \sigma_{im}) \quad (\text{A.63})$$

When $w_i = 0$, the security is held in proportion to its total market value and there is no excess demand for security *I*. This is the key insight to Sharpe's paper, for when $w_i = 0$, it is possible to equate the slope of the curve *IMI* ' with the capital market line and thus obtain an expression for the return on any risky security *I*. At equilibrium when $w_i = 0$, the slope along the *IMI* ' curve will equal

Fig. A.4 The Opportunity Set Provided by Combinations of Risky Asset (I) and Market Portfolio (M)

$$\frac{\partial E(R_P)}{\partial(\sigma_P)} = \frac{\frac{\partial E(R_P)}{\partial w_i}}{\frac{\partial(\sigma_P)}{\partial w_i}} = \frac{\frac{E(R_i) - E(R_M)}{\sigma_{im} - \sigma_m^2}}{\sigma_m} \quad (\text{A.64})$$

The slope of the capital market line at point M is

$$\frac{E(R_m) - R_f}{\sigma_m} \quad (\text{A.65})$$

Let Eq. A.64 equal to Eq. A.65, then rearranging the terms to solve for $E(R_i)$ gives the equation for the security market line or CAPM

$$E(R_i) = R_f + [E(R_m) - R_f] \frac{\sigma_{im}}{\sigma_m^2} \quad (\text{A.66})$$

This represents the return on any risky asset I . At equilibrium, every risky asset will be priced so that it lies along the security market line. It should be noted that the term σ_{im}/σ_m^2 represents the beta coefficient for the regression of R_i vs. R_m , so that Eq. A.66 can be rewritten as

$$E(R_i) = R_f + [E(R_m) - R_f] \beta_i \quad (\text{A.67})$$

Appendix K: Derivation of Black-Scholes Option Pricing Model

Assume the stock prices follow a lognormal distribution and denote the current stock price by S and the stock price at the end of t -th period by S_t then $\frac{S_t}{S_{t-1}} = \exp(K_t)$ is a random variable with a lognormal distribution, where K_t is the rate of return in t -th period and follows normal distribution with the constant mean μ and variance σ^2 , therefore,

$$\begin{aligned} E\left[\frac{S_T}{S}\right] &= E\left[\frac{S_1}{S} \frac{S_2}{S_1} \cdots \frac{S_T}{S_{T-1}}\right] \\ &= E[\exp(K_1 + K_2 + \cdots + K_T)] = T\mu + \frac{T\sigma^2}{2} \end{aligned} \quad (\text{A.68})$$

Under the assumption of a risk-neutral investor, the expected return $E\left[\frac{S_T}{S}\right]$ is assumed to be $\exp[rT]$ (where r is the riskless rate of interest). In other words, $\mu = r - \sigma^2/2$.

The call option price C can be determined by discounting the expected value of the terminal option price by the riskless rate of interest (r):

$$C = \exp[-rT]E[\text{Max}(S_T - X, 0)] \quad (\text{A.69})$$

where T is the time of expiration and X is the striking price, r is the riskless interest rate, S_T is the stock price at time T . Note that

$$\text{Max}(S_T - X, 0) = \left(S\left(\frac{S_T}{S} - \frac{X}{S}\right)\right) \quad \text{for } \frac{S_T}{S} > \frac{X}{S} \quad (\text{A.70})$$

Let $y = \frac{S_T}{S}$ has a lognormal distribution with mean $\mu T = (r - \frac{1}{2}\sigma^2)T$ and variance $\sigma^2 T$, then

$$\begin{aligned}
C &= \exp[-rT]E[\text{Max}(S_T - X, 0)] \\
&= \exp[-rT] \int_{\frac{X}{S}}^{\infty} S \left[y - \frac{X}{S} \right] g(y) dy \\
&= S \exp[-rT] \int_{\frac{X}{S}}^{\infty} y g(y) dy - \exp[-rT] S \frac{X}{S} \int_{\frac{X}{S}}^{\infty} g(y) dy
\end{aligned} \tag{A.71}$$

Let $x = \ln(y)$, then x follows normal distribution with mean $\mu T = (r - \frac{1}{2}\sigma^2)T$ and variance $\sigma^2 T$, and

$$\begin{aligned}
dx &= \frac{1}{y} dy, \frac{f(x)}{y} = g(y) \\
\int_{\frac{X}{S}}^{\infty} g(y) dy &= \int_{\ln(\frac{X}{S})}^{\infty} \frac{f(x)}{y} (y dx) \\
&= \int_{\ln(\frac{X}{S})}^{\infty} f(x) dx \\
&= \int_{\frac{\ln(\frac{X}{S}) - (r - \frac{1}{2}\sigma^2)T}{\sigma\sqrt{T}}}^{\infty} h(z) dz
\end{aligned} \tag{A.72}$$

Where $g(y)$ is the probability density function of y , $f(x)$ is the probability density function of x , z is standard normal distribution, and $h(z)$ is the probability density function of z . The first term of call option can be derived as

$$\begin{aligned}
\int_{\frac{X}{S}}^{\infty} e^{-rT} y g(y) dy &= \int_{\ln(\frac{X}{S})}^{\infty} e^{-rT} e^x \frac{f(x)}{y} (y dx) \\
&= \int_{\ln(\frac{X}{S})}^{\infty} e^{-rT} e^x f(x) dx \\
&= \int_{\ln(\frac{X}{S})}^{\infty} \frac{1}{\sqrt{2\pi\sigma^2 T}} e^{\left(\frac{-(x - (r - \frac{1}{2}\sigma^2)T)^2}{2\sigma^2 T} - rT + x \right)} dx \\
&= \int_{\ln(\frac{X}{S})}^{\infty} \frac{1}{\sqrt{2\pi\sigma^2 T}} e^{\frac{-(x - (r - \frac{1}{2}\sigma^2)T)^2}{2\sigma^2 T}} dx \\
&= \int_{\frac{\ln(\frac{X}{S}) - (r - \frac{1}{2}\sigma^2)T}{\sigma\sqrt{T}}}^{\infty} h(z) dz
\end{aligned} \tag{A.73}$$

Where z is standard normal distribution, and $h(z)$ is the probability density function of z . Therefore, the call option pricing model can be rewritten as

$$\begin{aligned}
 C &= S \int_{\frac{\ln\left(\frac{X}{S}\right) - \left(r + \frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}}}^{\infty} h(z) dz \\
 &\quad - Xe^{-rT} \int_{\frac{\ln\left(\frac{X}{S}\right) - \left(r - \frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}}}^{\infty} h(z) dz \\
 &= SN(d_1) - Xe^{-rT}N(d_2)
 \end{aligned} \tag{A.74}$$

where

$$\begin{aligned}
 d_1 &= - \left[\frac{\ln\left(\frac{X}{S}\right) - \left(r + \frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}} \right] = \frac{\ln\left(\frac{S}{X}\right) + \left(r + \frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}}, \\
 d_2 &= - \left[\frac{\ln\left(\frac{X}{S}\right) - \left(r - \frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}} \right] = \frac{\ln\left(\frac{S}{X}\right) + \left(r - \frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}} = d_1 - \sigma\sqrt{T}
 \end{aligned}$$

Based on put-call parity, it can be shown that the relationship between a call option (C) and a put option (P) can be defined as

$$C + Xe^{-rT} = P + S \tag{A.75}$$

Substituting Eqs. A.74 into A.75, we obtain the put option formula as

$$P = Xe^{-rT}N(-d_2) - SN(-d_1) \tag{A.76}$$

where S , C , r , T , d_1 and d_2 are identical to those defined in the call option model.

Appendix L: Hillier's Statistical Distribution Method

The riskiness of an investment proposal is generally defined as the variability of its possible returns. Decision situations can generally be classified into three types: certainty, risk, and uncertainty. The distinction between risk and uncertainty is that risk involves situations in which the probabilities of a particular event occurring are known, whereas with uncertainty these probabilities themselves are not known. Throughout this chapter, the terms “risk” and “uncertainty” will be used interchangeably, although the strict difference between them is not a matter to be taken lightly.

Economic factors peculiar to investment, competition, technological development, consumer preferences, and labor market conditions are a few of the factors that make it virtually impossible to foretell the future. Consequently, the revenues, costs, and economic life of investment projects are less than certain.

With the introduction of risk, a firm is no longer indifferent between two investment proposals having equal net present values or internal rates of return. Both net present value and its standard deviation (σ_{NPV}) should be estimated in performing capital-budgeting analyses under uncertainty. A NPV approach under uncertainty can be defined as

$$\tilde{NPV} = \sum_{t=1}^N \frac{\bar{C}_t}{(1+k)^t} + \frac{S_n}{(1+k)^N} - I_0 \quad (\text{A.77})$$

where C_t is the uncertain net cash flow in period t , k is the risk-adjusted discount rate, S_n is the salvage value, and I_0 is the initial outlay. The mean of the NPV distribution and its standard deviation can be defined as:

$$\overline{NPV} = \sum_{t=1}^N \frac{\bar{C}_t}{(1+k)^t} + \frac{S_n}{(1+k)^N} - I_0 \quad (\text{A.78})$$

$$\sigma_{NPV} = \left[\sum_{t=1}^N \frac{\sigma_t^2}{(1+k)^{2t}} + \sum_{\tau=1}^N \sum_{t=1}^N w_t w_\tau \text{Cov}(C_\tau, C_t) \right]^{1/2} \quad (\tau \neq t), \quad (\text{A.79})$$

where σ is the variance of the cash flow in the t th period and w_t and w_τ are the discount factors in the t th and τ th periods, respectively. The calculation of σ_{NPV} is similar to the standard deviation of a portfolio's returns.

$\text{Cov}(C_\tau, C_t)$ is used to measure the covariability between the cash flow in the t th and τ th periods. It is well known that:

$$\text{Cov}(C_t, C_\tau) = \rho_{\tau t} \sigma_\tau \sigma_t, \quad (\text{A.80})$$

where $\rho_{\tau t}$ is the correlation coefficient between the cash flow in the t th period and that in the τ th period. In one special case, the cash flows are perfectly correlated over time. If such is the case, then the deviation of the actual cash flow from the mean of its corresponding profitability distribution of expected cash flows for the period gives us the information that cash flows in future periods will deviate in a similar fashion. In other words, Eq. (A.79) can be rewritten as:

$$\sigma_{\text{NPV}} = \sum_{t=1}^N \frac{\sigma_t}{(1+k)^t} \quad (\text{A.81})$$

If the cash flows are mutually independent, then Eq. (A.81) reduces to:

$$\sigma_{\text{NPV}} = \sqrt{\sum_{t=1}^N \frac{\sigma_t^2}{(1+k)^{2t}}} \quad (\text{A.82})$$

Hillier (1963) combines the assumption of mutual independence and perfect correlation in developing a model to deal with mixed situations. The model as defined in Eq. (A.83) can be used to analyze investment proposals in which some of the expected cash flows are closely related, and others are fairly independent.

$$\sigma = \sqrt{\sum_{t=1}^N \frac{\sigma_{yt}^2}{(1+k)^{2t}} + \sum_h^m \left(\sum_{t=1}^N \frac{\sigma_{zt}^h}{(1+k)^t} \right)^2} \quad (\text{A.83})$$

where σ_{yt}^2 is the variance for an independent net cash flow in period t , and σ_{zt}^h is the standard deviation for stream h of a perfectly correlated stream of cash flows t . It is clear that Eq. (A.83) is a combination of Eqs. (A.81) and (A.82). Chen and Moore (1982) have generalized this model by introducing the estimation risk.

They argue that Hillier's (1963) approach is unrealistic due to the assumption of parameter certainty. In reality, the parameters of the probability distribution are never known with certainty, and thus the capital budgeting decisions based on Hillier's approach may be potentially misleading because this approach ignores estimation risk. Chen and Moore (1982) hence extend Hillier's approach with a Bayesian framework which leads to the derivation of a predictive distribution that is not conditioned on unknown parameters. Therefore, the effect of estimation risk in capital budgeting decisions can be eliminated in Chen and Moore (1982) approach.

In addition, Wang and Lee (2010) provide the fuzzy real option valuation approach to solve the capital budgeting decisions under uncertainty environment. In Wang and Lee's model framework, the concept of probability is employed in describing fuzzy events and the estimated cash flows are based on the fuzzy numbers which can better reflect the uncertainty in the project. By using a fuzzy real option valuation, the managers can select fuzzy projects and determine the optimal time to abandon the project under the assumption of limited capital budget.

To illustrate the model of (A.83), suppose that a firm is considering the introduction of a new product with returns expected over the next 5 years. Because the product's market reception is uncertain, management feels that, if initial reception exceeds expectations, actual acceptance in later years will also exceed expectations, in approximately the same proportions. For simplicity, it is believed that the net marketing cash flow (sales less marketing and advertising expenses) can be treated as perfectly correlated over time.

On the other hand, estimates of the initial investment in the project and the production costs are reasonably reliable, so that any deviation from expectations is assumed to be attributable to random fluctuations. Consequently, initial investment and net production cash flows are regarded as being mutually independent over time. The probability information for the introduction of the new product is shown in Table A.3. We assume that each of the probability distributions involved can be regarded as normal. If 10% is used as the risk-free rate, the expected value of the net present value for the proposal is:

$$\begin{aligned} NPV &= \sum_{t=0}^5 \frac{C_t}{(1.04)^t} = -600 + \frac{300 - 250}{(1.04)} + \frac{600 - 200}{(1.04)^2} + \frac{500 - 200}{(1.04)^3} \\ &\quad + \frac{400 - 200}{(1.04)^4} + \frac{300 - 100}{(1.04)^5} \\ &= \$419.95 = \$420.00. \end{aligned}$$

Table A.3 Expected cash flow for new product

Year	Source	Expected value of net cash flow (in thousands)	Standard deviation (in thousands)
0	Initial investment	−\$600	\$50
1	Production cash outflow	−250	20
2	Production cash outflow	−200	10
3	Production cash outflow	−200	10
4	Production cash outflow	−200	10
5	Production outflow – salvage value	−100	15
1	Marketing	300	50
2	Marketing	600	100
3	Marketing	500	100
4	Marketing	400	100
5	Marketing	300	100

Following Eq. (A.79), we can calculate the standard deviation as:

$$\begin{aligned}\sigma_{\text{NPV}} &= \left[50^2 + \frac{20^2}{(1.04)^2} + \dots + \frac{15^2}{(1.04)^{10}} + \left(\frac{50}{1.04} + \dots + \frac{100}{(1.04)^5} \right)^2 \right]^{1/2} \\ &= \$398.\end{aligned}$$

Thus, the expected net present value of the proposal is \$420 and the standard deviation of the distribution relating to NPV is \$398. Using this information, we can express an interval inference for NPV as:

$$\Pr(\$420 \pm \$398) = 68.27\%;$$

$$\Pr(\$420 \pm (2)(\$398)) = 95.45\%;$$

$$\Pr(\$420 \pm (3)(\$398)) = 99.73\%.$$

Hillier's approach takes us a long way toward coping with the correlation of cash flows over time, but his method is not always practically applicable. For many investment proposals, cash flows fall into neither of these categories, since in practice they show less than perfect correlation over time. If the correlation is moderate, then the classification suggested by Hillier will not be appropriate. The method suggested by Bonini (1975) and others for handling the problem of moderate correlation is with a series of conditional-probability distributions. Wang and Lee (2010) have expended Bonini's result in terms of fuzzy set and real option approach.

To illustrate the use of this model, we refer to Table A.4, where we consider a project requiring an initial outlay of \$10,000 (Column 1). In each of the following time periods (Columns 3, 5, and 7), the cash flow to be received is not known with perfect certainty, but the probabilities associated with each cash flow in each period are assumed to be known (Columns 2, 4, and 6), so that we are dealing with a case of risk, and not strict uncertainty. We note that Columns (4) and (6) are conditional-probability figures, where the later periods' expected cash flows depend highly on what occurs in earlier time periods. Given our cash flow and simple probability estimates for the periods 1, 2, and 3, we find 27 possible joint probabilities (Column 8), each of which corresponds to a cash-flow series. Thus in the uppermost path, we find the joint probability 0.015 being associated with a cash flow of \$2000 in Period 1, followed by cash flows of \$2000 and \$1000 in Periods 2 and 3, respectively. This particular path is the worst possible result; in nondiscounted dollar terms, there is a 50% loss on the investment. At the other end of the spectrum, we find the best possible outcome offers a return \$12,945 (the last line of Table A.5) with a joint probability of 0.0125. The returns and joint probabilities can be calculated similarly for the other 25 possible patterns.

While the primary hurdle in this process is in estimating the cash flows and the probabilities, we recognize that it is the NPV figures we are ultimately interested

Table A.4 Illustration of conditional-probability distribution approach

Initial outlay period 0	Initial probability $P(1)$	Net cash flow	Conditional probability $P(3 2,1)$	Net cash flow	Conditional probability $P(3 2,1)$	Cash flow	Joint probability
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)

					0.3	6000	0.06
					0.3	5000	0.045
			0.3	7000	0.4	7000	0.06
					0.3	9000	0.045
					0.25	4000	0.0125
			0.25	5000	0.5	6000	0.025
					0.25	8000	0.0125
					0.25	5000	0.025
	0.2	6000	0.5	7000	0.5	7000	0.05
					0.25	9000	0.025
					0.25	7000	0.0125
			0.25	8000	0.5	9000	0.025
					0.25	11,000	0.0125

in. Table A.5 gives the present value of the cash flows and the net present value of the project for each cash-flow series, where a constant 4% discount rate was employed. When we multiply each joint probability by the expected net present value associated with that probability, we obtain the expected net present value for the project as a whole, there shown to be \$2517.18. Also, from all 27 expected net-present-value figures, we can calculate the variance and the standard deviation for the project as a whole, shown in the lower portion of Table A.5 as \$20,359,090.91 and \$4512.11, respectively, where these figures can be used to assess the riskiness of the project.

The use of this form of conditional-probability distribution enables us to take account of the dependence or correlation in the cash flows over time. In the above

Table A.5 NPV and joint probability

PVA	NPV	Probability

Discount rate = 4%

NPV = \$2517.182

Variance = \$20,359,090.9093

Standard deviation = \$4512.105

example, the cash flow in Period 3 depends upon the size of the cash flow in Periods 2 and 1. Given the cash flow in Period 1, the cash flow in Period 2 can vary within a range, but more of a known range than if we did not know the cash flow in Period 1. Similarly, the cash flows in Period 3 are allowed to vary within a range of values, the range being determined in part by the realized cash flow in the prior period. Most importantly, it should be noted that we assume we know what the distribution of each cash-flow figure is, and the probabilities associated with each flow, and, further, that once we make the investment decision we more or less have locked ourselves into the project. In the following section, we relax this latter assumption and allow sequential decisions to be introduced into the conditional-probability decision framework.

Appendix M: Capital-Rationing Decision

In this section, we discuss a capital-budgeting problem that involves the allocation of scarce capital resources among competing economically desirable projects, not all of which can be carried out due to a capital (or other) constraint. This kind of problem is often called “capital rationing.” In this section, we show how linear programming can be used to make capital-rationing decisions.

Basic Concepts of Linear Programming

Linear programming is a mathematical technique used to find optimal solutions to problems of a firm involving the allocation of scarce resources among competing activities. Mathematically, the type of problem that linear programming can solve is one in which both the objective of the firm to be maximized (or minimized) and the constraints limiting the firm’s actions are linear functions of the decision variables involved. Thus, the first step in using linear programming as a tool for financial decisions is to model the problem facing the firm into a linear-programming form. To construct the linear-programming model, one must take the following steps.

First, identify the controllable decision variables involved in the firm’s problem. Second, define the objective or criterion to be maximized or minimized and represent it as a linear function of the controllable decision variables. In finance, the objective generally is to maximize the profit contribution or the market value of the firm or to minimize the cost of production.

Third, define the constraints and express them as linear equations or inequalities of the decision variables. This will usually involve (a) a determination of the capacities of the scarce resources involved in the constraints, and (b) a derivation of a linear relationship between these capacities and the decision variables.

Symbolically, then, if $X_1, X_2, \dots, X_n$ represent the quantities of output, the linear-programming model takes the general form:

$$\text{Maximize (or minimize) } Z = c_1X_1 + c_2X_2 + \cdots + c_nX_n, \quad (\text{A.84})$$

Subject to: $a_{11}X_1 + a_{12}X_2 + \cdots + a_{1n}X_n \leq b_1,$
 $a_{21}X_1 + a_{22}X_2 + \cdots + a_{2n}X_n \leq b_2,$
 $\vdots \qquad \qquad \qquad \vdots$
 $a_{m1}X_1 + a_{m2}X_2 + \cdots + a_{mn}X_n \leq b_m,$
 $X_j \geq 0, (j = 1, 2, \dots, n).$

Here Z represents the objective to be maximized (or minimized), profit, or market value (or cost); $c_1, c_2, \dots$, and c_n and $a_{11}, a_{12}, \dots$, and a_{mn} are constant coefficients relating to profit contribution and input, respectively; $b_1, b_2, \dots$, and b_m are the firm's capacities of the constraining resources. The last constraint ensures that the decision variables to be determined are nonnegative.

Several points should be noted concerning the linear programming model. First, depending upon the problem, the constraints may also be stated with equal signs ($=$) or as greater-than-or-equal-to. Second, the solution values of the decision variables are divisible, that is, a solution would permit $x(j) = 1/2, 1/4$, etc. If such fractional values are not possible, the related technique of integer programming, yielding only whole numbers as solutions, can be applied. Third, the constant coefficients are assumed known and deterministic (fixed). If the coefficients have probabilistic distributions, one of the various methods of stochastic programming must be used. Examples will be given below of the application of linear programming to the areas of capital rationing and capital budgeting.

Capital Rationing

The XYZ Company produces products A, B, and C within the same product line, with sales totaling \$37 million last year. Top management has adopted the goal of maximizing shareholder wealth, which to them is represented by gain in shareholder price. Wickwire plans to finance all future projects with internal or external equity; funds available from the equity market depend on share price in the stock market for the period.

Three new projects were proposed to the Finance Committee, for which the following net after-tax annual funds flows are forecast:

Project	Year					
	0	1	2	3	4	5
X	−100	30	30	60	60	60
Y	−200	70	70	70	70	70
Z	−100	−240	−200	400	300	300

All three projects involve financing cost-saving equipment for well-established product lines; adoption of any one project does not preclude adoption of any other. The following NPV formulations have been prepared by using a discount rate of 12%.

Investment	NPV
X	65.585
Y	52.334
Z	171.871

In addition, the finance start has calculated the maximum internally generated funds that will be available for the current year and succeeding 2 years, not counting any cash generated by the projects currently under consideration.

Year 0	Year 1	Year 2
\$300	\$70	\$50

Assuming that the stock market is in a serious downturn, and thus no external financing is possible, the problem is which of the three projects should be selected, assuming that fractional projects are allowed.

The problem essentially involves the rationing of the capital available to the firm among the three competing projects such that share price will be maximized. Thus, assuming a risk-adjusted discount rate of 12%, the objective function becomes:

$$\text{Maximize } V = 65.585X + 52.334Y + 171.871Z + 0C + 0D + 0E$$

where V represents the total present value realized from the projects, and C , D , and E will represent idle funds in period 0, 1, and 2, respectively. The constraint for period 0 must ensure that the funds used to finance the projects do not exceed the funds available. Thus,

$$100X + 200Y + 100Z + C + 0D + 0E = 300.$$

In this constraint, C represents any idle funds unused in period 0 after projects are paid for. Similarly, for period 1 and 2,

$$\begin{aligned} -30X - 70Y + 240Z - C + D + 0E &= 70, \\ -30X - 70Y + 200Z + 0C - D + E &= 50. \end{aligned}$$

Here $-D$ and $-E$ are included in the second and third constraints, ensuring that idle funds unused from one period are carried over to the succeeding period. In addition, to prevent the program from repeatedly selecting only one project (the “best”) until funds are exhausted, three additional constraints are needed:

$$X \leq 1, \quad Y \leq 1, \quad Z \leq 1.$$

The solution to the model, if $V = \$208.424$, is:

$$X = 1.0, \quad Y = 0.6586, \quad Z = 0.6305.$$

To give an indication of the value of relaxing the funds constraint in any period (the most the firm would be willing to pay for additional financing), the shadow price of the funds constraints are given below:

Funds constraint	Shadow price
1st period	0.4517
2nd period	0.4517
3rd period	0.0914

It should be noted that the constraints related to $X \leq 1$, $Y \leq 1$, and $Z \leq 1$ are required in solving capital-rationing problems. If these constraints are removed, then we will obtain $X = 2.4074$, $Y = 0$, and $Z = 0.5926$. This issue has been discussed by Copeland and Weston (2003) and Weingartner (1963, 1977).

Thus, linear programming is a valuable mathematical tool with which to solve capital-budgeting problems when funds rationing is required. In addition, duality has been used by the banking industry to determine the cost of capital of funds.

Appendix N: Noncentral χ^2 and the Option Pricing Model

It is well known that $Y = \sum_{i=1}^n \left(\frac{X_i - \mu}{\sigma_x} \right)^2$ is distributed as χ^2 with n degree of freedom.

This is a central χ^2 distribution. It can be shown that $Y' = \sum_{i=1}^n X_i^2$ is distributed as noncentral χ^2 with n degree of freedom and a noncentral parameter

$$\lambda = \frac{1}{2} \sum \mu_i^2.$$

If $\mu = 0$, the distribution of Y' reduces to the central χ^2 distribution.

The Black-Scholes Option Pricing Model assumed that the variance of stock rate of return (σ^2) is constant. If the variance of stock rate of return is a function of stock price per share, $\sigma^2 S^{\beta-2}$, then the Black-Scholes model can be generalized as¹

$$C = S \left[1 - \chi^2 \left(2n; 2 + \frac{2}{2-\beta}, 2m \right) \right] - Xe^{-r(T-t)} \left[\chi^2 \left(2m; \frac{2}{\beta-2}, 2n \right) \right] \quad (\text{A.85})$$

$(\beta < 2)$

$$C = S \left[1 - \chi^2 \left(2m; \frac{2}{2-\beta}, 2n \right) \right] - Xe^{-r(T-t)} \left[\chi^2 \left(2n; 2 + \frac{2}{\beta-2}, 2m \right) \right] \quad (\text{A.86})$$

$((\beta < 2))$

where T = time of expiration of option, t = current time, r = risk-free rate. $\chi^2(W, V, \lambda)$ is the cumulative noncentral chi-square distribution function with W , V , and λ being the upper limit of the integral, degree of freedom, and noncentrality, respectively. In addition, m , n , and K can be defined as:

$$m = KS^{2-\beta} e^{(2-\beta)\mu(T-t)}$$

¹The derivation of this formula can be found in Schroder (1989).

$$n = KS^{2-\beta}$$

$$K = \frac{2\mu}{\sigma^2(2-\beta)(e^{(2-\beta)\mu(T-t)} - 1)} \quad (\text{A.87})$$

Now, we discuss three possible special cases associated with Eqs. A.85 and A.86.

- (a) If $\beta = 2$, both m and n approach infinity. Then it can be shown that both Eqs. A.85 and A.86 reduce to the well-known Black-Scholes formula as defined in Appendix K.
- (b) If $\beta = 1$, it can be shown that Eqs. A.85 and A.86 reduce to

$$C = (S - Xe^{-r(T-t)})N(y_1) + (S + Xe^{-r(T-t)})N(y_2) + \nu[n(y_1) - n(y_2)]$$

where

$$\nu = \sigma \sqrt{\frac{1 - e^{-2r(T-t)}}{2r}}$$

$$y_1 = \frac{S - Xe^{-r(T-t)}}{\nu}$$

$$y_2 = \frac{-S - Xe^{-r(T-t)}}{\nu}$$

$N(y_1)$ and $N(y_2)$ = cumulative standardized normal distribution function in terms of y_1 and y_2 , respectively.

$n(y_1)$ and $n(y_2)$ = standardized normal density function in terms of y_1 , and y_2 , respectively.

- (c) If $\beta = 0$, it can be shown that Eqs. A.85 and A.86 reduce to

$$C = SN[q(4)] - Xe^{-r(T-t)}N[q(0)] \quad (\text{A.88})$$

where

$$q(w) = \frac{1 + h(h-1)\left(\frac{w+2y}{(w+y)^2}\right) - h(h-1)\left(2 - h(1-3h)\left(\frac{(w+2y)^2}{2(w+y)^4}\right) - \left(\frac{z}{(w+y)}\right)^h\right)}{\left\{2h^2\left(\frac{w+2y}{(w+y)^2}\right)\left(1 - (1-h)(1-3h)\left(\frac{w+2y}{(w+y)^2}\right)\right)\right\}^{1/2}}$$

$$h(w) = 1 - \frac{2}{3}(w+y)(w+3y)(w+2y)^{-2}$$

$$y = \frac{4rS}{\sigma^2(1 - e^{-r(T-t)})} \quad \text{and} \quad z = \frac{4rX}{\sigma^2(e^{-r(T-t)} - 1)}$$

The elasticity of variance ($\sigma^2 S^{\beta-2}$) with respect to stock price per share S is

$$\eta_s = \left[\frac{\partial(\sigma^2 S^{\beta-2})}{\partial S} \right] \left[\frac{S}{\sigma^2 S^{\beta-2}} \right] = \left[\frac{(\beta - 2)\sigma^2 S^{\beta-2}}{S} \right] \left[\frac{S}{\sigma^2 S^{\beta-2}} \right] = \beta - 2 \quad (\text{A.89})$$

This implies that the Option Pricing Model defined in Eqs. A.85 and A.86 is a constant elasticity of variance (CEV) type of OPM.

The CEV type of option pricing model can be reduced to the following special models.²

- (a) $\beta = 2$, Eqs. A.85 and A.86 reduce to the Black-Scholes model.
- (b) $\beta = 1$, Eqs. A.85 and A.86 reduce to the absolute model as defined in Eq. A.88.
- (c) $\beta = 0$, Eqs. A.85 and A.86 reduce to the square root model as defined in Eq. A.89.

Appendix O: Impacts of Financing Decisions on Capital Budgeting Decisions

This appendix is intended to briefly review net-present value (NPV) method and explain how financing decision can affect investment decisions.

Chambers, Harris, and Pringle (1982) (CHP) examined four standard, discounted cash-flow models and considered the implications of using each as opposed to the other three. By way of simulation, they were able to deal with differences in financing projects as well as with possible differences in the risk underlying the operating cash flows generated by each project. The problem inherent in this and any project evaluation (not to say that there are no other difficulties) is in concentrating on the specification of the amount of debt used to finance the investment project. Project debt is therefore defined as the *additional debt capacity* afforded the firm as a result of accepting the project and can alternatively be described as the difference between the firm's optimal debt level *with* the project and *without* it.

The CHP analysis considered the following four methods; (i) the Equity Residual method; (ii) the “after-tax Weighted Average Cost-of-Capital” method; (iii) the “Arditti-Levy” weighted cost-of-capital method; and (iv) the Myers “Adjusted Present Value” method. For simplicity, Table A.6 contains the definitions of the variables used in the following discussion, after which we briefly discuss the formulation of each method, and then elaborate on the way in which each method incorporates interacting effects of financing and investment decisions.

Using the variables defined in Table A.6, we now explicitly define the equations for the four alternative methods.

Equity-Residual Method

The equity-residual method is formulated in Eq. (A.90) in a manner that emphasizes the goal of financial management, the pursuance of the interests of shareholders:

$$NPV(ER) = \sum_{t=1}^N \frac{[(R_t - C_t - dep_t - rD_t)(1 - \tau_c) + D_t] - (D_t - D_{t+1})}{(1 + k_e)^t} - [I - NP]. \quad (A.90)$$

Table A.6 Definitions of variables

R_t	= Pretax-operating cash revenues of the project during period t
C_t	= Pretax-operating cash expenses of the project during period t
dep_t	= Additional depreciation expense attributable to the project in period t
τ_c	= Applicable corporate tax rate
I	= Initial net cash investment outlay
D_t	= Project debt outstanding during period t
NP	= Net proceeds of issuing project debt at time zero
r_t	= Interest rate of debt in period t
k_e	= Cost of the equity financing of the project
k_w	= After-tax weighted-average cost of capital (i.e., debt cost is after-tax)
k_{AL}	= Weighted average cost of capital – debt cost considered before taxes
ρ	= Required rate-of-return applicable to unlevered cash-flow series, given the risk class of the project
r , k_e , and ρ are all assumed to be constant over time	

The formula presented above can be interpreted as stating that the benefit of the project to the shareholders is the present value of the cash flows not going to pay operating expenses or to service or repay debt obligations.

With these flows identified as those going to shareholders, it is appropriate, and rather easy, to discount these flows at the cost of equity. The only difficulty involved is identifying this cost of equity, a problem embodied in all capital-budgeting methods.

After-Tax, Weighted-Average, Cost-of-Capital Method

The after-tax, weighted-average, cost-of-capital method, depicted in Eq. (A.91), has two noticeable differences from the formulation of the equity-residual method:

$$NPV = \sum_{t=1}^N \frac{(R_t - C_t - dep_t)(1 - \tau_c) + dep_t}{(1 + k_w)^t} I. \quad (\text{A.91})$$

First, no flows associated with the debt financing appear in the numerator, or as relevant cash flows. Second, the cost of capital is adjusted downward, with k_w being a weighted average of debt and equity costs, the debt expense accounted for on an after-tax basis. In that way, debt financing is reckoned with an indirect manner. With the assumption that r and k_e are constant over time, k_w can be affected only by the debt-to-equity ratio, a problem most often avoided by assuming a fixed debt-to-equity ratio.

Arditti and Levy Method

The Arditti-Levy method is most similar to the after-tax weighted-average cost-of-capital method. This formulation can be written as:

$$NPV(AL) = \sum_{t=1}^N \frac{[(R_t - C_t - dep_t - rD_t)(1 - \tau_c) + dep_t] + rD_t}{(1 + k_{AL})^t} - I \quad (A.92)$$

It was seen as necessary to restate the after-tax, weighted-average, cost-of-capital formula in this manner because the tax payment to the government has an influence on the net cash flows, and for that reason the cash-flow figures would be misleading. To rectify this problem, the discount rate must now be adjusted since the interest tax shield is reflected in the cash flows and double counting would be involved. While the after-tax, weighted-average cost of capital recognized the cost of debt in the discount rate, it was akin to the equity-residual method in considering only returns to equity. The Arditti and Levy formulas imply that a weighted average discount rate including the lower cost of debt could only (or best) be used if all flows to all sources of financing were included; hence the term rD_t is found at the end of the first term. This can be rationalized if one considers the case of a firm where there is one owner. The total cash flow to the owner is the relevant figure, and the discount rate applicable is simply a weighted average of the two individual required rates of return.

Myers Adjusted-Present-Value Method

This method is closely related to the Arditti-Levy method except for the exclusion of the interest-expense flows to the bondholders. In treating the financing mix, Myers implicitly assumes that the tax shield, created by the interest payments and afforded to the equity holders, has the same risk for the equity holders as the coupon or interest payments have for the bondholders. Instead of aggregating all factors and attempting to arrive at a suitable weighted-average discount rate, Myers found it less difficult to leave operating- and financing-related flows separated, and to discount each at an appropriate rate. This formulation can be written as:

$$APV = \sum_{t=1}^N \frac{(R_t - C_t - dep_t)(1 - \tau_c) + dep_t}{(1 + \rho)^t} - I + \sum_{t=1}^N \frac{\tau_c r D_t}{(1 + r)^t} \quad (A.93)$$

This formulation appears to be closely related to the Modigliani and Miller with-tax firm-valuation model, and it should, given Myers' motivation for this work. We choose not to discuss it here, but the reader should be aware that Myers' emphasis was not solely on the tax advantage of debt, as the last term in the above equation tends to imply.

The four methods are obviously comparable but usually give different figures for the net present value. The equity-residual, after-tax, weighted-average cost of capital and the Arditti-Levy weighted-average, cost-of-capital formulations are comparable if the value of the debt outstanding remains a constant proportion of the remaining cash flows; this is often taken to mean a constant debt ratio. This will

not guarantee that the Myers APV method will yield the same results, although the Myers method is equivalent to the other three only if the project life can be described as one period, or as *infinite with constant perpetual flows* in all periods. By way of numerical examples, we now address the task of determining the factors that create the differences in the net-present-value figures generated by each method.

The first example involves the simplest case, where a \$1000 investment generates operating flows of \$300 per year for all 5 years of the project's life. Debt financing comprises \$600 of the project's total financing, and the principal is repaid over the five time periods in equal amounts. The discount and tax rates employed are included below in Table A.7 with the results for each of the four methods.

Because the Arditti-Levy method recognizes the acquisition of the debt capital and uses a lower discount rate, as does the after-tax WACC, these two methods give the highest net-present-value figures. The equity-residual method recognizes only the \$400 outflow at time zero, but the higher discount suppresses the net-present-value figure. The Myers APV method, though discounting financing-related flows at the cost of debt, also attains a low net-present-value figure because the majority of the flows are discounted at a higher unlevered cost-of-equity rate.

Basically, we can speak of three differences in these methods that create the large discrepancies in the bottom-line figures. The risk factor, reflected in discount rates that may vary over time, is a major element, as was evidenced in the example presented above. The pattern of debt and debt payments will also be an important factor, particularly so when the debt repayment is not of the annuity form assumed earlier. Finally, the recognition and valuation of the debt tax shields will play an important role in net-present-value determination, especially when the constant-debt-repayment assumption is dropped, and the interest expenses and associated tax shields grow larger.

Since the Myers APV method is recommended, it is worthwhile for us to show the procedure for obtaining the APV, as discussed in Table A.7. Let the information needed to establish APV be $R_t = \$4000$, $C_t = \$1000$, $dep_t = \$500$, $D_t = \$3600$, E_t (equity financing) = \$2800, $I = \$7000$, $k_e = 0.15$, $r = 0.09$, $\tau_c = 0.46$, $w = D/(D + E) = \$4200/\$7000 = 0.6$, and $N = 6$.

Table A.7 Application of four capital budgeting techniques

Inputs: 1. $k_e = 0.112$ 2. $r = 0.041$ 3. $\tau_c = 0.46$ 4. $\rho = 0.0802$ 5. $w = 0.6$		
Method	NPV results	Discount rates
1. Equity-residual	\$230.55	$k_e = 0.112$
2. After-tax WACC	270.32	$k_w = 0.058$
3. Arditti-Levy WACC	261.67	$k_{AL} = 0.069$
4. Myers APV	228.05	$r = 0.041$ and $\rho = 0.0802$

From this information, we can assemble the information needed to estimate APV as follows:

$$\begin{aligned}\text{Operating flows} &= (R_t - C_t - dep_t)(1 - \tau_c) + dep_t \\ &= (\$4000 - \$1000 - \$500)(1 - 0.46) + \$500 \\ &= \$1850.\end{aligned}$$

$$\begin{aligned}\text{Financial flows} &= \tau_c r D_t \\ &= (0.46)(0.09)(\$3600) \\ &= \$149.04\end{aligned}$$

$$\begin{aligned}k_w &= wr(1 - \tau_c) + (1 - w)k_e \\ &= (0.6)(0.09)(1 - 0.46) + (1 - 0.6)(0.15) \\ &= (0.029) + (0.06) \\ &= 0.089.\end{aligned}$$

$$\begin{aligned}\rho &= \frac{k_w}{(1 - \tau_c w)} \\ &= \frac{0.089}{(1 - (0.46)(0.6))} \\ &= 0.1229\end{aligned}$$

From this information, we can calculate APV as:

$$\begin{aligned}APV &= \$1850 \left(\sum_{t=1}^6 1/(1 + 0.1229)^t \right) + \$149.04 \left(\sum_{t=1}^6 1/(1 + 0.09)^t \right) - \$7000 \\ &= (\$1850)(4.0784) + (\$149.04)(4.4859) - \$7000 \\ &= \$1213.62.\end{aligned}$$

By using appropriate budget constraints, Lambrecht and Myers (2012) have theoretically shown that investment dividend and financing policy are interrelated. To test this theory developed by Lambert and Myers, Lee et al. (2016) investigated the interrelationship among investment, financing, and dividend decisions using 2SLS, 3SLS, and GMM methods based on the US listed firm annual data between 1965 and 2012. Their results were consistent with Lambrecht and Myers' (2012) theory that dividend and investment decisions are jointly determined. In addition, these three corporate decisions are codetermined and the interaction among them should be taken into account in a simultaneous equation framework.
